

ENCYCLOPEDIA of WORLD CLIMATOLOGY

Edited by
John E. Oliver

ENCYCLOPEDIA *of*
WORLD CLIMATOLOGY

Encyclopedia of Earth Sciences Series

ENCYCLOPEDIA OF WORLD CLIMATOLOGY

Volume Editor

John E. Oliver is Professor Emeritus at Indiana State University. He holds a BSc from London University, and an MA and PhD from Columbia University. He taught at Columbia University and then at Indiana State where he was formerly Chair of the Geography-Geology Department, and Associate Dean, College of Arts and Sciences. He has written many books and journal articles in Climatology, Applied Climatology and Physical Geography.

Advisory Board

Howard Bridgman Newcastle University Australia	John Hay IGCI University of Waikato New Zealand
Henry Diaz NOAA/CDC/OAR USA	Tim Oke University of British Columbia Canada
Michael Glantz ESIG NOAA USA	John Thornes University of Birmingham United Kingdom

Aim of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students.

See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to www.eseo.com to visit the "Earth Sciences Encyclopedia Online" – the online version of this Encyclopedia Series.

About the Editors

Professor Rhodes W. Fairbridge has edited more than 30 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He is currently Emeritus Professor of Geology at Columbia University and is affiliated with the Goddard Institute for Space Studies.

Professor Michael Rampino has published more than 100 papers in professional journals including *Science*, *Nature*, and *Scientific American*. He has worked in such diverse fields as volcanology, planetary science, sedimentology, and climate studies, and has done field work on six continents. He is currently Associate Professor of Earth and Environmental Sciences at New York University and a consultant at NASA's Goddard Institute for Space Studies.

Introduction

World-wide events are creating an unprecedented growth of interest in regional and global climates. Extensive media coverage of droughts, floods, and very cold or exceptionally warm winters is exposing people from all segments of society to the significance of climate. The modern age of communications has permitted many formerly esoteric climatological terms, with El Niño providing an excellent example, to be widely known and frequently cited. The realization that climate, and its potential for change, can have profound influences on both the quality of life and the nature of the Earth's environment provides the basis for global actions. International conferences, publications, and agreements, many sponsored by the United Nations, are based upon the necessity of establishing international climate programs that assist nations in both understanding and responding to natural and human-induced climate processes and their implications. Results are widely reported and have become the basis for some controversies, especially regarding future climate scenarios.

Given that the public is becoming more aware of the importance of climate, it is necessary for the professional climatologist to respond to the public's needs. Research in both theoretical and applied climatology is beginning to provide a greater understanding of the actual and potential impacts of past, present and future climates, and it remains for the professional to provide the educated layperson with climatic information that is accurate, meaningful and readily comprehended. It is hoped that *The Encyclopedia of World Climatology* will be of value in this respect, for its content provides the basis for the understanding of many aspects of climate while, at the same time, providing information on recent advances in the field.

The content of this work reflects, in part, that of the *Encyclopedia of Climatology* that was published in 1986. However, there are many essential differences between the current volume and the earlier work, with the most obvious being the inclusion of modern developments in the field. Of importance, too, is the way in which past climates are treated. In this volume, apart from an overview of changes over geologic time, past climate articles deal with changes that have occurred in historic times and their impacts. This time restriction results from the explosive development of paleoclimatology in recent

decades. So significant is this growth, that a companion volume, *Encyclopedia of Paleoclimatology and Ancient Environments*, is necessary. Such a volume is currently being composed and edited for the same *Encyclopedia of Earth Sciences Series*.

The transfer of paleoclimate articles to another volume permits the *Encyclopedia of World Climatology* to include many more articles dealing with impacts of climate, examined from both environmental and social points of view. For example, changes in atmospheric quality are discussed not only as an atmospheric process but also as a human hazard. Additionally, a number of biographies of climatologists who have played a significant role in the development of climatology are provided. Those included should be considered representative of the many scholars who contributed to the discipline at various stages of its development. It is, of course, impossible to include all those individuals whose research has added to the intellectual content of climatology.

The 1986 volume contained contributions by outstanding scholars who are now deceased. The skill with which such authors as Helmut Landsberg, Elmer Reiter, J. Murray Mitchell and Derek Schove presented their ideas and concepts was not something that I wished to lose. As a result, their works have been suitably and carefully revised and edited while retaining enough of the original to reflect the writings of the original contribution. Completing such a task is no easy undertaking, and the writers who completed those revisions are certainly to be commended.

Organization

Entries are in alphabetical order, with their length being related to the relative importance of the topic. In some cases the same topic is considered under separate headings, and there are a number of ways to find relevant information. Initially, to find a particular topic it is best to look for that subject in the alphabetical listing of entries. Beyond that, the index and article cross-references locate the required subject matter. The comprehensive index at the back of the volume will list, for a given name or term, every page where that item appears in the volume.

Each article is followed by a list of cross-references that locate related entries to that article. It should be noted that these cross-references are not intended to be exhaustive, for this would lead, in many instances, to a very long listing. Instead, the reader is guided to other topics which themselves are cross-referenced. In this way, the many aspects of a given topic may be meaningfully selected.

To further assist the reader to complete research, references are given at the end of each entry. The number of references usually varies in direct proportion to the length of the entry. It will be noted that some articles provide older citations. These are intended to allow the reader to examine the historical development of a topic if desired. For the most part, however, the references provide recent significant information.

Acknowledgements

Editing a multiauthored volume such as this is not without its problems. Ranging from selection of topics to be included to determining an appropriate length, the decisions I made were greatly helped by many others. I gratefully acknowledge the ideas and suggestions of my Advisory Board members who provided an international perspective upon selection of topics and authors:

Howard Bridgman, Newcastle University, Australia;
Henry Diaz, NOAA/CDC/OAR, USA;

Michael Glantz, ESIG, NOAA, USA;
John Hay, IGCI, University of Waikato, New Zealand;
Tim Oke, University of British Columbia, Canada;
John Thornes, University of Birmingham, United Kingdom.

At all stages, the sage advice of Rhodes Fairbridge was invaluable.

All of the major articles in this volume were peer-reviewed. In addition to the acknowledgements given following selected articles, I gratefully acknowledge the comments of each of the following:

Richard Allen, Eric Alfaro, Huug van den Dool, John Feddema, James Hansen, John Horel, John Hidore, Arun Kumar, Tim Osborn, David Robinson, Thomas Schmidlin, Andrew Sturman, Tsegaye Tadesse, Martin Wadley.

Additionally, the support of Dr. Susan Berta, Chair, and colleagues in the Department of Geography, Geology and Anthropology at Indiana State University is appreciated.

Given the magnitude of the task, compiling a work of this nature requires someone of infinite patience, organizational ability, and all office management skills. I am fortunate that my wife Loretta filled this role. Without her considerable effort and continuing support, this volume might never have been completed.

John E. Oliver
Terre Haute, Indiana, 2005

A

ACID RAIN

Acid rain is one of the major environmental issues confronting industrialized countries, and is a wet form of acid deposition. Acid deposition is composed of sulfuric acid, nitric acid and ammonium, and occurs as wet deposition (rain, snow, sleet, hail), dry deposition (particles, gases and vapor), and cloud or fog deposition. Understanding the nature of acid rain and its impact requires a working knowledge of the concept of acidity and means by which atmospheric processes affect the potential for acid deposition.

Acidity

The acidity of a material is associated with the relative abundance of free hydrogen ions (H^+) when that substance is in a water solution. The pH scale is a logarithmic scale, where a value of 7 indicates neutrality; decreasing values on the scale indicate an increase in acidity and increasing values represent alkalinity.

A pH scale with representative examples is shown in Figure A1.

Absolutely pure water (distilled) has a pH of 7, but if it is allowed to react with clean air its pH will decrease to near 5.6. This is a result of the absorption of carbon dioxide in the atmosphere to form weak carbonic acid. Most rainwater will have this pH; acid rain occurs when the pH is less than 5.6. For this reaction to occur, the atmosphere must be composed of chemicals

that provide an acidic source. The atmosphere must also be able to deposit the material at the surface. This deposition is accomplished through the process of atmospheric cleansing.

Atmospheric cleansing

Acid deposition is a result of the “wet deposition” process, which involves the removal of chemicals through precipitation. Impurities in the atmosphere are incorporated in the entire precipitation process, beginning with cloud droplet formation, and are deposited as part of the resulting precipitation. Cleansing can also happen via “dry deposition”, which implies that substances in the atmosphere are deposited through gravitational settling. Large particles settle under their own weight; very small particles may be transported far from their source to eventually polymerize until they are large enough to fall under their own weight. These particles generally are returned to earth through the wet deposition process.

Wet and dry depositional processes do not include all aspects of deposition. Other forms include fog droplet interception (especially prevalent in high-altitude forests), dew, frost, and rime icing.

The current distribution of wet-deposition acid in the United States is shown in Figure A2. The eastern part of the country, centered on the northeastern states, clearly has higher acidity than the remainder of the area. In part, this distribution reflects the conditions in the drier west where the chemistry of precipitation is altered by alkaline substances contributed to the atmosphere.

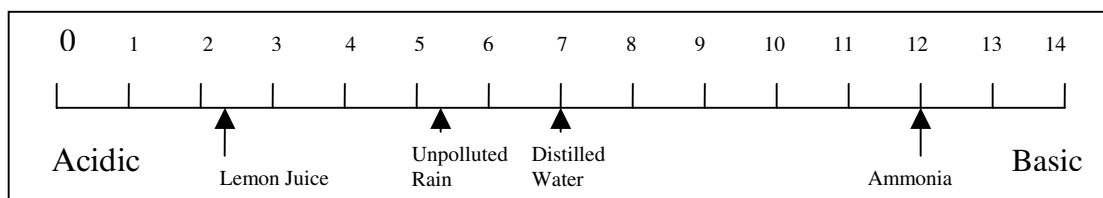

Figure A1 The pH scale denoting examples of some common substances.

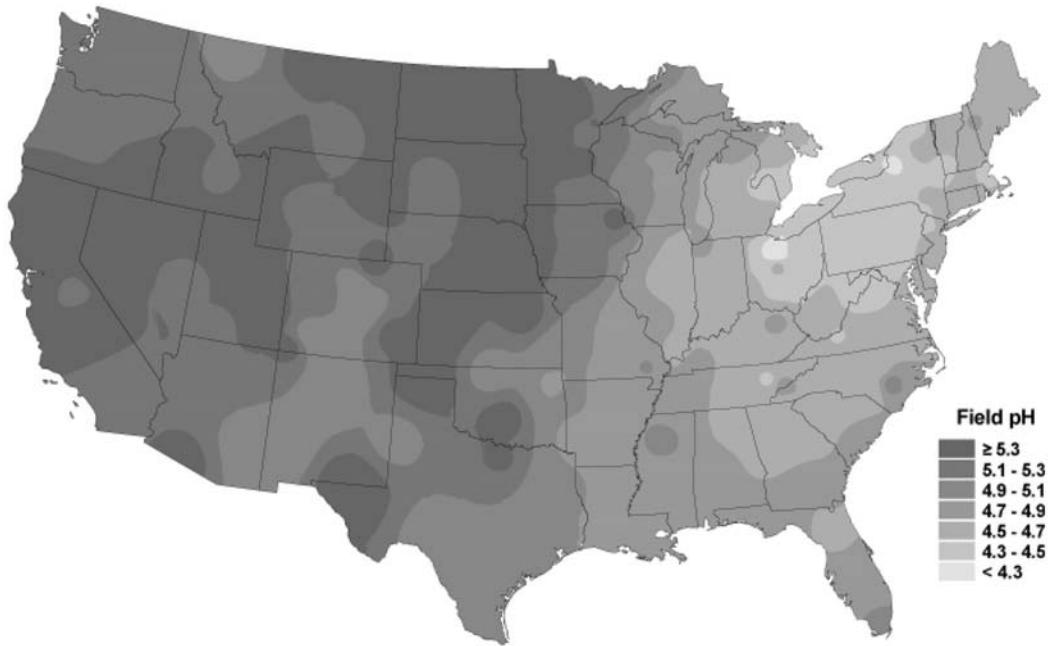

Figure A2 Distribution of acidity in the United States (National Atmospheric Deposition Program/NTN). Hydrogen ion concentration as pH from measurements made at the field laboratories, 2002.

Acid rain sources

Acid rain is primarily a result of the release of sulfur oxides (SO_2) and nitrogen oxides (NO_x) into the air by industrial and transportation sources. These oxides are transformed into sulfuric acid and nitric acid through oxidation and hydrolysis. Oxidants play a major role in several of these acid-forming processes. Rates of transformation are controlled by environmental conditions such as temperature, humidity, clouds, sunlight, and the presence of other select chemicals.

Table A1 summarizes all the major chemicals that influence the acidity of rain, with both natural and man-made sources identified. As noted above, man-made sources of SO_2 and NO_x contribute significantly to the development of acid rain. It is important to note that 95% of the elevated levels of NO_x are the result of human activities, including transportation sources (50%), electric utilities (26%), and industrial combustion (14%). The major sources of sulfur dioxide emissions were electric utilities (60%), industrial combustion (17%), and industrial processes (8%), measured in 1997.

Central to this conclusion is the question of a transport mechanism for air pollutants responsible for acid rain and the location of the source to areas that are currently experiencing acid deposition. Given that pollutants can return to earth instantaneously or remain airborne for a week or longer, then atmospheric circulation patterns and prevailing winds are significant. Examination of continental air currents demonstrates that seven states in the Midwest comprise the dominant source area for sulfur dioxide emissions that travel downwind to the Northeast (Driscoll et al., 2001). These states contributed 41% of the total national emissions of SO_2 in 1997. Furthermore, five of these states accounted for 20% of the total national emissions of NO_x .

Defining the location of actual sources contributing chemicals to acid rain is compounded by both political and economic

circumstances. As mentioned above, there has been much controversy over the role of Midwestern industries and power plants using high-sulfur coal, thereby advancing acid rain in the northeastern United States. However, Phase I of the Clean Air Act Amendment, Title IV (1995) has resulted in lower sulfate concentrations in precipitation in both the Eastern US and along the Ohio River Valley.

In 1980 the US Congress established the National Acid Precipitation Assessment Program to research the effects of acid deposition. Studies identified electric power generation as responsible for two-thirds of SO_2 emissions and one-third of NO_x emissions. Utilizing findings from these studies, Congress created the Acid Rain Program under Title IV (Acid Deposition Control) of the Clean Air Act Amendments (CAAA) of 1995. The Acid Rain Program set a goal of reducing NO_x by two million tons from 1980 levels, and requires a 50% decrease in SO_2 emissions from electric-generating facilities by 2010. By 2001, SO_2 levels have been reduced by 30% in the United States. However, nitrogen oxide emissions were not significantly affected. Research in the northeast United States has shown that acid rain is still a significant issue.

Effects of acid rain

In the 1960s and 1970s researchers in Scandinavia and the United States found that there was an increase in acidity and decrease in fish population in certain lakes and streams. Although acid rain can degrade water quality by lowering pH levels, the relationship is much more complex. Surrounding soils and vegetation contribute chemical ions that also modify acidity. Acid rain can also decrease the acid-neutralizing capacity and increase the aluminum concentrations of surface water.

Table A1 Chemicals that influence the acidity of rainfall

Ions in deposition	Source	Type	Significance
Sulfate (SO_4)	Swamps	Natural	Minor
	Volcanoes	Natural	
	Oceans	Natural	
	Power plants	Human activities	
	Industrial processes	Human activities	Major
	Smelters	Human activities	
Nitrate (NO_3)	Lightning	Natural	Minor
	Soil biologic activity	Natural	
	Industrial processes	Human activities	Major
	Transportation	Human activities	
Chloride (Cl)	Oceans	Natural	Minor
	Land surface	Natural	Minor
	Industrial processes	Human activities	
	Road salt	Human activities	
Ammonium (NH_4)	Biologic processes	Natural	Moderate
	Animals	Natural	
	Industrial processes	Human activities	Minor
	Agriculture	Human activities	
Calcium (Ca)	Land surface	Natural	Moderate
	Industrial processes	Human activities	Minor
	Agriculture	Human activities	
Sodium (Na)	Oceans	Natural	Minor
	Land surface	Natural	
	Road salt	Human activities	Minor
Magnesium (Mg)	Industrial processes	Human activities	
Potassium (K)	Land surface	Natural	Minor
	Agriculture	Human activities	

Acid rain is also thought to have a detrimental effect on forests. Trees may be injured by the direct action of acid on leaves or needles, or by changes in soil chemistry caused by the acid solution. By the early 1980s 20–25% of European forests were classified as moderately or severely damaged by acid rain. The decline of red spruce and sugar maple trees in the northeast United States has been occurring for the past four decades and has been linked to acid rain. Agricultural productivity may also be adversely impacted by acid rain.

Scientists have determined that, in soils impacted by acid rain, nutrients such as potassium, magnesium, and calcium are displaced by excess hydrogen ions, and that plant growth is retarded. Aluminum may also be released by excess hydrogen. Aluminum can be toxic to plants and, when released, can compromise the plant's ability to absorb water and nutrients. Acid rain also increases the accumulation of sulfur and nitrogen in the soil.

Buildings and monuments are also impacted by acid rain. Chemical reactions resulting from both wet and dry deposition have been recognized as a cause of extensive damage to historical buildings. Monuments such as the Acropolis in Athens and Jefferson Memorial in Washington DC show signs of damage from acid rain. Marble and limestone are susceptible due to the acids attacking the calcium carbonate in these materials. In addition to stone structures, acid rain also damages other building materials, particularly iron, steel, zinc, paint, and wood, and

can cause the lifetimes of these structures to be shortened noticeably.

The chemicals comprising acid rain can also have an impact on human health, among other things. EPA has associated NO_x with photochemical smog, respiratory illness, ecosystem changes, visibility impairment, acidification of fresh-water bodies, eutrophication of estuarine and coastal waters, and increasing levels of toxins harmful to fish and other aquatic life. Likewise, high levels of SO_2 concentrations have been associated with increased respiratory difficulties.

The future

There are still many unanswered questions concerning acid rain. If acid rain proves to be as destructive as suggested by many writers, then it is certainly one of the major environmental concerns that must be dealt with in the near future.

Climatology will play an integral role in deriving many of the answers. Of importance is the transport of pollutants in the atmosphere, a problem that is associated with both meso- and macro-circulation patterns; a complete understanding of the chemistry involved in the wet deposition process; and comprehension of dry deposition processes. Additionally, politics, both national and international, will also play a role.

 Climatic Hazards
 Precipitation

Large-scale atmospheric motions are approximately adiabatic, and clouds and snow or rain associated with them are primarily adiabatic phenomena in that they result from cooling air associated with decreasing pressure of upward air motion. Simpler adiabatic phenomena occur on a smaller scale. A common example is that of rising “bubbles” of air on a warm day, leading to cumulus cloud forms. The growth of such cumulus clouds into thunderclouds is more complex but still a largely adiabatic phenomenon.

An example of the reverse effect, heating due to an increase in pressure, is the warm Foehn or Chinook wind that results from the descent of air from higher levels.

ADIABATIC PHENOMENA

An adiabatic process is one in which the system being considered does not exchange heat with its environment. The most common atmospheric adiabatic phenomena are those involving the change of air temperature due to change of pressure. If an air mass has its pressure decreased, it will expand and do mechanical work on the surrounding air. If no heat is taken from the surroundings, the energy required to do work is taken from the heat energy of the air mass, resulting in a temperature decrease. When pressure is increased, the work done on the air mass appears as heat, causing its temperature to rise.

The rates of adiabatic heating and cooling in the atmosphere are described as lapse rates and are expressed as the change of temperature with height. The adiabatic lapse rate for dry air is very nearly 1°C per 100 m. If condensation occurs in the air parcel, latent heat is released, thereby modifying the rate of temperature change. This retarded rate is called the pseudo-adiabatic lapse rate; it is not a constant for its value depends on the temperature at which the process takes place and the amount of water vapor in the air mass. However, for general descriptive purposes it is assumed as 0.5°C per 100 m.

The usefulness of the adiabatic approximation has led to the development of special thermodynamic diagrams that enable the results of adiabatic processes to be determined graphically. These charts are characterized by having two thermodynamic variables as coordinates and the values of various others represented by isopleths. Well-known examples of these “adiabatic diagrams” are the Tephigram, Stuve diagram, and Skew-T diagram.

AEROSOLS

Aerosols are technically defined as a relatively stable dispersion of solid or liquid particles in a gas. However, in common usage in the atmospheric sciences the term refers to the particles themselves. Aerosols are involved in a number of important atmospheric processes. These include atmospheric electricity; visibility; cloud and precipitation formation, including acidity of the precipitation; atmospheric biogeochemical cycles; and the radiative properties of the atmosphere. In all of these processes the size distribution of the aerosols is particularly important, as is their chemical composition.

Atmospheric aerosols are generated by a number of natural processes and as a result of human activities. Aerosols may be classified as “primary” or “secondary”, depending on their production process. Primary aerosols are particles that are injected into the air directly, often by some mechanical process such as wind erosion of land surfaces (mineral aerosol), or wave breaking (sea salt aerosol). Secondary aerosols result from gas-to-particle conversion processes within the atmosphere that generate new particles. Table A2 presents the estimated source strengths for different types of primary and secondary aerosols. In terms of mass, sea salt and mineral aerosols (or dust) dominate the primary aerosols and also total global aerosol production. Industrial dust, various combustion processes and direct injection of particles from vegetation are also significant primary aerosol sources. The most significant secondary aerosols include sulfate, nitrate and organic particles, all resulting from the reaction of gaseous precursors in the atmosphere.

Table A2 Sources and radiative forcing of aerosols^a

Aerosol type	Source strength (Tg/year)	Anthropogenic fraction (%)	Fine fraction (%)	Global mean direct radiative forcing ^b (W m ⁻²)
Primary				
Sea salt	3300	0	<1	—
Mineral dust	2200	~50	20	-0.60 to +0.40
Biomass burning	60	>90	~100	-0.20
Fossil fuel burning	35	100	~100	-0.10 or +0.20 ^c
Biogenic	55	0	small	—
Industrial dust	100	100	~100	—
<i>Total Primary</i>	~5800	~20	~10	
Secondary				
Sulfate	200	~60	~100	-0.40
Nitrate	18	~80	~100	—
Organic compounds	17	~4	~100	—
<i>Total Secondary</i>	~235	~60	~100	
<i>Global total</i>	~6000	~25	~15	

^a Numbers are derived from Houghton et al. (2001); 1 Tg = 1×10^{12} g.

^b Values have uncertainties of a factor of 2 to 3. The global mean total *indirect* aerosol radiative forcing is estimated at 0 to -2.0 W m⁻².

^c Organic carbon is -0.10 and black carbon is +0.20.

Table A2 also provides information on the size of the particles from each of these sources. Typically aerosols are categorized according to size as “coarse” (generally greater than ~ 1 μm radius) and “fine” (generally less than ~ 1 μm radius). Essentially all of the aerosol mass for secondary aerosols is in the fine category, whereas most of the mass of the primary aerosols is in the “coarse” category. The “fine” particles in turn have two components: the nuclei mode, from about 0.005 to 0.1 μm radius; and the accumulation mode, from about 0.1 to 1.0 μm radius. Particles in the nuclei mode are formed from the nucleation of atmospheric gases. The accumulation mode particles result from the coagulation of nuclei mode particles as well as from some condensation of gases onto existing particle surfaces.

The “fine” and “coarse” aerosols not only have very different sources, they are transformed differently, they have different chemical composition and optical properties, and they are removed from the atmosphere by different processes. For example, size has a significant impact on the atmospheric lifetimes of “coarse” and “fine” aerosols. The nuclei mode fraction of the “fine” aerosols has relatively short lifetimes (roughly hours or less) within that size range due to their rapid growth via coagulation with themselves or other particles into the larger accumulation mode aerosols. Accumulation mode aerosols can have atmospheric lifetimes of days to a week or more and can thus be transported great distances in the atmosphere. The primary removal mechanism for the accumulation mode aerosols is by precipitation. The “coarse” aerosols generally have atmospheric lifetimes of from hours to a day or two, with the lifetime decreasing as the particle size increases. Direct dry deposition is important for the coarse aerosol, and this becomes increasingly

important as the particle size increases. Even “coarse” aerosols can be transported great distances, however. There have been numerous occasions when mineral dust from the Chinese deserts has been transported in the atmosphere to the east across the Pacific Ocean and North America to the Atlantic Ocean. Similarly, mineral dust from the Sahara Desert in Africa is often carried west across the tropical North Atlantic Ocean and Caribbean Sea to the eastern Pacific Ocean. Similar transoceanic transport of pollution-derived aerosols has also been observed on numerous occasions. Atmospheric sea salt aerosols from oceanic regions are also often observed in mid-continent locations.

The data in Table A2 indicate that about 20% of the primary aerosols and 60% of the secondary aerosols are derived from human-related, or anthropogenic, sources. This is particularly important for sulfate aerosols, which are often primarily responsible for visibility degradation and precipitation acidity in urban and near-urban regions. The predominant sources for the gaseous precursors for the secondary sulfate aerosols are industrial emissions and the combustion of fossil fuels. Similarly, fossil fuel combustion is the major source for the gaseous precursors of nitrate aerosols. Contrary to earlier estimates, anthropogenic sources do not appear to be a significant source of organic aerosols.

Table A3 provides information on typical number and mass concentrations of aerosols in different regions. In urban areas particle number concentrations of millions per cubic centimeter are common, whereas in the remote marine atmosphere concentrations can be less than 100 particles per cubic centimeter. In urban areas the mass concentrations can range up to several hundred micrograms per cubic meter, whereas under some

Table A3 Typical properties of aerosols in different regions*

Region	Total number (cm ⁻³)	Mass	
		<1 µm (µg m ⁻³)	1–10 µm (µg m ⁻³)
Urban (pollution)	1×10^5 – 4×10^6	30–150	70–150
Rural	2×10^3 – 1×10^4	3–8	5–30
Remote continental	1×10^2 – 1×10^4	0.5–3	1.5–7
Remote marine	1×10^2 – 4×10^2	1–4	10–35

* Derived from Seinfeld and Pandis (1998).

conditions in remote continental regions the mass concentrations can be as low as one microgram per cubic meter or less. In areas near major dust storms concentrations of 1 gram per cubic meter or more have been observed.

Aerosols have both a direct and an indirect role in the radiative forcing of climate. The direct forcing results because they can absorb and scatter both infrared and solar radiation in the atmosphere. Indirect forcing occurs because aerosols can affect and change the processes that control cloud and precipitation formation, which in turn can affect the radiative properties of the atmosphere. There has been strong interest in aerosol forcing. This is because the forcing is negative for most aerosol types, rather than the positive forcing associated with the major radiatively active trace gases, such as carbon dioxide, methane, nitrous oxide, halocarbons and tropospheric ozone. Once again, size distribution and chemical composition are critical factors in the efficiency of aerosols in affecting these forcings. While significant progress has been made in recent years in determining the importance of aerosols of various types in radiative forcing, the uncertainties are still quite large. The most recent Intergovernmental Panel on Climate Change (IPCC, Houghton et al., 2001) report has developed new estimates of aerosol forcing, and some of their results are shown in Table A2. Note that the numbers given represent the mean direct radiative forcing for the aerosols described (except for mineral dust, where only a range was given), but the uncertainties in these estimates range from a factor of 2 to 3. Aerosol types where the evidence shows negative forcing include sulfate aerosols, organic carbon aerosols, and aerosols from biomass burning. The sign of the net forcing for mineral aerosols is still uncertain. Black carbon aerosols appear to cause a positive forcing. Note also that the indirect forcing is estimated to be from 0 to -2.0 W m^{-2} . The values for aerosol forcing in Table A2 can be compared with the best estimate for carbon dioxide forcing of $+1.46 \text{ W m}^{-2}$.

AFRICA: CLIMATE OF

Africa covers an area of more than 30 million km² and is second in size only to Asia. Of all continents it is the most symmetrically located with regard to the equator, and this is reflected in its climatic zonation. The coastline is remarkably smooth and the continent has been called a giant plateau, since there is a relative absence of very pronounced topography, although some high mountains exist, especially in the East African region (Kilimanjaro, 5894 m; Mount Kenya, 5199 m; and the Ruwenzoris, 5120 m). Lake Victoria, astride the equator, covers an area of 70 000 km² and is exceeded in size only by Lake Superior among the world's fresh water lakes.

We will note below how certain evidence can be used to reconstruct the early climate of Africa, but climatic observations really only began with the European explorers of the late eighteenth and nineteenth centuries. Then, in the last few decades of the nineteenth century, meteorological services were formed that began systematic observations at a network of stations. In most cases the meteorological service followed the meteorological practices of the colonial or governing power and this characteristic has tended to persist, even after independence was obtained. A number of the countries have suffered from internal disturbance since independence, a fact often leading to a hiatus in the records. Nevertheless, the standard of observation generally has remained high at the first-order or synoptic stations, but care must be taken when using data from many of the cooperative or second-order stations.

Weather controls

As in other regions of the globe, the pattern of solar radiation is the major control of climate. However, the nature of the air-surface interface and topography also play important roles. Although ocean currents help to determine the climate of some narrow bands of land, it is by appreciating the nature of the air masses reaching a region that one can begin to understand the observed climatic pattern.

Most of the time the continent is affected by tropical air masses, often maritime (moist) in nature, but in certain areas and during certain months they can be of continental (dry) origin. At the extreme latitudinal boundaries of the continent, in the littoral region of the Mediterranean Sea, and in the area around and east of Cape Town, the effects of polar air masses cannot be ignored at the time of low sun. The terms high sun (summer) and low sun (winter) are often used when discussing seasonal variation in the topics.

Temperature, at a particular station, is a rather conservative element with a relatively small annual range, and wind speeds are normally low compared to areas in higher latitudes. Precipitation, mostly rainfall, is the significant feature of the African climate. For rainfall to occur two criteria must be met – an adequate amount of water vapor within the atmosphere and the initiation of a cooling mechanism.

The cooling mechanism is usually obtained through the ascent of a large parcel of air. Such uplifting is generally due either to topography or to horizontal convergence of the air, which is simply the coming together of air parcels or masses. The ways in which such horizontal convergence can occur over Africa are detailed in Johnson and Morth (1960).

There are four important phenomena that determine rainfall amounts and patterns over the tropical continents: (1) the intertropical convergence zone (ITCZ), (2) the equatorial trough (ET), (3) easterly waves, and (4) tropical cyclones. The latter two play relatively minor roles over Africa.

The ITCZ, defined as a surface discontinuity separating the trade winds of the two hemispheres, can be identified readily on climatic charts, but it is not easily found on daily weather maps. The confluence of convergence of the usually relatively moist air masses leads to rainfall patterns that reflect the seasonal migration of the sun, with a time lag.

The equatorial trough (ET), the zonal pressure minimum, is detected up to an average height of 500 mbar (5500 m) with a mean position near the equator at that height. At lower levels there is evidence of a pronounced shift in location with season.

Weather situations

To set the stage for an appreciation of the various climatic patterns experienced, it is helpful to understand the weather situations dominant during certain months.

January

A broad low-pressure region is noted north of the equator with only light winds in evidence. In the upper air the divergent northeasterlies act to suppress rainfall. The surface position of the ET is north of the rain belt in Central Africa whereas, in the southern sector, upper-level troughs cause heavy rains over the Angolan plateau. Frontal activity brings rain to the North African coast.

April

There has been a movement of the ET northward from the January situation. In West Africa the ET becomes identified more easily on the daily surface charts. Thompson (1965) considers the rainfall now to be the result of many complex interplays among synoptic processes and dismisses the concept of a continuous zonal belt of rainfall moving northward.

July

The position of the surface ET is now at about its furthest north, near 20°N. There is a meridional (longitudinal) pressure gradient extending from the high-pressure belt of the southern hemisphere to the intense heat lows of Arabia and North Africa. In

East Africa the topography leads to periods of convergence above the 700 mbar (3000 m) level, giving rise to the wettest month, while there is subsidence at 850 mbar (1500 m), where little rainfall is reported.

October

The rain belt is now moving southward, while a new trough begins to develop over Somalia and the Arabian Sea. Like April, this is a transitional month between the extremes of January and July.

Continental patterns of important climatic elements

The best method of identifying analogous climatic zones is to consider aspects of each of the important elements separately and then to combine them to obtain the overall picture. The elements selected here are temperature, precipitation, humidity and radiation.

Temperature

The mean annual temperature range (MATR), the difference between the mean temperatures of the hottest and coldest months, is of small magnitude over most of the continent, being less than 6°C over about half the continent. Its minimum value is 1.4°C at Barumbu in northernmost Zaire whereas the greatest is 23–24°C in parts of the Algerian Sahara. The dependence of the MATR on the continentality of the station, as well as its latitude, is shown in Table A4.

The mean annual diurnal temperature range is extremely dependent on continentality, as shown in Figure A3. Nearly all the coastal regions exhibit values of below 10°C, whereas in the central Sahara the range reaches 20°C, one of the highest values for any region of the world.

Actually, the best measure of the temperature variation is the highest mean monthly maximum temperature (H) and the lowest mean monthly minimum temperature (L). The patterns of these two variables are given in Figures A4 and A5. Figure A4 shows that it is only north of the equator where values exceeded 35°C and only in parts of the foggy coastal strip of southwestern Africa where values less than 20°C were reported. In Figure A5 the effects of elevation and latitude are more evident than those of continentality. Values below 5°C are unusual and only at high altitudes (over 1000–1500 m) in Algeria, Morocco

Table A4 Mean annual temperature range (MATR)

	Latitude E	Longitude N	MATR (°C)
Port Harcourt	7°01'	4°46'	2.5
Lokoja	6°44'	7°48'	3.6
Kano	8°32'	12°32'	5.8
Zinder	9°00'	13°48'	9.4
Agadez	7°59'	16°59'	13.3
Tamanrasset	5°31'	22°42'	16.7
Ourgla	5°20'	31°54'	23.3
Biskra	5°44'	34°51'	22.7
Constantine	6°37'	36°22'	18.3
Philippeville	6°54'	36°52'	14.2

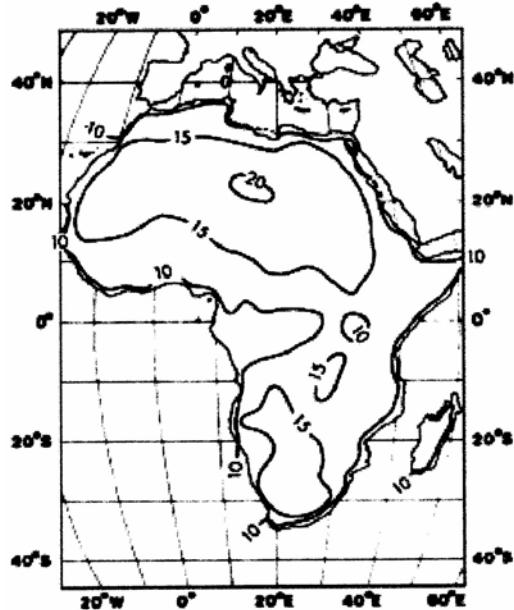

Figure A3 The mean diurnal temperature range ($^{\circ}\text{C}$).

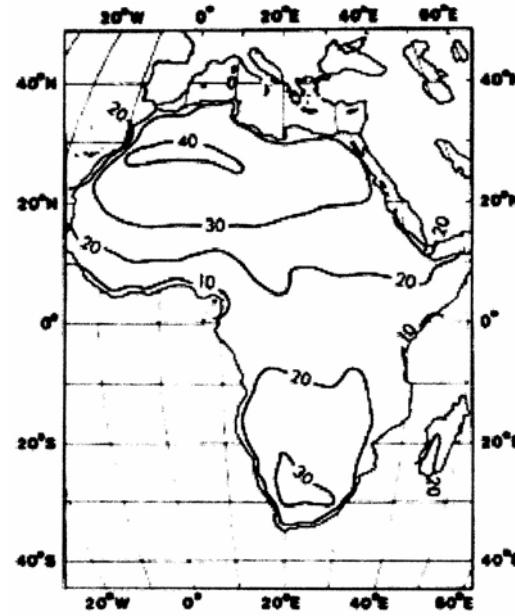

Figure A5 The lowest mean monthly temperature ($^{\circ}\text{C}$).

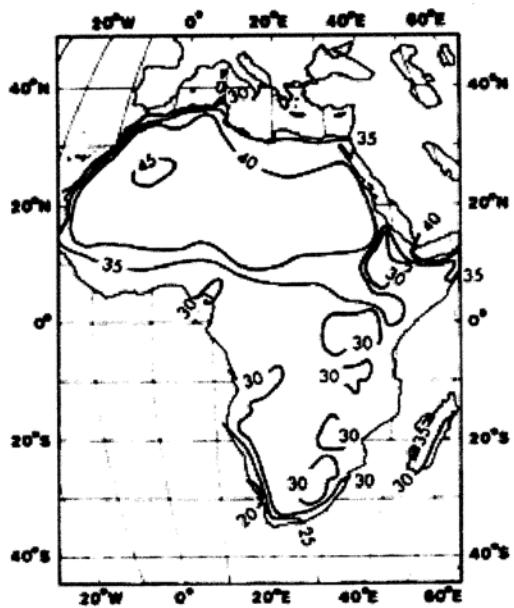

Figure A4 The highest mean monthly temperature ($^{\circ}\text{C}$).

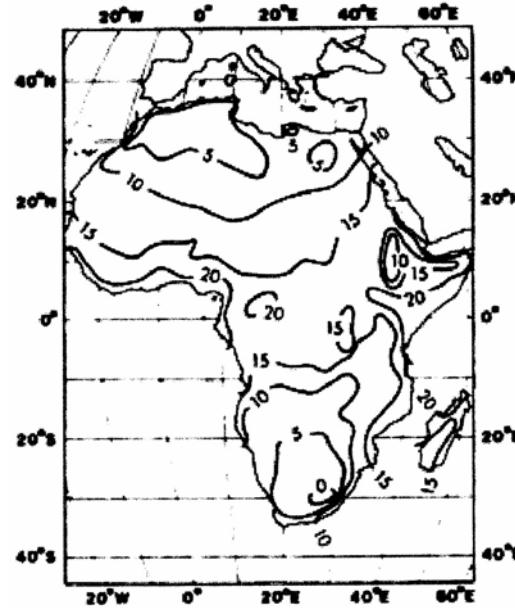

Figure A6 The difference between the highest mean monthly maximum temperature and the lowest mean monthly temperature.

and South Africa does L go below 0°C . The largest value is 26°C noted at Dallol, Ethiopia. The mean annual temperature variation (MATV), defined as $H - L$, which is depicted in Figure A6, is a combined measure of both annual and diurnal range and shows a relationship with both latitude and continentality. Again, the maximum values (above 30°C) occur in drier areas, the greatest being at Adrar in western Algeria, with 42°C . As would be expected, the equatorial littoral yields the lowest values, reaching only 8°C in Liberia and Sierra Leone.

Precipitation

Because both the ITCZ and the polar front lows exhibit large spatial movements, a basic seasonal pattern of precipitation can be identified on the continent. However, the complexities introduced by topography, upper-air conditions, ocean currents and inland lakes, among others, make the detailed pattern extremely complicated. An example of this is given by Griffiths (1972) for East Africa, whereby overlaying the spatial patterns of mean

monthly precipitation, 52 separate regions with 30 different rainfall seasons evolve.

Over most of the continent the seasonal distribution of precipitation exhibits the single significant maximum pattern, such as shown in Table A5. The season of maximum amount is generally around the time of high sun. In Figure A6 those regions in which three consecutive months receive at least 50% of the annual rainfall are shown. Only in the eastern sector of the Mediterranean coast is there a maximum at the time of low sun, but amounts involved are very small.

In the central belt of the continent most stations exhibit some degree of double maxima. However, the areas in which there is a really significant double swing during the year are quite small (Figure A7). For this illustration, significance is defined as occurring when the difference between the secondary maximum and secondary minimum exceeds 5% of the annual mean (see example of Lagos in Table A5), and this criterion limits the regions to just two. The sector in the Horn of Africa is mostly semiarid, except around Nairobi, Kenya. For stations with annual mean rainfall of over 1000 mm, Kitui, Kenya, is unique; its mean monthly totals (mm) being 41, 24, 118, 244, 56, 5, 3, 5, 0, 82, 304 and 143, giving a 22% swing.

The average annual rainfall totals show a wide range (roughly 0–10 000 mm), exhibiting a decrease away from the equatorial regions to reach a minimum around 20–30° latitude, then showing a slight increase (Figure A8). Since snow and hail amounts are generally small, all precipitation can be considered as rain. Nevertheless, snowfalls have been recorded in the Sahara, as far south as 15°N. Some falls have been quite heavy and reference to Dubief (1959, 1963) will give fuller details and some interesting photographs.

A distinctive feature of tropical rainfall is its large variability, interpreted as the difference within monthly, seasonal and annual totals. The station of Makindu, Kenya, is outstanding in this respect. Although its mean annual value is 610 mm, it has recorded as low as 67 mm and as high as 1964 mm of precipitation. On the other hand, April, its wettest month (111 mm average), has had amounts ranging from 822 mm, which exceeds the annual mean, to 0 mm. In Figure A9 a measure of annual rainfall fluctuations is depicted. Use is made of the relative variability statistic, V_r , defined as mean deviation/mean:

$$V_r = \Sigma(X_i - \bar{X})/\Sigma X_i$$

where X_i is individual yearly amounts and \bar{X} is the yearly mean. Values of V_r show dependence on the mean, \bar{X} , so data for

500 stations were used to compute the expected value of V_r as a function of \bar{X} , called $V_r(\bar{X})$, and comparing V_r for the station with its corresponding $V_r(\bar{X})$. Differences are given as a percentage of $V_r(\bar{X})$.

The great variability in certain areas of the continent can be illustrated further by two examples. Quseir, Egypt, has received 33 mm in a day – 11 times its average annual total; Lobito, Angola, had 536 mm of rain in one day – over 1.5 times its annual average fall of 330 mm.

Hail is not a common phenomenon on the continent, especially on the coast of the tropical regions. However, Maputo, Mozambique, experienced a very heavy fall in October 1977 that did considerable damage. Few places have more than five incidences annually, but a region around Kericho, Kenya, reports as many as 80 hailstorms per year. (Fresby and Sansom, 1967)

Thunderstorm days are frequent with over 20% of the continent reporting in excess of 100 annually. This band of 100 occurrences stretches from about Sierra Leone across the central area as far as Lakes Victoria and Malawi. There are a few locations where convective instability leads to annual values of more than 200, with Kampala, Uganda, 242; Bukavu, Zaire Republic, 221; and Calabar, Nigeria, 216 holding the top places.

Humidity

Relative humidity, as an expression of the atmospheric moisture condition, can be rather misleading because its impact on human comfort is dependent on the air temperature occurring at the same time. For this reason it is preferable to use the dew point temperature as an indicator since this shows little diurnal variation and can be related more readily to human comfort. Values in excess of around 21°C can be considered very sultry, and this isopleth is indicated by a thick line in Figures A10 and A11. Some scientists consider dew points above 18°C uncomfortable. With this threshold about 30% of the continent falls into this category in January and 25% in July.

Along the humid and hot coastal regions of Africa the trade winds and/or sea breezes provide reasonably comfortable conditions, contrary to most people's concepts of the humid tropics. When there is little wind, as is often the case inland, in cities or in wooded areas, the situation is quite enervating. For a good discussion of and information on human comfort conditions consult Terjung (1967).

Table A5 Seasonal distribution of precipitation

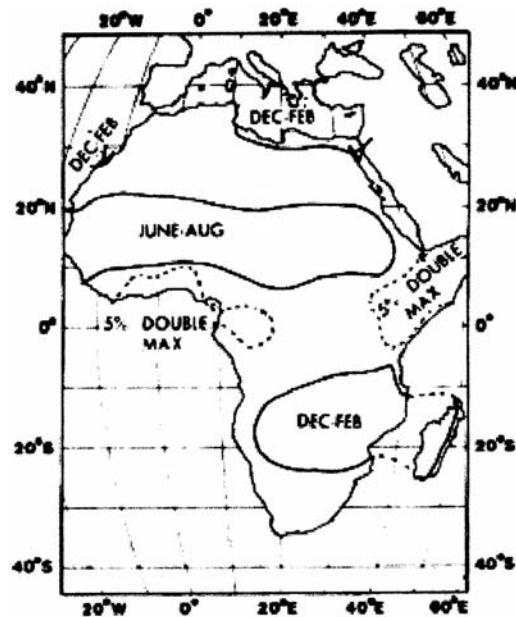

Figure A7 The 3-month period of maximum precipitation and those areas with a significant double maximum distribution.

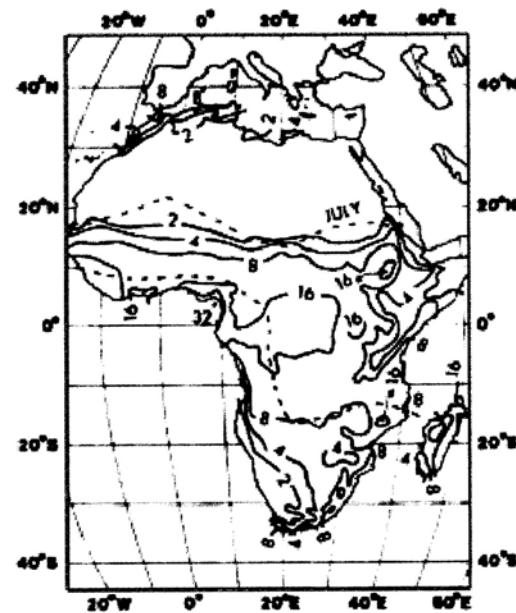

Figure A8 Mean annual precipitation (mm).

Radiation

Africa extends from 38°N to 35°S, so that the annual fluctuation of solar radiation at the top of the atmosphere is small compared with that in higher latitudes. Mean annual global radiation (solar radiation measured on a horizontal plane at the surface) varies from nearly 600 J day⁻¹ in the Sahara–Nubia area to something less than 400 J day⁻¹ around Gabon, the Algerian coast and East London, South Africa.

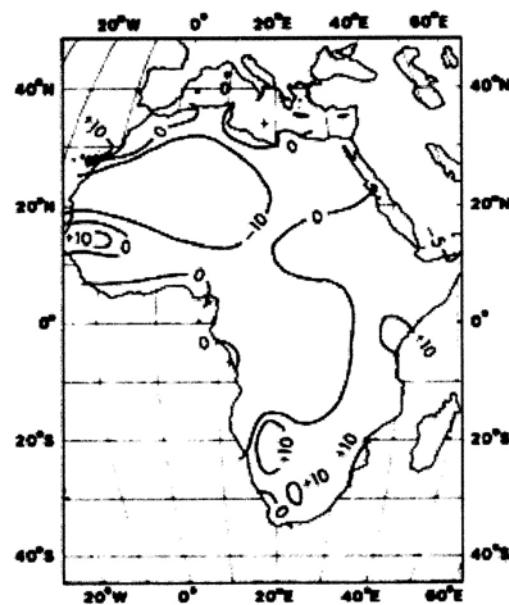

Figure A9 Variation of annual precipitation values in per cent (see text for details).

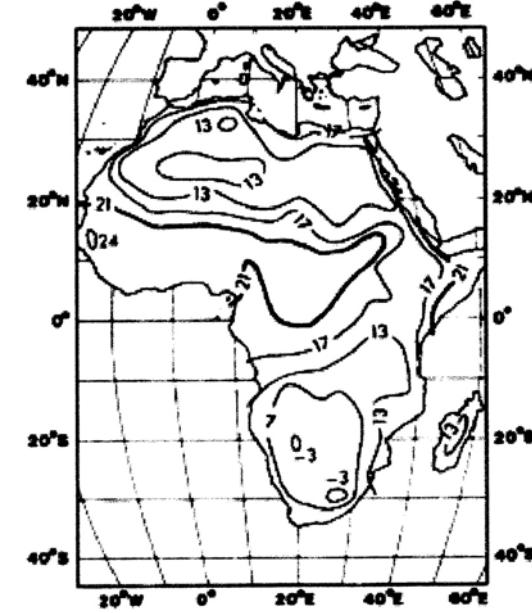

Figure A10 Mean January dewpoint temperature (°C).

Climatic zones

Using the findings of the earlier sections, it is possible to identify eight important climatic zones in Africa: (1) tropical wet; (2) tropical, short dry spell; (3) tropical, long dry spell; (4) tropical desert; (5) tropical highland; (6) subtropical desert; (7) subtropical, summer rain; and (8) subtropical, winter rain.

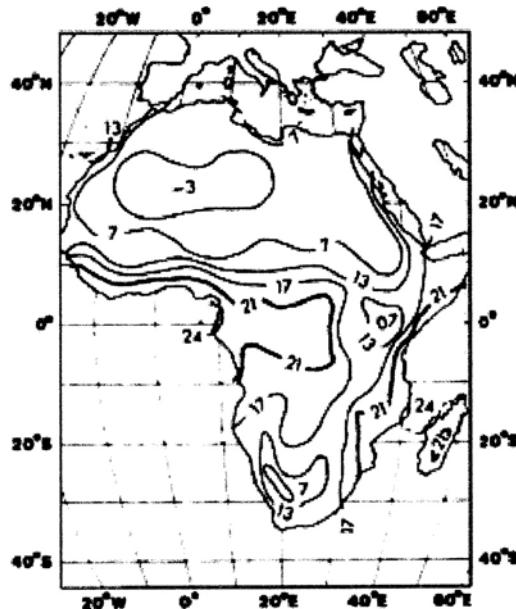

Figure A11 Mean July dewpoint temperature (°C).

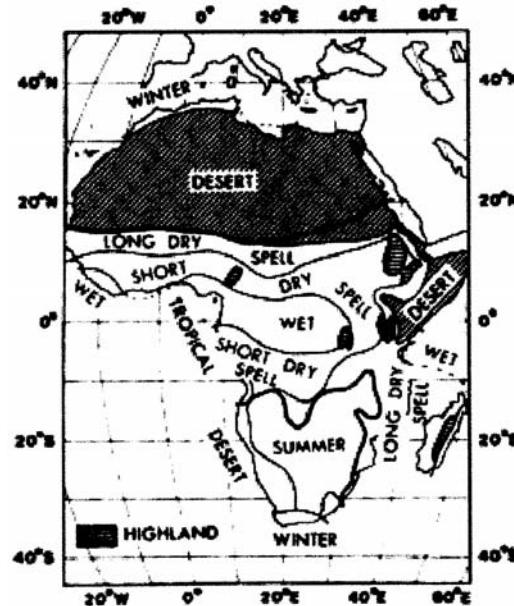

Figure A12 A simple climatic classification. Thick lines (N and S) indicate tropical boundaries (see text for details).

In addition, smaller zones of subtropical, uniform rain and subtropical highland can be found. The eight major zones are shown in Figure A12. For these purposes “tropical” designates that the mean temperature of each month is 18°C or greater; “desert” occurs when the mean annual rainfall (cm) is less than $16 + 0.9\bar{T}$, where \bar{T} is the mean annual temperature (°C), and “highland” is where the altitude causes the region to be classified in a different thermal zone from what it would be if at sea level.

The tropical wet climate (Kisangani, Table A6) exhibits some rain in all months. Temperatures are uniformly high all year round and the conditions are very enervating, although sea breezes and/or trade winds can reduce the stress along the coast. The tropical rainforest is found in abundance in this zone.

Surrounding the first zone is the tropical, short dry spell climate (Kinshasa, Table A6). Here a period of 3–5 dry months is experienced. Precipitation and temperature are still high, but the annual temperature range tends to be larger than in the wet climate. Vegetation changes from forest near the boundary with the previous zone to deciduous woodland on the drier side although, because this is an important climate for agriculture, much clearing has taken place.

The tropical, long dry spell climate (Niamey, Table A6) is on the equatorial side of the desert regions and has low rainfall for at least 6 months. Rainfall amounts are less than in the two zones discussed above and temperatures show a much larger seasonal swing. The area is susceptible to drought and at such times the often marginal agriculture suffers tremendously. Vegetation is normally savanna and scrubland. The northern belt is referred to as the Sahel, a region in which famine has afflicted millions of inhabitants. The extreme variability of rainfall amount and frequency is a characteristic of the zone (Todorov, 1984).

Tropical desert climates (Obbia, Table A6) are not common, the biggest region being in the Horn of Africa where the prevailing winds, NE at low sun and SW at high sun, ensure that very few moist air masses reach the area.

The tropical highlands climate (Nairobi, Table A6) offers relief from the tropical heat, as well as a decrease in absolute humidity. Precipitation amounts can change quite rapidly in short distances as exposure to prevailing winds plays a dominant role. Generally, there is an increase in annual amount with height up to a belt of maximum rainfall, often around 2000 m or more, but changing according to the direction of slope. If the elevation is high enough (over about 5500 m) the region is permanently snowcapped. This transition from sea level to snowfield means that many vegetation belts are identifiable on the slopes.

The subtropical desert climate (Wadi Halfa, Table A6) is the most extensive of all zones on the continent. Summer temperatures in the Sahara are among the highest in the world, although they are not quite as great as in Namibia. Due to the low relative humidity and clear skies, diurnal temperature ranges can be extreme, with values in excess of 20°C often being reported. As may be expected, radiation and sunshine amounts are extremely large. Vegetation, while sparse, springs to life after any brief shower.

The subtropical, summer rain climate (Harare, Table A6) is found mainly in the southern plateau. Precipitation usually is so concentrated that about half the annual total falls in 3 months. Winters are generally very pleasant and comfortable.

The subtropical winter rain (or Mediterranean) climate (Cape Town, Table A6) is found at the extremities of the continent. These areas can experience extremely hot and dusty winds in summer from their adjacent deserts, but from fall to spring conditions are ideal. Vegetation is xerophytic, able to withstand the long dry spell.

Table A7 lists some climatic extremes for the continent. It is interesting to note how many of these are also world record extremes. Even in the precipitation class only two stations, Waialeale, Hawaii, with 1455 mm and Cherrapunji, India, with 10 820 mm, exceed Ureka’s total. At another site near Cherrapunji a 5-year mean of 12 650 mm has been reported.

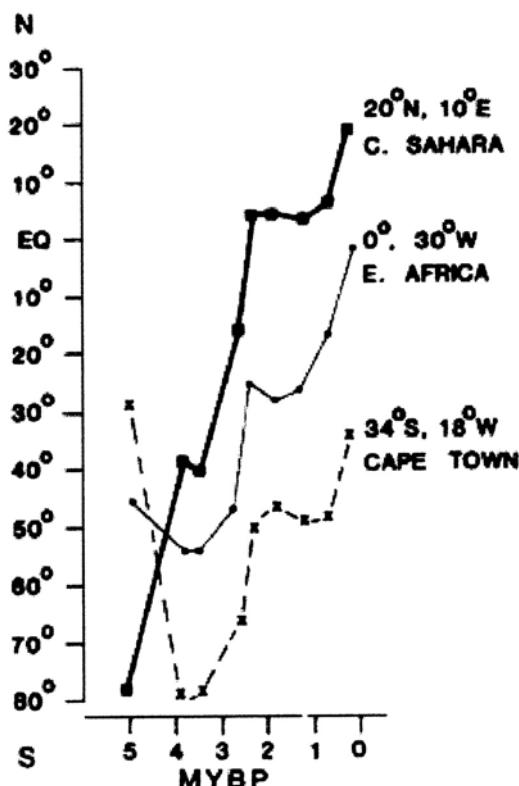

Figure A13 Latitudinal changes at three locations during the past 500 million years. (After Newell, 1974.)

Past climates

There has been relatively little study of past climates in Africa compared with studies of Europe and North America. However, it is known that the continent has occupied very different latitudes from that in which it is presently situated due to tectonic plate movements. In Figure A13 the latitudinal changes in the positions of three points on the continent are shown. From this alone it can be appreciated that in the period 450–200 million years before present (Ma BP) the Cape Town site, occupying a position within the Antarctic Circle, must have had a very cold climate, whereas now it is in relatively the same latitude as it was 500 Ma BP. The Central Saharan site has shown an almost steady progression from 80°S and it is likely that around 300 Ma BP it was also semiarid to arid, but from 200 to 50 Ma BP it was quite wet and humid. The East African location has not shown such extreme latitudinal variation but, nevertheless, must have experienced midlatitude and subtropical climates before reaching its present equatorial situation.

Some remark must be made concerning climate changes in the Saharan area. There have been many papers on this subject and the consensus of opinion is that from 20 000 to 12 000 years ago there was great aridity and the desert advanced southward. Following this period there were some very moist periods, while over the past 2000 years the rainfall has declined sufficiently to make the agriculture practiced in the time of Roman occupation no longer feasible (Carpenter, 1969). Murphey (1951) claimed that the cause is basically artificial and, even today, the growth of the desert must be attributed in great measure to anthropogenic influences. It is interesting to note that there are reports of ice on the Nile in the ninth and eleventh centuries (Oliver and Fairbridge, 1987).

For eastern Africa a more recent study (Hastenrath, 1984) suggests that there was a distinct retreat or disappearance of glaciers around 11 000–15 000 years ago, the deglaciation beginning at lower altitudes (*ca.* 3000 m). The most detailed studies of the historical climatology of Africa have been published by Nicholson (1976, 1978) and Nicholson and Flohn (1980). Nicholson finds, in the times of anomalous climate and climatic discontinuities, reasonable correlation between the sub-Saharan area and that of southern Africa. She identifies anomalous weather patterns in the 1680s and 1830s and a major rainfall change around 1800. Apparently the nineteenth century had greater snowfall than the twentieth century.

In the period 1870–1895, both the Sahara and eastern Africa had above-average rainfall, after which drier conditions set in and by the mid-1910s severe droughts were common in much of the tropics and subtropics. In the 1920s and 1930s there were indications of wetter conditions – Nile discharge up 35%, Lake Chad depth up 50%, and Sierra Leone reporting a third more rainfall than in the late nineteenth century.

Studies of African climate during the last 100 years or so are made problematic because of the vast areas for which the periods of record are very short. It is true that some temperature and precipitation measurements exist from the first half of the nineteenth century, such as in Tripoli and western Africa, but in general few reliable records exist before about 1890. Exceptions to this would include the island of Mauritius which has an almost unbroken record since around 1851.

A special project of the Global Climate Laboratory, part of the National Climatic Data Center, located in Asheville, North Carolina, is concerned with locating, extracting and digitizing data of monthly mean maximum and minimum temperatures and precipitation amount. In a few countries, including Egypt,

Nigeria and South Africa, there are enough stations to allow a regional investigation.

AGROCLIMATOLOGY

Agroclimatology, often also referred to as agricultural climatology, is a field in the interdisciplinary science of agrometeorology, in which principles of climatology are applied to agricultural systems. Its origins relate to the foremost role that climate plays in plant and animal production. Formal references

to the terms "agrometeorology" and "agroclimatology" date to the beginning of the twentieth century, but use of empirical knowledge can be traced back at least 2000 years (Monteith, 2000). Agroclimatology is sometimes used interchangeably with agrometeorology, but the former refers specifically to the interaction between long-term meteorological variables (i.e. climate) and agriculture. As such, they share common fundamental principles, methods and tools, but specific concepts are applied as described here.

Fundamental principles

Understanding the interactions between atmospheric variables and biological systems in agriculture, and applying this knowledge to increase food production and improve food quality, are the main goals of agrometeorology. Biological systems in agriculture are comprised of crops and forests, including the soil in which these grow; animals; and associated weeds, pests and diseases. Atmospheric variables that may affect these systems range from physical variables, such as solar radiation, precipitation, wind speed and direction, temperature, and humidity, to chemical variables, such as trace gas concentrations (e.g. CO₂, O₃). Agrometeorology is concerned with the characterization of these variables not only in the natural environment, but also in modified environments (e.g. irrigated areas, greenhouses, and animal shelters).

The fundamental principles used in the study of interaction between the atmosphere and agricultural systems are: (1) conservation of mass and energy, (2) radiation exchange, and (3) molecular and turbulent diffusion. The response of biological systems to these interactions draws on principles of soil physics, hydrology, plant and animal physiology, plant and animal pathology, entomology and ecology. Topics of research include water and radiation use efficiency by crops, animal comfort levels as affected by the physical environment, air pollution damage to crops, disease and pest development as a function of environmental conditions, and greenhouse gas emission by agricultural activities.

Methods and tools

Spatial scales in agroclimatology cover a wide range, from <0.1 m (e.g. response of fungi to leaf wetness) to regional and global scales (e.g. drought monitoring). Temporal scales may span past, present or future climate. Choice of instrumentation and measurement methods for weather and biological variables occurs according to the spatial and temporal scales of interest. Most often, agroclimatologists rely on long-term climate data provided by national meteorological services. In some countries weather stations originally were established in association with agricultural research institutes, attesting to the importance of weather and climate to agricultural production. Expertise in instrumentation, typically sensors for air temperature and humidity, solar radiation, precipitation, and wind measurement, is required from agroclimatologists in some applications, particularly those involving smaller spatial scales than provided by weather stations (i.e. microclimatological scales).

In all cases data describing the condition of the biological system are also needed. These include observations of developmental stages in crops, weeds, or insects; crop, milk or meat yield; grain or forage quality; and other physical and

physiological measurements. Increasingly, remote sensing measurement techniques are being used to obtain regional and global scale estimates of variables, such as vegetation indices, or surface temperature.

Data handling, management, and processing procedures, spatial and temporal interpolation, statistical analyses, mathematical models that simulate the response of biological systems, and geographical information systems (GIS), decision support systems (DSS) are examples of tools used by agroclimatologists.

Concepts

A few concepts widely used in agroclimatology are presented here. The reader is referred to Griffith (1994) for additional background and examples of applications.

Degree-days and length of growing season

The concept of thermal time, or degree-days, was one of the earliest concepts developed, with wide application in agroclimatology. Climate records are matched to cardinal temperatures of crops, and daily mean temperatures above a minimum threshold, but below a maximum threshold, are accumulated over phenological phases. Stages in development for specific species or varieties occur once a certain degree-day value has been reached. Degree-day requirements for crops to reach maturity are then used to select suitable climatic regions for each crop or variety. Conversely, climatic records are used to calculate degree-days during the growing season. Provided water is available, length of growing season has its starting date defined by last mean spring frost date and ending date defined by first mean fall frost date. Probability distributions of historical degree-day records allow for selection of adequate crops and cultivars, those that will reach maturity for an accepted risk level.

The same concept can be applied to predict probability of occurrence of damaging development phases of pests in crops during certain times of the year, guiding the application of control measures.

Evapotranspiration and water balance

Water loss from the soil–plant system, through soil evaporation and plant transpiration, is termed evapotranspiration (ET). This is an energy-consuming process fueled mostly by net radiation absorption by the soil–plant surface. Soil water availability also determines the ET rate, with additional control provided by plant stomata. Under optimum water conditions plants do not need to control water loss, and carbon dioxide uptake also proceeds without restriction. Hence, crop yields are optimum under non-limiting water conditions. Numerous models have been developed for prediction of ET from crops given optimal and limiting soil water conditions. The Penman–Monteith equation, and the use of crop coefficients are commonly used (Allen et al., 1998) in agroclimatology to predict seasonal crop water requirements, and to determine irrigation needs of crops. This is accomplished through a soil water budget, where losses due to ET, runoff and deep percolation are compared to inputs such as precipitation and irrigation. Water stored, as determined by soil characteristics and rooting depth, decreases if outputs exceed inputs, and vice-versa. Limiting growth conditions, and reductions in yields, occur if soil water available to crops falls

below a critical level, signaling the need for irrigation. A water budget applied using climatic data determines crop water requirements for optimal yields, and irrigation viability, contributing to long-range planning of land and water resource use.

Agroclimatic zoning

In contrast to climatic classifications, which are usually based on temperature and precipitation, agroclimatic classifications also take soil type, crop potential productivity and moisture deficiency, among other variables, into consideration (Bishnoi, 1989). Agroclimatic zoning allows for assessment of resources for agriculture, crop planning, and improvement in crop productivity. This concept was expanded to include environmental impact, resulting in the concept of agroecological zoning (AEZ) by the United Nations Food and Agriculture Organization (FAO). Recently, AEZ has been used to establish a global environmental resource database, including climatic, soil, terrain, and land cover, assessing the agricultural potential of 28 crops at three levels of farming technology (Fischer et al., 2001).

Animal comfort

The energy budget of homeothermic animals determines the level of comfort experienced, and if additional energy needs to be expended in keeping the body in a thermally comfortable zone. Excessive energy spent in thermal regulation results in reduced productivity, and may affect survival in extreme cases. Different livestock species and breeds have contrasting climatic requirements, and resistance to diseases typical to each environment. Consequently, climatic factors play a role in determining the level of success of the livestock enterprise. For example, a temperature–humidity index (THI), calculated from climate normals, has been used to indicate when temperate-evolved Holstein cows become less productive in various climate zones (Johnson, 1994).

Importance

Understanding of interactions between weather and agriculture leads to opportunities to use this knowledge for increased agricultural production, and also for minimizing agriculture's risks and impact on the environment. Thus, agrometeorology can play an important role in promoting sustainable development, through protection of the atmosphere and fresh water resources, desertification and drought control, sustainable agriculture, and education and training (Sivakumar et al., 2000). Knowledge obtained through research in agrometeorology is applied to guide: (1) strategic decisions in long-range planning; (2) tactical decisions in short-term planning, and (3) agrometeorological forecasts (WMO, 1981). Agroclimatology addresses needs in long-range planning, with typical examples of strategic decisions being selection of crops, livestock or forest species that match the existing climatic environment (agroclimatic characterization); and scheduling of agricultural operations (planting, pest control, etc.) that take into account long-term records and minimize risks. Hence, agroclimatology also provides tools needed in assessing the impact of climate change on agriculture, and strategies for farmers to adapt to a changing climate.

AIRMASS CLIMATOLOGY

An airmass is a large body of air with relatively uniform temperature, humidity, and lapse rate characteristics across its horizontal extent. Especially in the midlatitudes, large seasonal and daily changes of weather commonly result from alternating dominance by airmasses derived from a variety of source regions. Specific types of these airmasses, typically covering hundreds of kilometers, are also responsible for stretches of days with similar weather, such as a cold polar outbreak in winter, or a hot-humid string of days in summer. Airmass climatology generally will describe the types of airmasses found in an area, will classify them according to their temperature and moisture characteristics, and will determine their seasonal or annual frequency of occurrence. This focus on temperature and moisture characteristics contrasts with weather-typing schemes that typically concentrate on pressure patterns and circulation features.

Airmass climatology grew out of the so-called “Norwegian” school of synoptic weather analysis. Bergeron (1928) formulated the concept of the airmass in the 1920s and proposed that a study be made of airmass characteristics and frequencies as a means of explaining recurring weather patterns (see Willet, 1931, for an English-language discussion). Pettersen (1940) first put together a northern hemisphere summary of airmasses. Strahler (1951) presented a worldwide synthesis showing general source regions and areas of dominance. Although too

general for application to specific locations or during specific seasons, Strahler’s model served well as a framework for other more detailed climatologies. Growing as it did out of midlatitude weather analysis, airmass climatology is most applicable where weather changes are frequent and airmasses numerous. The weather and climate of the tropics, poles, or other areas having a relative constancy of a single airmass type are generally less amenable to analysis by airmasses, since the significant weather patterns are caused by other mechanisms.

Classical airmass analysis is a manual exercise that requires subjective interpretations by the researcher that can be difficult to replicate, and often lack the precision necessary for successful applications. The availability of upper-air data and rise of numerical techniques, overshadowed the utility of the airmass as a weather forecasting tool by the late 1950s. Starting in the 1960s, dissatisfaction with the limitations of all manual classifications, coupled with increasing computer power, led to a dramatic reduction in their use. They were replaced by experimentation with many automated weather-typing techniques. None was widely adopted, nor did these schemes match the elegant simplicity and utility of the airmass concept for explaining midlatitude weather phenomena. However, neither did it appear possible to make classical-style airmass climatologies sufficiently rigorous for modern use.

Starting in the early 1990s, a new body of airmass work has grown from a commitment to a hybrid approach, combining manual and automated classification techniques to rehabilitate airmass climatology as a modern research tool (Schwartz, 1991; Kalkstein et al., 1996; Sheridan, 2002). Applications of the new approach have been successfully demonstrated in many areas, including describing the seasonal climate of an area, showing coherent upper-level circulation relationships to surface airmass distributions, interpreting precipitation intensity, assessing climate change, characterizing urban heat islands, identifying excessive heat-stress conditions, and even evaluating GCM output. Airmass climatology is again a fertile ground for discussion and research.

Airmasses

Formation

The critical properties of airmasses are temperature, humidity, and lapse rate. Of these, temperature and humidity are largely determined by the surface over which an airmass originates, whereas lapse rate is controlled by a number of factors. Usually, the geographic origin of an airmass within features of the general circulation (such as subtropical high pressure system or intertropical convergence zone) determines the lapse rate of the airmass.

In order for an extensive portion of the atmosphere to become recognizable as an airmass, it must reside for a time over a surface that is rather homogeneous across large expanses. The most effective way for this to occur is for a large anticyclone (high-pressure system) to remain stationary over an area for a number of days or weeks. Within the anticyclone, pressure gradients are weak, winds are light and slow subsidence induces radial drainage of air away from the center, which assures little mixing of foreign airstreams into the anticyclone. As the system stagnates, the atmosphere is slowly modified through radiative and convective processes to take on the temperature and humidity characteristics of the surface. For

example, within a wintertime polar anticyclone the resident air will lose heat through radiative transfer to the surface, and the airmass will become cold and dry as water-holding capacity decreases with temperature. This airmass will have a relatively stable lapse rate because of cooling in the lower layers and adiabatic warming of subsiding air aloft.

Oceans, deserts, and extensive continental plains at high and low latitudes are the usual birthing places of the classical airmasses, as it is in these locations that large pieces of the atmosphere can reside for a long time over a relatively homogeneous surface. Mountainous areas and continental plains at mid-latitudes are usually not considered source regions of airmasses, since the surface conditions of mountains are too heterogeneous, and midlatitudes continents do not often experience the stable weather conditions necessary for the formation of airmasses. On the other hand, midlatitude oceans typically are source regions for airmasses, since horizontal temperature variation in the oceans is usually rather small. The damp foggy conditions of midlatitude, west coast locations (marine type climate) are attributed to continual dominance by marine airmasses.

The subtropical high pressure systems (STH) near 30° latitude illustrate the complex interaction between general circulation features and surface conditions in influencing lapse rates of airmasses. These semipermanent high-pressure systems are strongest over subtropical oceans, and they are stronger to the east and weaker to the west. In addition, subtropical oceans usually have a relatively cold ocean current along their eastern portion and a warm ocean current in their western part. Airmasses formed within the strongly subsident eastern portion of a STH therefore have a very stable lapse rate aloft resulting from subsidence and adiabatic warming, and they also experience a slight cooling in the lower layers from contact with the cold ocean water. These airmasses are extremely stable; they typically have a surface temperature inversion and may also have a middle-level temperature inversion. With such a stable lapse rate it is almost impossible for these airmasses to produce rain. The aridity of coastal areas in eastern Australia, western North America, the Atacama Desert (South America) and the

Kalahari Desert (Africa) is the result of the continual dominance by these stable airmasses that originate over oceans. Airmasses formed in the less strongly subsident western portion of a subtropical high originate over a warm water surface and are usually rather unstable. They often contain thunderstorms and are responsible for much of the precipitation received by the east coast of continents at subtropical latitudes (for example, southeastern United States or Japan).

Airmass types

Airmasses are traditionally classified based on temperature and humidity, although the location or latitude of the source region and lapse rate or stability are also important variables in classification. A typical qualitative air mass classification is shown in Table A8 (a good treatment of traditional manual airmass classification and weather patterns is provided in Trewartha and Horn, 1980; see also Pettersen, 1956). The temperature symbols in Table A8 (A, P, T, E) reflect both the midlatitude origin and evolution of airmass analysis since the original airmass meteorological work in Scandinavia, Canada, and the United States emphasized the role of cA, mP, cP, and mT airmasses in midlatitude weather systems. The gradual evolution of this terminology has caused some confusion, since polar airmasses, in reality, originate at latitude 45–66° and are more properly termed subpolar airmasses (James, 1970). The extremely frigid air originating in polar latitudes has come to be called Arctic (or Antarctic) air. A symbol for equatorial airmasses (E) has also joined the list, primarily because airmasses originating from the unstable western limb of subtropical anticyclones near 30° latitude are usually classified as maritime tropical (mT) air, although their origin may not have been strictly in tropical latitudes. The mE classification, then, refers to actual tropical airmasses and mT air refers to the hot, moist, subtropical air experienced in summer by midlatitude locations.

In addition, other letters can be added to manual classifications to provide information on the lapse rate or the temperature of the airmass relative to the surface across which it moves. For

Table A8 Classical airmass types

Variable	Abbreviation	Source	Airmass characteristics
Temperature	A (Arctic)	Arctic	Frigid
	P (polar)	50°–70° Latitude	Cold
	T (tropical)	Subtropical	Hot
	E (equatorial)	Equatorial	Hot
Humidity	m (maritime)	Over water	Moist
	c (continental)	Over land	Dry
Symbol	Airmass name	Airmass characteristics	
mE	Maritime equatorial	Hot, moist	
mT	Maritime tropical	Hot, moist	
mP	Maritime polar	Cool, moist	
cT	Continental tropical	Hot, dry	
cP	Continental polar	Cold, dry	
cA	Continental Arctic	Frigid, dry	

The abbreviations in the upper part of the table are usually combined to give a specific airmass a two-letter identification symbol as shown in the lower part of the table.

Table A9 Integrated method airmass types (Schwartz, 1991)

Symbol	Airmass name	Airmass source
C	Continental	Central Canada
Pa	Pacific	Pacific, via Rocky Mountains
Po	Polar	C + Pa (summer only)
D	Dry tropical	SW USA (mostly summer)
dT	Dilute tropical	Modified T (non-summer)
T	Tropical	Gulf of Mexico
U	Unclassed	Transition and mixing

Table A10 Spatial synoptic classification airmass/weather types (Kalkstein et al., 1996)

Symbol	Airmass name	Airmass characteristics
DP	Dry polar	Similar to cP
DM	Dry moderate	No traditional source region
DT	Dry tropical	Analogous to cT
MP	Moist polar	Large subset of mP
MM	Moist moderate	Warmer, more humid than MP
MT	Moist tropical	Analogous to mT
TR	Transitional	Days one type yields to another

example, a cP airmass moving over a warm surface is colder than the surface, receives fluxes of energy and moisture, and is therefore unstable. This airmass would be given the classification cPk_u, where the k stands for cold (relative to the surface), and u stands for unstable. This type of airmass would be typical of conditions along the east coast of a midlatitude continent in winter, with cold, polar airmasses being advected across warmer ocean water, resulting in fog and frequent cyclogenesis.

Recent airmass climatologies using hybrid manual-automated techniques have started to move away from the classical definitions. Schwartz's (1991) methodology was not directly comparable to previous work, but tried to use generic names similar to the classical ones to recognize major airmass types in the north central United States (Table A9). Kalkstein et al. (1996) decided that the classical definitions were too limited for application to environmental problems, and developed a revised set of airmass/weather types for the spatial synoptic classification (SSC), for use in the conterminous USA (Table A10).

Airmass modification

One of the major difficulties in identifying and classifying particular airmasses is that their properties change over space and time. Schwartz (1991) and Kalkstein et al. (1996) employed differential station airmass criteria and new types to account for these effects. Central North America provides two excellent examples of these problems of identification, modification, and classification of airmasses. In the summertime, mT air from the Gulf of Mexico frequently streams northward across central North America, but convection and mixing with other non-mT air modifies the properties of these airmasses. Air that had a temperature of 32°C and a dewpoint temperature of 21°C over the Gulf may have a temperature of 28°C and a dewpoint temperature of 17°C by the time it reaches the Great Lakes. In the interim, midtropospheric dry air from the Rocky

Mountains, subsiding beneath a ridge (or high-pressure system) in the upper air westerlies, has significantly diluted the mT air flowing northward at the surface.

Central North America also provides another example of a different style of airmass modification. Borchert (1950) found that, for over 6 months of the year, the central Great Plains are occupied by airmasses that originate over the Pacific Ocean and that are then advected over the western North American cordillera. In the process these Pacific airmasses lose most of their moisture over the mountains and gain latent heat. As these airmasses subside over the Great Plains they are much warmer and drier than when they originated. Borchert classified these airmasses as mP air, but he referred to them as modified mP air, recognizing that they are relatively warm and dry; in fact, mP would better refer to "mild Pacific" rather than "maritime Polar" air. Schwartz (1991) recognized this mP air as "Pacific" and Kalkstein et al. (1996) as "moist polar". These examples illustrate several of the problems associated with attempting a rigorous manual classification based solely on the origin of airmasses, and demonstrates some reasons why the new hybrid classification techniques are desirable.

Methods of airmass analysis

One of the central problems in airmass climatology is identification of particular airmasses. Classical airmass identification techniques may be grouped into two broad categories: those aimed at determining some characteristic of an airmass, and those that trace the path of movement of an airmass. Airmasses originate in core areas, and a single airmass ought to resemble closely the characteristics of the core area. Airmass identification for a given station usually begins, therefore, with an identification of the major airmass core areas and airmass types that might be expected to influence the study area. Further identification and classification of a single airmass occurring away from its core area is usually accomplished by comparing airmass characteristics such as temperature, relative humidity, dewpoint temperature, or lapse rate with characteristics of source regions. The weak link in this type of analysis is identification of source region characteristics: although these core areas are usually located based on widely agreed upon features of the general circulation, it is still a subjective judgement by the analyst who determines their temperature and moisture values. In North America, Brunschweiler (1952) first attempted to classify climate based on airmass patterns, but his technique was not considered rigorous and remains unused. Other regional climatologies of note include Borisov (1965) for the USSR, Arakawa (1937) for Japan, Belasco (1952) for the British Isles, and Tu (1939) for China.

For rigorous scientific analysis some automated methods of airmass identification are desirable to reduce the possible bias introduced by analyst's assumptions. The partial collective method has been used to identify airmass dominance based on some property such as temperature. In the partial collective method, airmasses from a single source region are theorized to have temperatures that tend toward a modal value, and the deviation of the temperature of a specific airmass away from the mode is apparently caused by longer or shorter residence time in the source area. Theoretically, the daily temperature distribution at any weather station can be decomposed into a group of normal distributions (partial collectives of the whole distribution), each of which has a separate modal temperature representing multiple occurrences of a certain airmass. Bryson

(1966) used this method to determine North American airmass regions, but some of his airmass boundaries did not coincide with boundaries determined by Barry (1967), using frontal analysis methods. Ozorai (1963) did not find this method particularly useful for Hungary, since the temperature histogram of Budapest displayed many more partial collectives than existing airmass categories.

Taljaard (1969) attempted a southern hemisphere synthesis of airmass dominance, while Oliver (1970) concentrated on classifying Australia's climate based on airmass dominance. These two studies are notable since airmass literature concentrates strongly on northern hemisphere topics, and southern hemisphere climatologies are few in number. Oliver (1970) offered an alternative to the partial collective method. He assigned characteristics to airmasses in Australia based on thermohygric diagrams showing temperature, specific humidity, and relative humidity, as well as through theoretical identification of the presumed source areas. Monthly data were plotted and clusters of points were identified as airmass types. Oliver was able to generalize the analysis so that temperature and precipitation data could be used to identify regions of airmass dominance in Australia. His scheme for identifying the airmass dominance at a station (called monthly airmass identification, MAMI) remains largely untested for the rest of the world.

Trajectory analyses trace the path of an airmass as it moves and is modified. Again, the use of a trajectory method usually presupposes that source regions for airmasses are already known. An alternative type of this analysis attempts to trace airmass trajectories back to the source region. Wendland and Bryson (1981) determined such "airstream" regions for the northern hemisphere by tracing mean resultant near-surface wind flow, under the assumption that airmass trajectories follow wind flow. Source regions were identified as areas where mean wind flow diverged in many directions from a single point. Several areas were shown to be dominated by airstreams of relatively consistent and conservative properties, and these regions are analogous to airmass regions identified in other ways.

Schwartz (1991) explored the airmass classification problem with a hybrid manual – automated methodology, in order to benefit from the inherent advantages of each approach. The new scheme addressed the nonreplicability problem of manual classifications, the boundary identification problem of automated methods, and the difficulty in quantifying misclassification error common to all techniques. The manual portion of Schwartz's "integrated method" analysis identified maxima and minima of 850-hPa temperature and dewpoint values for each airmass type, at every station in the north central USA (NCUS) study area, during the four seasons (represented by the months of January, April, July, and October). The 850-hPa level was chosen because it is close enough to the ground to reflect surface conditions, but enough removed to be free of diurnal boundary layer processes, and fairly conservative of temperature and moisture characteristics. Trajectory analysis was used on a number of airmasses of known origin, until the accuracy of the specific numerical limits defining each airmass was ensured.

The automated portion of the integrated method used the partial collective technique to identify normal curve components in the temperature and dewpoint frequency distributions for each station-month, starting from initial estimates of each components' mean, standard deviation, and weight (percent of the total distribution), and the number of different air mass types present, based on the results of the manual analysis. The manual and automated analyses were combined to produce the final

numerical limits and transition zones for each airmass type in the four seasons (Figure A14). Ideally, the transition zones were centered on the values where the component normal distributions crossed (had the same Z-score probability). In order to assess classification error, each airmass limit was assigned a probability value based on its relationship to the component normal distributions.

The results supported the validity of the normal component theory of airmasses, as average Z-score probabilities of the numerical limits were largest in the west-central portion of the NCUS. They then decreased consistently toward the outer edges of the study area, indicating stronger single airmass dominance and more distinct separation in airmass characteristics when moving closer to the respective Continental, Pacific, Dry

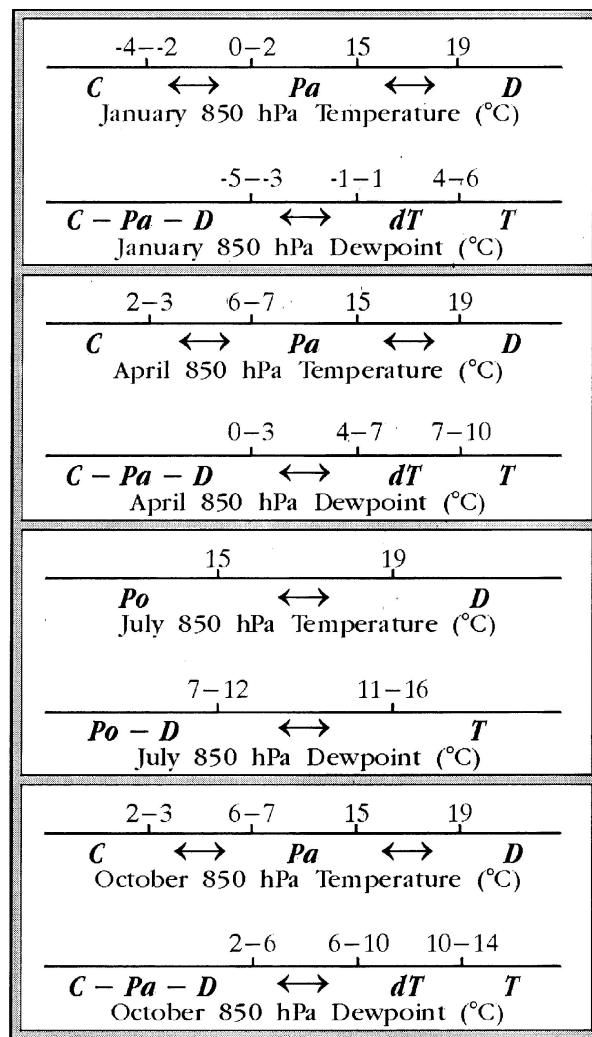

Figure A14 Integrated-method airmass criteria in January, April, July, and October for the north central United States (NCUS). Each airmass is defined by a range of temperature and dewpoint values except for dT and T airmasses which are distinguished by dewpoint alone. Double-ended arrow symbols show the U areas. A range of values indicates that limits vary depending on location within the NCUS. See Table A9 for names associated with airmass symbols (source: Schwartz, 1995).

Tropical, and Tropical air source regions (Table A9). Thus, the integrated method scheme is an easily interpreted approach to major airmass type classification that is numerically precise and allows assessment of misclassification error.

Kalkstein et al. (1996) continued development of hybrid techniques, by introducing the spatial synoptic classification (SSC) system, for the conterminous USA. Surface air temperature and dewpoint criteria were still central to the approach, but integration of multiple measurements each day, and the additions of other variables such as cloud cover, sea level pressure, and diurnal ranges of temperature and dewpoint, allowed for more detailed airmass definitions (Table A10). SSC's core was the manual selection of seed days for each airmass at every station location. A seed day is an actual day that displays the typical conditions for the given airmass at a selected station. Care was taken to ensure that adjacent stations have similar criteria for the same airmasses in order to create spatial continuity.

SSC used simultaneous discriminant analysis of all input variables to automate determination of the appropriate airmass type. Additionally, a parallel procedure identified and reassigned selected days as transitional situations (when one airmass yields to another). The result was a generally robust and replicable airmass classification scheme that has proven useful for many applications. However, an important limitation of SSC was its availability for only the winter and summer seasons.

Sheridan (2002) introduced enhancements to the SSC technique, with a revised approach labeled SSC2. Most notable were the creation of a new "sliding seed day" method that allowed the classification to be applied throughout the entire year, improvement in the spatial cohesiveness among stations, and expansion of the areas covered to include Canada, Alaska, and Hawaii, in addition to the conterminous USA.

Applications

One of the interesting applications of airmass climatology is ecology and paleoecology. Bryson (1966) showed that major vegetation boundaries in North America correlated very well with transition zones between major airmass types. He concluded that the location of each major vegetation regime was controlled by the dominance of a single airmass for more than 50% of a mean year. Barry (1967) questioned some of Bryson's methods and data, but Krebs and Barry (1970) found significant correspondence between vegetation transitions and mean frontal positions between airmass types in Eurasia. The implication that certain airmass types, through their influence on weather patterns, influence plant ecology, provides an exciting means of inquiry into the dynamics of plant distributions and the reasons behind the location of major natural regions.

Other researchers have used the correspondence between mean airmass dominance and vegetation regions to construct paleoairmass climatologies that describe the airmass climate of an area thousands of years ago. In this extremely complex analysis, researchers begin by making assumptions that climate (airmass dominance) largely determines the type of vegetation in a region, and the "pollen rain" from plants onto the surface of the earth is a reflection of the type of vegetation in an area. Although relatively few geologic deposits contain identifiable plants, certain ideal locations (peat bogs, lakes, ponds) have preserved a sediment accumulation for thousands of years, and from these sediments pollen found in ancient sediments presumably mirrors the types of vegetation grown in the area some time in the past and, from the pollen and radiocarbon dating of

organic remains in the sediments, it is possible to reconstruct the type of vegetation that grew in an area thousands of years ago. It is assumed that vegetation regions are controlled by airmass dominance (for example, tundra vegetation exists in areas experiencing dominance by Arctic air for over 6 months of the year), then, from the records of many peat bogs or ponds across the continent, it is possible to piece together airmass climatologies for periods in Earth history from which we have no climatic records. For example, a profusion of grassland types of pollen found in 5000–7000-year-old sediments of peat bogs in currently forested areas of the eastern United States apparently records an expansion of the prairies of North America eastward as a result of expanded dominance by dry "mP" airmasses from the Pacific Ocean and Rocky Mountains (Wright, 1968). From today's correspondence between vegetation, pollen, and airmasses, along with the paleopollen record, it is possible to reconstruct a paleoclimatology of airmasses. These airmass paleoclimatologies provide an efficient means of understanding the character of past climates. (For example, see Bryson and Wendland, 1967; Webb and Bryson, 1972; Moran, 1973; and Sorenson and Knox, 1973.) However, these questions still need to be explored in greater detail.

A large number of applications have been undertaken in the broader field of synoptic climatology using automated "synoptic indices" that are similar to airmass climatologies. For example, the temporal synoptic index (TSI) developed by Kalkstein et al. (1987) has been applied to many problems, such as air pollution monitoring, glacier energy balance, and climate change detection (summarized in Kalkstein et al., 1990). Yarnal et al. (2001) provide an overview of developments in this and other areas of synoptic climatological research during the 1990s.

Applications have also been explored with modern hybrid airmass classification schemes since the mid-1990s. Schwartz and Skeeter (1994) showed that specific NCUS airmass distributions can be related to a small number of meaningful North American 500-hPa height and surface pressure patterns in all seasons, and also that key transects within these patterns can be used to describe changes in monthly airmass dominance from one year to another. Schwartz (1995) explored the use of airmass analysis as a tool for detecting structural climate change in the NCUS. Examinations of airmass temperature, dewpoint, and frequency changes over time, are superior to simple analyses of changes in monthly mean temperatures, as they may point to potential causes of change. Schwartz found increasing amounts of tropical air, coupled with decreasing polar air in summer over the 1958–1992 period, which suggested increases in the number of 500-hPa troughs over the western USA.

Schwartz (1996) used airmass analysis to assess the accuracy of a GCM control run. The results suggested that seasonal GCM performance was promising, but that substantial differences may exist between the control runs and observed climate data at the daily time scale. Greene (1996) used SSC to assess summertime precipitation intensity, and Sheridan et al. (2000) examined the urban heat island effect. Lastly, another important application of modern hybrid airmass analysis has been to identify excessive heat-stress conditions, and the development of health watch/warning systems (Sheridan and Kalkstein, 1998; Kalkstein, 1999). Sheridan (2002) summarized earlier work in this area, and recent studies incorporating SSC2 into systems designed for a number of cities in North America, Europe, and China.

AIR POLLUTION CLIMATOLOGY

Air pollution is defined as an atmospheric condition in which substances (air pollutants) are present at concentrations higher than their normal ambient (clean atmosphere) levels to produce measurable adverse effects on humans, animals, vegetation, or materials (Seinfeld, 1986). Polluting substances can be noxious or benign, and can be released by natural and anthropogenic (human-made) sources. According to the World Health Organization an estimated 3 million people die each year because of exposure to air pollution (WHO, 2000). Air pollution climatology is concerned with the study of atmospheric phenomena and conditions that lead to occurrence of large concentrations of air pollutants and with their effects on the environment.

Air pollutants are typically classified into three categories: suspended particulate matter (SPM), gaseous pollutants (gases and vapors) and odors. SPM in the air includes PM₁₀ (particulate matter with median diameter less than 10 µm), PM_{2.5} (particulate matter with median diameter less than 2.5 µm), diesel exhaust, coal fly-ash, mineral dusts (e.g. asbestos, limestone, cement), paint pigments, carbon black and many others. Gaseous pollutants include sulfur compounds (e.g. sulfur dioxide (SO₂)), nitrogen compounds (e.g. nitric oxide (NO), ammonia (NH₃)), organic compounds (e.g. hydrocarbons (HC), volatile organic compounds (VOC) and polycyclic aromatic compounds (PAH), etc.). Known odorous agents are generally sulfur compounds such as hydrogen sulfide (H₂S), carbon disulfide (CS₂) and mercaptans.

The past few decades have seen much progress in the understanding of air pollution climatology and meteorology, due to rapid progress in pollutant measurement techniques, increased understanding of atmospheric dynamics, and computational capabilities, particularly for areas with complex terrain. At the time of the last edition of this *Encyclopaedia* (1986), the processes of air pollution dispersion were well understood for

Table A11 Typical spatial and temporal scales of air pollution problems

Air pollution type	Horizontal scale	Vertical scale	Temporal scale
Indoor	10–100 m	Up to 100 m	Minutes–hour
Local	100 m–10 km	Up to 3 km	Minutes–hours
Urban	10–100 km	Up to 3 km	Hours–days
Regional	100–1000 km	Up to 15 km	Hours–months
Global	40 000 km	Up to 50 km	Months–decades

Source: Modified after Stern et al. (1984).

urban areas over relatively simple terrain. However, knowledge gaps existed regarding the dispersion of pollutants in cities near coastlines or lake shores, or in areas of complex topography such as mountainous areas – all of which may be considered as “complex terrain”. In addition, air pollution climatology now considers not only localized issues, but also global problems such as stratospheric ozone reduction. The role of long-range transport of pollutants in degradation of air quality in remote/distant regions has also been recognized. Over the past few decades a combination of field observational studies – such as the European Tracer Experiment (ETEX; Girardi et al., 1998) and the Across North America Tracer Experiment (ANATEX; Draxler et al., 1991) – in conjunction with different modeling approaches – has added to a growing knowledge base concerning the complexities of air pollution dispersion.

Natural air pollution has always occurred throughout Earth’s history. Volcanic eruptions, natural fires and wind-blown dust are examples of natural phenomena that introduce pollutants into the atmosphere. Anthropogenic sources have only become a serious problem during the past 200 years with the growing population, increased urbanization and accelerating industrialization. It is estimated that 2 billion metric tons of air pollutants are released into the atmosphere world-wide (Arya, 1999). Air quality is affected not only by emissions into the atmosphere, but also by the pollution potential of air. Stern et al. (1984) provide a useful classification for the types and scales of air pollution problems (Table A11).

Earlier examples of important literature on air pollution climatology include Slade (1968), Williamson (1972), Stern (1976), Holzworth (1974) and Pasquill (1974). However, several introductory books that contain in-depth information on recent developments in this discipline are now available. Arya (1999) is an invaluable book that covers the physics of meteorology and dispersion, while Jacobson (2002) includes perspectives on history and science. The book by Seinfeld and Pandis (1998) also contains a wide range of topics on the physics and chemistry of air pollution. Those who require an extensive treatment of atmospheric chemistry (ambient and polluted) are encouraged to consult Finlayson-Pitts and Pitts (1986). A concise literature review is provided by Sturman (2000).

This account will focus on air pollution climatology by first introducing contemporary air pollution problems and issues; then by considering the components of air pollution, including emissions, atmospheric conditions and receptor response. The item continues by discussing air pollution dispersion models and air quality guidelines and standards.

Contemporary air pollution problems and issues

Air quality issues came to the forefront of scientific and societal attention during the 1950s. In 1952 London’s “killer fog”

caused a great increase in human fatality (4000 excess deaths), especially in people with a history of cardiopulmonary problems. The episode resulted in the implementation of air pollution mitigation measures by the authorities (Brimblecombe, 1987). The air pollution in London was due to the emission of smoke from the burning of coal and other raw materials into the foggy atmosphere; this type of pollution is known as the London-type smog (smoke plus fog). In the same decade another type of smog, which is formed by chemical reactions in the atmosphere – the Los Angeles photochemical smog – also gained notoriety. During the 1970s acid rain emerged as the top environmental concern. A decade later the reduction of stratospheric ozone due to emission of anthropogenic compounds became the top international concern.

Major air pollution problems facing humanity in the 21st century include urban smog, acid deposition, indoor air pollution, Antarctic stratospheric ozone depletion (global stratospheric ozone reduction), and the highly contentious issue of global warming due to alteration of the global longwave (infrared) radiation balance caused by emission of greenhouse gases (GHG) such as carbon dioxide, methane, and nitrous oxide. Table A12 lists some of the polluting substances present in the atmosphere.

Urban smog

This is characterized by build-up of harmful gases and particulates emitted from vehicles, industry, or other sources (primary pollutants) – that cause the London-type smog, or is formed chemically in the air from emitted precursors (producing secondary pollutants) – that cause the Los Angeles-type smog. London-type smog events have been observed in various places around the world, such as the Meuse Valley in Belgium, Pittsburgh in the United States, and Christchurch in New Zealand, to name just a few. Photochemical smog has been observed in most cities around the world; the problem is particularly severe in mega-cities such as Mexico City, Tokyo, Beijing and Tehran.

Transboundary pollution

This is characterized by transport of pollutants across political boundaries and/or vast distances. Examples of such pollution include acid deposition (also known as acid rain – a term introduced by Robert Angus Smith in the nineteenth century) and regional haze caused by forest fires. Acid deposition happens when sulfuric acid (H_2SO_4), hydrochloric acid (HCl), or nitric acid (HNO_3) is deposited on the ground in vapor form or dissolved in rainwater, fogwater, or particulates. This increased acidity in turn harms soils, lakes, vegetation and materials. Cowling (1982) provides an historical perspective on the discovery of and mitigation measures used to deal with acid rain. Natural examples of transboundary pollution include the 1998 dust clouds caused by intense storm events in western China, which carried vast quantities of particulate matter across the Pacific Ocean, contributing to increased concentrations in Vancouver, Canada (McKendry et al., 2001).

Indoor air pollution

Most people spend a large amount of time indoors where they are constantly exposed to indoor air pollution. This is caused from either the emission of gases and particulates in enclosed

buildings or transport of pollutants from outdoors; but it is not as extensively researched as outdoor air pollution (Wanner, 1993). Health effects of indoor air pollutants can be severe and directly affect the respiratory and cardiovascular systems. Indoor air pollutants include radon gas, ammonia, volatile organic compounds (VOC), polycyclic aromatic hydrocarbons (PAH) and second-hand cigarette smoke. Radon gas has a long-term health effect and is naturally released by soil due to radioactive decay of radium (Bridgman et al., 2000). Indoor exposure to particulate matter increases the risk of acute respiratory infections, leading to an increase in infant and child mortality rates in developing countries. WHO reports that such exposure is responsible for between half and one million excess deaths in Asia, and 300 000–500 000 excess deaths in sub-Saharan Africa (WHO, 2000).

Antarctic ozone depletion

Antarctic ozone depletion and the reduction of global stratospheric ozone are due to emission of chlorine and bromine compounds such as chlorofluorocarbons (CFC). CFC break down by photolysis reaction (breakdown of molecules by solar radiation) after they have traveled to the upper atmosphere. The reduction of ozone increases the amount of ultraviolet (UV) radiation that reaches Earth's surface. UV radiation can damage genetic material of organisms and in humans it is known to cause skin cancer.

Scientific consensus supports the theory that human emission of carbon dioxide, methane, nitrous oxide and other gases may play a significant role in the cause of global warming (IPCC, 2001). Therefore global warming is also an air pollution issue.

Components of an air pollution problem

Air pollution problems usually have three components: (1) emission of polluting substances into the air; (2) the pollution

potential of the atmosphere characterized by its ability to transport, diffuse, chemically transform and remove the pollutants; and (3) response of the receptors (e.g. people, animals, vegetation) to the exposed concentration. Each of these components is considered in this section.

Pollution emissions

Emission sources can be categorized as follows:

1. Urban and industrial. Industrial sources include power generation plants that use fossil fuel, mining, manufacturing, smelting, pulp and paper plants, and chemical industries. Major gaseous pollutants emitted are carbon monoxide (CO), carbon dioxide (CO_2), sulfur dioxide (SO_2) and volatile organic compounds.
2. Agricultural and rural. Agricultural areas can be sources of air contaminants due to decaying waste from animals and plants which can release ammonia, methane (CH_4 , a powerful greenhouse gas) and other noxious gases. In addition, windblown dust due to plowing, tilting, and harvesting, and smoke and haze due to slash burning can lead to severe degradation in air quality. An interesting example of air pollution caused by agricultural practices is the regional haze and smog events that plagued the Southeast Asian countries in 1997 due to forest fires in Indonesia (Davies and Unam, 1999; Khandekar et al., 2000). Burning forests is a traditional way of clearing land for agricultural purposes in Indonesia (and indeed in many other parts of the world), but the fires became unmanageable due to prolonged drought and the delayed onset of the monsoon rains caused by the 1997 El Niño episode. A strong increase in tropospheric ozone concentrations occurred over tropical Southeast Asia, reaching as far as Hong Kong (Chan et al., 2001).
3. Natural. In addition to anthropogenic sources, many natural sources can contribute to air pollution. These include: volcanic

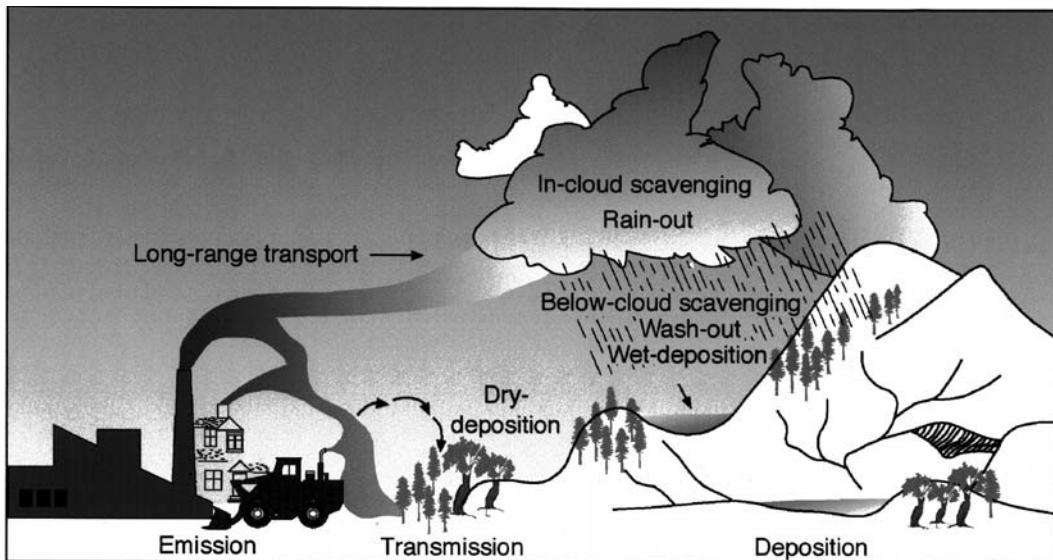

Figure A15 Schematic illustration of emission, transmission and deposition of air pollution.

eruptions that release vast quantities of particulate matter, CO₂, SO₂, and other gases, into the atmosphere; *biogenic* (from biological sources) emissions from forests and marshlands of compounds such as hydrocarbons (terpenes and isoprenes; Guenther et al., 1995), methane and ammonia; and soil microbial processes which contribute NO, CH₄ and H₂S.

Atmospheric conditions

The state of the atmosphere determines its pollution potential, which is affected by three important processes: *dispersion* which is the horizontal and vertical spread and movement of pollutants; *transformation* which involves chemical reactions that occur between pollutants or to pollutants under certain temperature and sunlight conditions; and *removal* of pollutants through such mechanisms as dry and wet deposition (Figure A15). Each of these processes will be considered in turn, but first the overriding control of synoptic conditions will be considered.

Synoptic controls

“Synoptic conditions” refers to an intermediate scale of atmospheric activity between global and regional scales and includes circulation systems such as anticyclones and cyclones. Synoptic circulation features have a spatial dimension of the order of thousands of kilometers and may last about a week on average. Atmospheric circulation at this scale has an important control on air pollution since it influences cloud (amount, thickness, height and type), temperature and relative humidity of the airmass, the type and amount of precipitation, and the wind speed and direction. These parameters in turn influence the vertical temperature structure of the atmosphere which determines the atmospheric stability. If the air temperature decreases rapidly with height (i.e. at a rate greater than the dry adiabatic lapse rate of 9.8°C km⁻¹) then the atmosphere is unstable. This means that vertical motion is promoted and any emissions will mix well into the boundary layer (the lowest layer of the atmosphere that is affected by the diurnal cycle of temperature, humidity, wind, and pollution). However, in stable conditions,

which occur when temperature either decreases slowly with height (at a rate less than the dry adiabatic lapse rate) or increases with height (which is known as a temperature inversion), pollution may become trapped close to the emission source, resulting in increased concentrations. The layer through which the mixing of pollutants occurs is known as the mixed layer, and the height to which pollutants mix is called the mixing depth or mixing height.

Anticyclonic circulation is more conducive to pollution episodes since it usually involves weaker synoptic winds and clear skies. In summer, stronger surface heating under anticyclonic flow results in warmer temperatures in the boundary layer, and this warmth, together with high solar radiation levels and generally calm or light airflow, can lead to the formation of photochemical smog (discussed in more detail later). Since anticyclonic circulation involves subsidence of air towards the surface (and hence warming), this results in elevated inversions which can trap pollutants in a shallow mixed layer (Figure A16a).

In winter, clear skies and light winds during anticyclonic conditions lead to strong nocturnal radiative cooling of the surface which results in surface or radiative inversions (Figure A16b). During such conditions any pollutants emitted at the surface (e.g. through industrial emissions, domestic heating or traffic) become trapped very close to the surface and may result in high pollutant concentrations. This is the typical scenario that produces classic smog as a combination of smoke and fog. Figure A17 shows the severe degradation in air quality in Christchurch, New Zealand, as a result of emission of smoke from solid-fuel burning (wood) into a shallow surface inversion layer.

Dispersion

The dispersal of air pollutants is governed mainly by the mean wind speed and the characteristics of atmospheric turbulence. Together these factors determine the stability characteristics of the atmosphere. Turbulence consists of horizontal and vertical eddies that mix pollution with the surrounding air. As turbulence increases, so too does mixing, which results in good dispersion

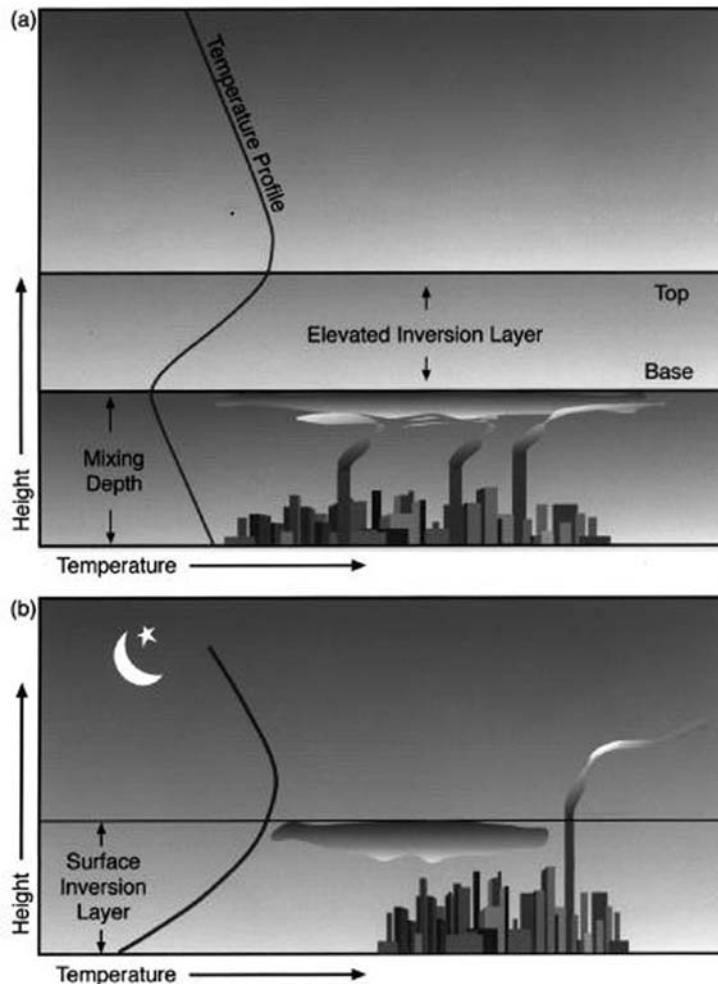

Figure A16 Air pollutants emitted at the surface can become trapped by (a) an elevated inversion layer and (b) a surface inversion layer (modified after Whiteman, 2000).

and lowered pollutant concentrations. Strong turbulence occurs in an unstable atmosphere in which vertical motion is enhanced. Conversely, when turbulence is weak, there is little propensity for mixing to occur and pollutant levels may increase. Conditions of weak turbulence are often typical of clear mornings in winter.

Turbulence can be generated through both thermal and mechanical means. Thermally generated turbulence results from heating of the surface, which leads to buoyancy-induced convective motion (i.e. vertical transport of heat away from the surface). With stronger heating of the surface, thermal turbulence will increase. Mechanically generated turbulence can result from wind shear as the wind blows across the Earth's surface. Mechanical turbulence increases with increasing wind speed and is greater over rougher surfaces (e.g. cities and forests). For a more in-depth explanation of the theory and mathematical representation of turbulence in the boundary layer refer to Stull (1998) or Garratt (1992).

A typical diurnal cycle of radiative heating and cooling in cloud-free conditions results in varying stability conditions throughout the day (Figure A18). In the early morning, before

sunrise, the nocturnal temperature inversion is still present. Any pollutants emitted close to the ground may be trapped in this inversion, if the chimney stacks are lower than the inversion top, smoke plumes will take on a fanning shape (Figure A18a). After sunrise, surface heating results in the generation of convection which mixes the air close to the surface within the layer beneath the remains of the nocturnal inversion. This situation is one of the worst for pollutant concentrations at ground level as *fumigation* occurs (downward movement of pollutants from aloft because of a growing mixed layer), resulting in pollution originally emitted and trapped aloft being mixed to ground level, often in quite high concentrations (Figure A18b). As day-time heating continues the nocturnal inversion is completely eroded and replaced by a *lapse* profile (decrease of temperature with height; Figure A18c). This is typical of an unstable atmosphere which promotes vertical mixing. This mixing is evident in the behavior of smoke plumes which may take on looping behavior (Figure A18c). In late afternoon the atmosphere may become neutral, in which the environmental lapse rate equals the dry adiabatic lapse rate (Figure A18d). This results in coning of smoke plumes (Figure A18d). As the sun sets the surface begins

Figure A17 Christchurch, New Zealand, on a winter morning. The thick smoke at the surface is the result of poor ventilation due to a surface inversion layer that formed overnight. Smoke and particulate matter is emitted from home heating with solid-fuel burners (courtesy of The Christchurch Press).

to cool and the nocturnal inversion is again established (Figure A18e). If the smoke stack is above the inversion height, then lofting of the plume is observed (Figure A18e).

A common and relatively simple estimate of stability is the Pasquill–Gifford stability classification (Table A13). This scheme assumes that stability in the layers near the ground depends on net radiation as an indication of convective eddies, and on wind speed as an indication of mechanical eddies. At low wind speeds and with strong daytime insolation (i.e. radiative heating from the sun), the atmosphere will be extremely unstable (class A). As both cloud and wind speed increase, the atmosphere becomes less unstable (B, C) and may become neutral (D). Under light winds and clear skies at night the atmosphere may become stable (E and F).

Air pollution episodes are typically worse during stable atmospheric conditions since these restrict or limit the amount of vertical mixing. Temperature inversions, which are characteristic of a moderate to strongly stable atmosphere, can occur through several different mechanisms including surface cooling, warming of air aloft and *advection* (mean horizontal movement of air). Surface or radiation inversions occur during clear, calm nights as the ground cools rapidly due to the loss of long-wave radiation to the outer atmosphere. Their strength and depth may be locally increased by cold air drainage. Surface cooling can also occur through evaporative cooling as water evaporates from a moist surface during the day in fine weather.

Inversions due to warming can occur through subsidence during anticyclones (as described earlier) or in the lee of mountains. In both cases the descending air warms adiabatically and creates elevated inversions which can effectively cap any mixing of pollution from below. In the lee of the Rocky Mountains in winter, radiative cooling over the interior of North America creates a very cold air mass which ponds against the mountains. Descending warm air spreads over the top of this stagnant pool and severely inhibits any upward dispersion (Oke, 1992).

Advection inversions can occur when warm air blows across a cooler surface such as a cold land surface, water body or snow cover. In this situation the cooling of the underside of the air mass creates an inversion with its base at the surface (Figure A19a). Existing inversion structures can also be modified during advection. For example, when a cool sea breeze (or rural air) flows over warmer land (or urban) areas, the inversion becomes elevated, and this can lead to serious fumigation problems if chimney stacks are located in the coastal zone (Figure A19b, c).

Complex terrain such as in coastal or alpine regions, or indeed anywhere that has significant variation in topography, can lead to complex airflows. In such areas under clear skies and light synoptic winds, local circulation systems often develop, such as land–sea breezes or mountain–valley winds. These circulation systems are not good pollution ventilators since they tend to have low wind speeds, are often closed systems and have a diurnal reversal of flow. Thus the pollution can be recirculated over the source area and may build up to high levels.

Pollutant transformation

Air pollutants may often undergo chemical transformations in the air to produce what are termed secondary pollutants. The damaging London smogs of 1952, which killed thousands of people, involved sulfuric acid fogs which remained stagnant for 4–5 days. These fogs occur when SO_2 (which is generated by the combustion of fuels – particularly from coal with high sulfur content) is oxidized in the air to sulfur trioxide (SO_3) which then reacts with water vapor (H_2O) in the presence of catalysts to form sulfuric acid mist. If the meteorological conditions are such that dispersion is poor, these toxic mists can have deadly consequences.

More common in recent decades is the formation of photochemical smog. There is a naturally occurring NO_2 photolytic cycle in which solar radiation results in the photo-dissociation

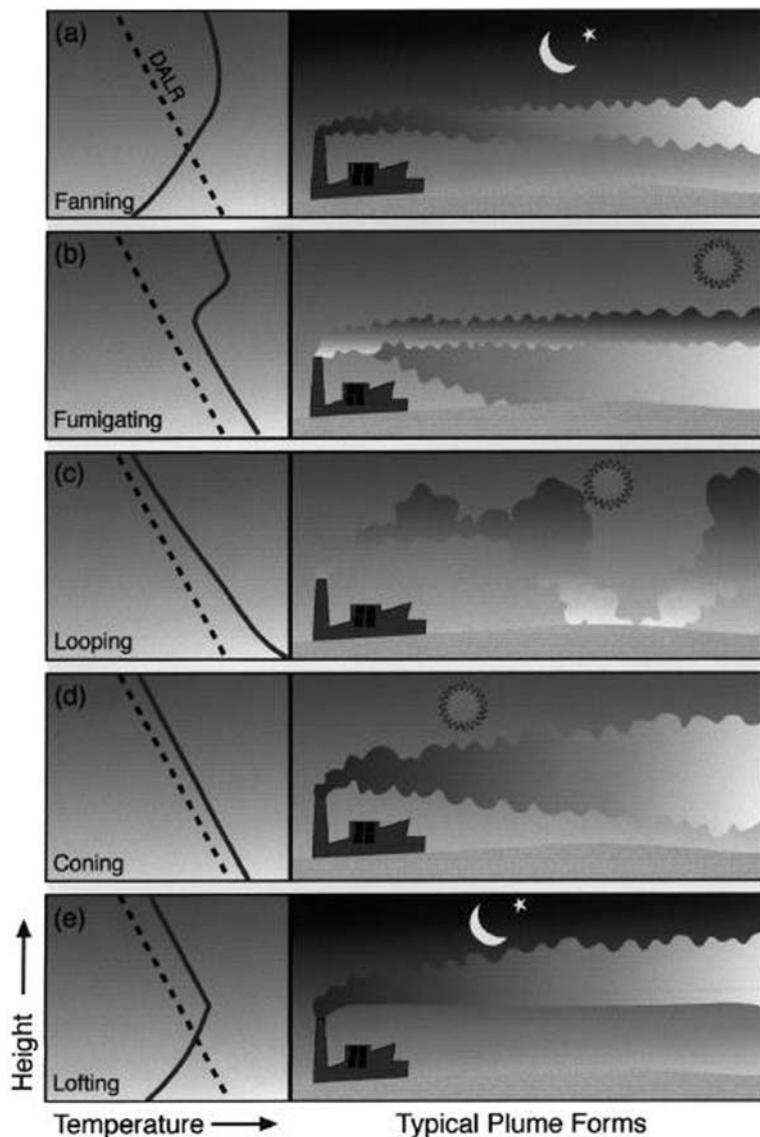

Figure A18 Stability changes throughout the day and effects on smoke plumes (modified after Whiteman, 2000). The dashed line (DALR) is the dry adiabatic lapse rate and the solid line is the environmental lapse rate.

Table A13 Pasquill–Gifford stability class

Wind speed at 10 m (ms^{-1})	Day-time insolation			Night-time cloudiness	
	Strong	Moderate	Slight	$\geq 4/8$ Cloudiness	$\leq 3/8$ Cloudiness
<2	A	A–B	B	—	—
2–3	A–B	B	C	E	F
3–5	B	B–C	C	D	E
5–6	C	C–D	D	D	D
>6	C	D	D	D	D

A, extremely unstable; B, moderately stable; C, slightly unstable; D, neutral, E, slightly stable; F, moderately stable. Insolation is the rate of solar radiation received per unit of Earth's surface and cloudiness is defined as the fraction (in octas) of sky above the local apparent horizon that is covered by clouds.

of NO_2 into NO and O (Figure A20). The oxygen atom (O) is highly reactive and combines with an oxygen molecule (O_2) to produce ozone (O_3). The ozone then reacts with NO to give NO_2 and O_2 . However, the presence of reactive organic gases (ROG – which may be sourced from vehicles, but also naturally from vegetation) disrupts the cycle and can accelerate the production of ozone and other chemicals, such as aldehydes and ketones and peroxyacetyl nitrates (PAN) and even some particulates. Photochemical smog has a characteristic odor (partly due to the aldehydes), a brownish haze (due to NO_2 and light scattering by particulates) and may cause eye and throat irritation and plant damage. Figure A20 illustrates the sequence of chemical reactions that lead to formation of ozone as a by-product of photochemical smog following the emission of NO and ROG (the primary pollutants) into the atmosphere.

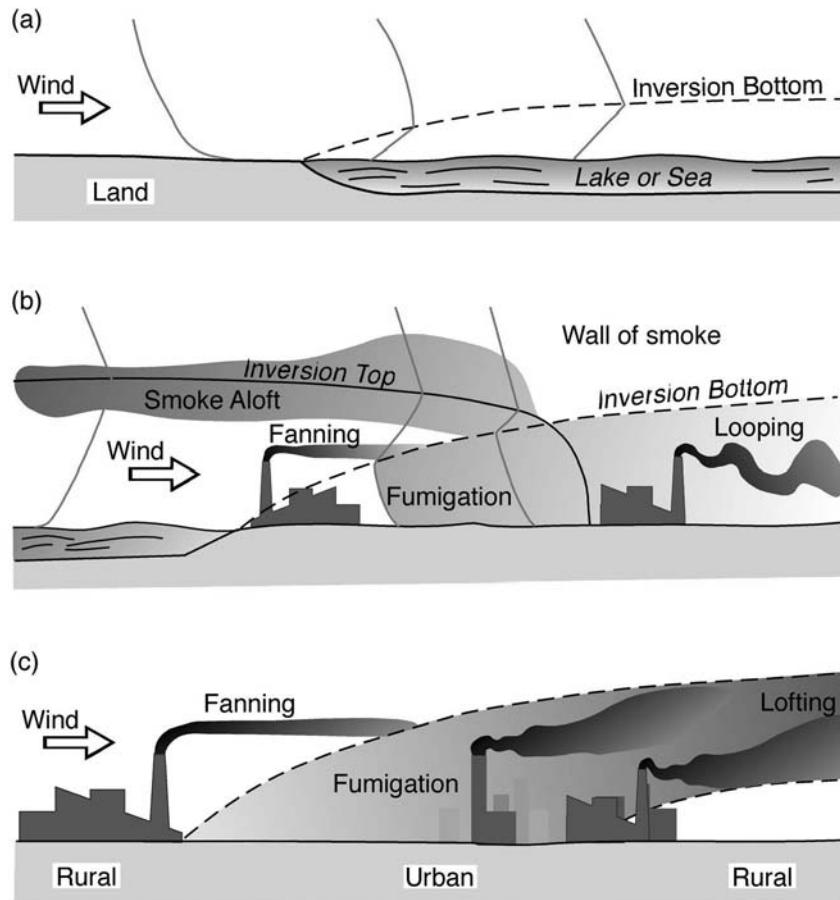

Figure A19 Examples of advection inversions. (a) Warm air flowing over cooler water, (b) sea breeze fumigation on a clear day and (c) fumigation over an urban area (modified after Oke, 1992 and Karl et al., 2000).

Organic peroxy radicals (RO_2) are formed by the break-up of ROG, which by reaction with NO form ozone. This type of smog has been reported from many cities around the world, including cities in Australia, Brazil, Britain, Canada, Greece, Netherlands, Iran, Israel, Japan and the United States.

Pollutant removal

As well as through chemical reaction, pollutants can be removed from the atmosphere by other processes, such as gravitational settling, and dry and wet deposition (Figure A15). Gravitational settling removes larger particulates, with the rate of removal related to the size and density of the particles and the strength of the wind. This process removes most particulates larger than 1 micrometer (μm) in diameter, but smaller particles become influenced by turbulence and may remain aloft for long periods. Dry deposition is a turbulent process in which there is a downward flux of pollutants to the underlying surface. The amount of deposition depends on the characteristics of turbulence, with increased rates under stronger turbulence.

Wet deposition involves the removal of air pollutants through absorption by precipitation elements (water droplets, ice particles and snowflakes) and consequent deposition to the Earth's

surface during precipitation. This removal process includes the attachment of pollutants to cloud droplets during cloud formation, incloud scavenging (also known as *washout*), and through coalescence of rain drops with material below the cloud (*rain-out*; Arya, 1999). Slin (1984) provides a comprehensive review of precipitation scavenging processes.

Receptor response

Air pollution is a concern due to its adverse effects on organisms and damage to materials. Research has demonstrated that air pollution can affect the health of humans and animals, damage plants, reduce visibility and solar radiation, and affect weather and global climate.

Effects on humans, animals and vegetation

During extreme air pollution episodes in urban areas the concentration of air pollutants can reach high levels for several hours or days. This can cause extreme discomfort, exacerbate illnesses and increase mortality rates among the most vulnerable part of the population (children, the elderly and the sick). Health-effect studies have revealed a number of adverse effects associated with common air pollutants. Peroxyacetyl nitrates (PAN), which are a

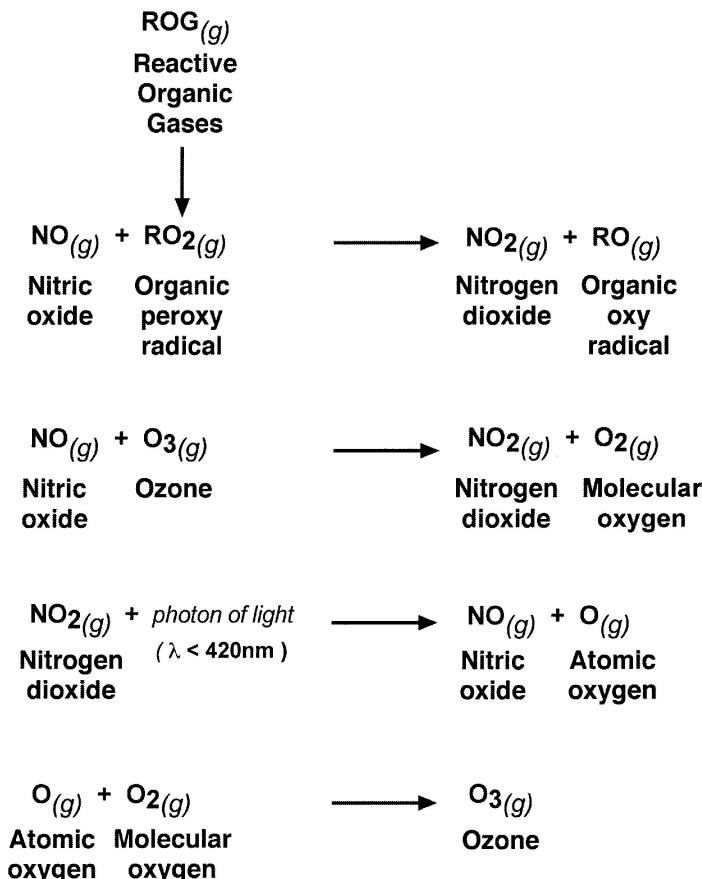

Figure A20 Chemical reactions in a polluted troposphere leading to photochemical ozone formation.

component of photochemical smog, can cause eye and throat irritation. Other health hazards of air pollutants include chronic bronchitis, pulmonary emphysema, lung cancer and respiratory infections. Even short-term exposure to particulate matter can cause an increase in the rate of asthma attacks.

Adverse effects of air pollution on vegetation include leaf damage, stunting of growth, decrease in size and yield of fruit, and severe damage to flowers. Domesticated animals such as cattle and dogs cannot only breathe in toxic air, but may also ingest pollution-contaminated feeds. The air pollutants that are of major concern are fluoride, lead, and other heavy metals and particulate matter.

Effects on materials

Air pollutants affect materials by chemical reactions and soiling. Extensive damage can occur to structural metals, building stones, fabrics, rubber, leather, paper, and other materials. For example, a well-known effect of photochemically produced ozone in the troposphere is cracking of rubber products. The number of cracks in automobile tyres, as well as their depth, has been related to ambient ozone concentrations.

Air pollution dispersion models

During the past two decades advances in computer technology have allowed the use of increasingly sophisticated air

pollution dispersion models (also known as air quality models). Numerous books are now available that give an in-depth explanation of the theory and derivation behind the mathematical formulations used in air pollution models. For example, Zannetti (1990) provides information on a wide spectrum of dispersion models, while Jacobson (2000) offers an excellent and exhaustive treatise on the theory, the numerical techniques and chemistry of air pollution models. Arya (1999) also describes the diffusion/dispersion theories behind the modeling systems including detailed mathematical formulation. These models are used for both regulatory and research purposes.

Box models

The simplest air pollution models are single- and multi-box models (Lettau, 1970). Box models predict the concentration of primary pollutants inside a box using mass conservation principles, where the box represents a large volume of air over a city. A box model considers the emission source at the surface (lower boundary), advective inflow and outflow at the sides (lateral boundaries), and the evolution of the mixing depth and subsequent entrainment of pollutants from aloft. More complicated box models include chemical and photochemical transformations to predict concentrations of secondary pollutants like ozone (Demerjian and Schere, 1979; Dodge, 1977).

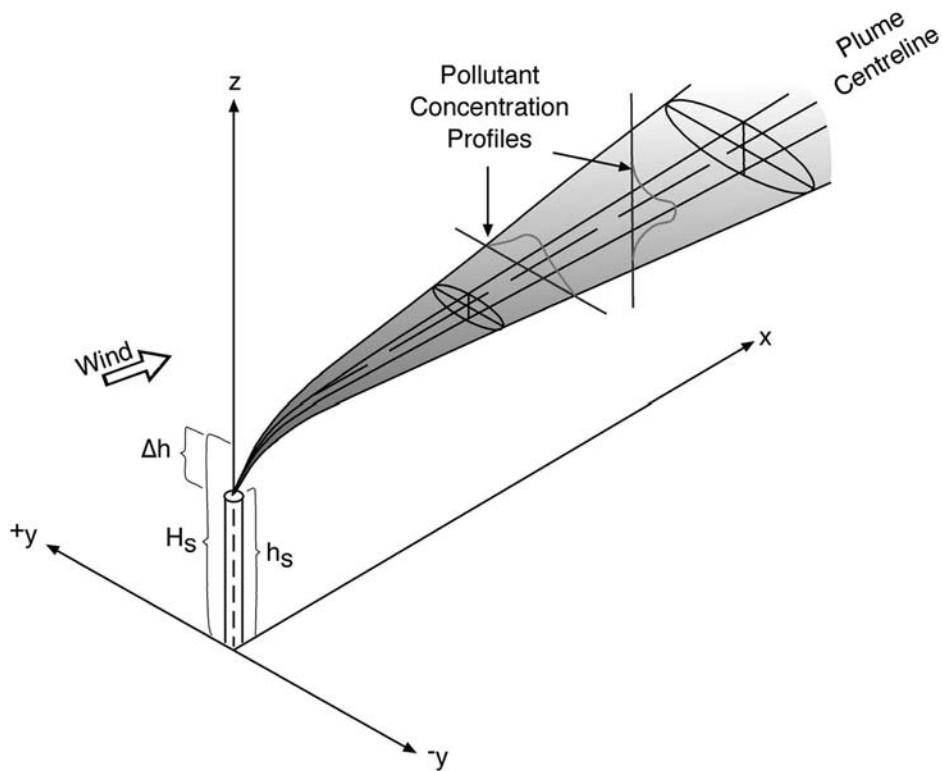

Figure A21 Schematic of plume dispersion from a stack with Gaussian distribution in horizontal and vertical (H_s is the height of the plume centerline and h_s is the stack height) (modified from Arya, 1999).

Gaussian plume models

Gaussian plume and puff models are used to estimate three-dimensional pollutant concentrations resulting from emissions generated at a point source, under stationary (unchanging) meteorological situations (Gifford and Hanna, 1973; Turner, 1964), although some models also incorporate non-stationary conditions. The underlying assumption in the Gaussian model is that with sufficiently long averaging periods (e.g. 1 hour) a bell-shaped (Gaussian) concentration distribution is produced in both horizontal and vertical directions (Figure A20). A plume model assumes a continuous point source with a uniform strong background flow, where release time and sampling time are longer than travel time. Puff models are used in cases where emission from a source is almost instantaneous and much shorter than travel time of the plume, such as accidental releases of hazardous material into the atmosphere. Gaussian models are commonly used in a regulatory framework because of their simplicity and cheap computational demands (relative to three-dimensional numerical models, which are described below). The severe limitation of the Gaussian models is that they generally do not work in calm conditions; in addition, the complexity of local terrain and variation of atmospheric conditions with time is ignored.

Numerical meteorological models

The most sophisticated and hence computationally demanding way of calculating pollutant concentrations is by simulating detailed meteorology (three-dimensional fields of wind,

turbulence, temperature and water content) and coupling these fields to emission scenarios. The role of the meteorological component of the model is to provide input for the pollutant diffusion component. A numerical meteorological model uses numerical techniques to approximate meteorological equations that describe fluid flow – collectively known as the Navier-Stokes equations. These are highly complex and nonlinear, and at present, no analytic solution is known for them. Stull (1998) and Pielke (2002) describe the numerical techniques and turbulence parameterizations behind these types of models. The Navier–Stokes equations take into account conservation of mass, heat, momentum and water. Air pollution scientists use many names for numerical models, but they are frequently referred to as grid-based and mesoscale.

Diagnostic models

Diagnostic models by definition do not provide a forecast for the state of the atmosphere. Diagnostic outputs are three-dimensional fields of meteorological variables obtained by interpolation and extrapolation of available meteorological measurements. They are computationally economical and appear to be effective analysis tools when the dominant factor driving the boundary layer airflow is the terrain. A major drawback is the requirement for sufficient observational data as input for the analysis. A three-dimensional diagnostic model such as CALMET – which is the meteorological component of the CALPUFF modeling system (Scire et al., 1990) – is widely used by regulatory/environmental organizations such as the US Environmental Protection Agency. The Earth Tech Corporation

Table A14 Summary of air quality standards from Canada, United States, New Zealand, and United Kingdom

Pollutant	Canada Air Quality Objectives and Standards ^a	United States Federal Primary Standards (NAAQS)	New Zealand Air Quality Guidelines ^c	United Kingdom National Standards

Prognostic models

Prognostic models are able to forecast the evolution of the state of the atmosphere by numerically solving (both in time and space) the detailed set of approximations to the Navier–Stokes equations. Prognostic models take into account the evolution of synoptic scale winds and allow the formation of diurnally reversing local scale circulations such as sea/land breezes and valley/mountain flows (Whiteman, 2000). A great appeal of prognostic models, aside from their research applications, is that they can be the core of real-time air quality forecasting systems in case of accidental or intentional release of pollutants into the atmosphere. The forecast for the meteorological variables, in conjunction with appropriate turbulence statistics, is used to determine the probable spread and diffusion of the plume. Scientific centers that generate such forecasts and issue warnings use supercomputers, since expediency is important and prognostic models are computationally demanding. Examples of such organizations include the Atmospheric Research Division at the Commonwealth Scientific and Industrial Research Organization (CSIRO), which has implemented the Australian Air Quality Forecasting System (AAQFS), and the Lawrence Livermore National Laboratory in the United States which has the National Atmospheric Release Advisory Centre (NARAC). AAQFS routinely predicts daily levels of photochemical smog, atmospheric particles and haze, whereas NARAC is generally designed for emergency response purposes in case of accidental emissions of hazardous pollutants (e.g. radiological, chemical and biological substances).

Air quality guidelines and standards

Good health is (should be) a fundamental human right. The primary aim of air quality guidelines is to protect public health from the harmful effects of air pollution, and to eliminate or substantially reduce exposure to hazardous air pollutants. To achieve these aims, many countries use regulatory control through legislation to set legally enforceable air quality standards (AQS). These represent values that are the maximum average ground-level concentration allowed by law. AQS values are derived from air quality guidelines (AQG) determined purely from epidemiological/toxicological analysis. AQS have to consider technological feasibility; cost of compliance; and social, economic and cultural conditions. The maximum concentrations allowed are categorized by averaging periods, the most commonly used being hourly, daily and yearly. The air quality standards are different in each country. For example, in the United States they are referred to as National Ambient Air Quality Standards (NAAQS), while in Canada they are known as National Air Quality Objectives. Currently, the maximum allowable concentration for each pollutant (and for each averaging period) is prescribed differently in each standard. Table A14 shows maximum allowable concentrations for some common pollutants.

ALBEDO AND REFLECTIVITY

Albedo

Albedo is the percentage of solar radiation reflected by an object. The term is derived from the Latin *albus*, white. A pure white object would reflect all radiation that impinges on it and have an albedo of 100%. A pure black object would absorb all radiation and have an albedo of 0%. Bright Earth features such as clouds, fresh snow, and ice have albedos that range from 50% to 95%. Forests, fresh asphalt, and dark soils have albedos between 5% and 20%. Table A15 presents representative albedos for a variety of objects. Knowledge of albedo is important because absorbed solar radiation increases the amount of energy available to the Earth's surface and atmosphere, whereas reflected radiation returns to space.

Appreciation of the relation between albedo and climate extends historically to at least classical Greek times. P. Bouguer and J. Lambert first formulated the principles and theories by which albedo and reflectivity may be explained and measured in the eighteenth century, but accurate measurements did not begin until the early twentieth century (Fritz and Rigby, 1957). The work of early investigators, including A. Ångström, C. Dorno, N. Katlin, F. Götz, H. Kimball, and others, rapidly developed an extensive body of knowledge concerning albedos that is still drawn on today (see annotated bibliography by Fritz and Rigby, 1957). One of the more interesting approaches to early observations of the Earth's planetary albedo employed measurements of earthshine and sunshine on the moon (Danjon, 1936, cited in Fritz and Rigby, 1957). Similar efforts continue today (Goode et al., 2001). Use of aircraft and spacecraft as observing platforms has significantly expanded albedo studies in recent decades (Barrett, 1974; Brest and Goward, 1987; Schaaf et al., 2002).

Reflectivity

Reflectivity is the capacity of an object to reflect solar radiation. It is described as a function of radiation wavelength and is determined by the physical composition of the object. The adjective “spectral” is frequently used in conjunction with reflectivity to indicate that reflectivity varies as a function of solar wavelength.

Representative spectral reflectivity measurements for common Earth surface features are given in Figure A22. Soil reflectivity in general increases monotonically with increasing wavelength to about 1.3 μm and then decreases with sharp dips at 1.4 μm and 1.9 μm because of absorption by soil water. Living green vegetation reflectivity is low in the visible portion of the spectrum (0.4–0.7 μm) as a result of absorption by chlorophyll and related pigments, high in the near infrared (0.7–1.3 μm) because of light scattering by internal leaf cellular structures, and decreases past 1.3 μm in a manner similar to soils due to absorption by water within leaves. Snow is highly reflective in the visible and decreases to low values in the infrared, again as a result of water absorption. Water reflects little radiation in any portion of the spectrum when solar elevation is high.

Spectral reflectivity varies significantly for each surface type as a function of physical condition and composition. Soil reflectivity varies because of variations in moisture content, particle size, organic matter content, surface roughness and mineral composition. Figure A23 presents the variation of a silty loam soil reflectivity due to changes in moisture content. Vegetation reflectivity varies with percentage ground cover, canopy geometry, leaf size, and area and plant growth stage. Snow reflectivity varies with crystal size, compaction, age, and liquid water content. Water reflectivity is affected by turbidity, depth, and phytoplankton concentrations. Also, because water in its pure form is a dielectric, its albedo increases as the angle of incidence of radiation decreases. Water albedo is lowest when the sun is near zenith and increases to near 100% when the sun is near the horizon. (For further discussion see chapter 4, Kondrotiev, 1973; chapter 8, Miller, 1981). Other factors may affect the reflectivity of these surfaces, such as lichen crusts, and other materials such as rocks, and man-made materials (e.g. asphalt and concrete) also display unique spectral reflectivity patterns.

Relation of reflectivity to albedo

Albedo is the integrated product of incident solar radiation spectral composition and the spectral reflectivity of the object. Outside the atmosphere, solar radiation spectral composition is relatively constant, peaking at about 0.5 μm , decreasing rapidly at shorter wavelengths to small amounts at 0.2 μm , and decreasing less rapidly at longer wavelengths to small amounts at about 4.0 μm .

The atmosphere selectively absorbs and scatters solar radiation. As a result, at the Earth’s surface the spectral composition of solar radiation varies significantly as a function of atmospheric conditions (e.g. clouds, water vapor, and dust) and solar elevation (Robinson, 1966; Dickinson, 1983). The majority of albedo measurements have been carried out under clear-sky, high-sun elevation conditions (Table A15). Under cloudy conditions radiation is predominantly in the visible spectrum. This decreases the albedos of soils and vegetation but increases snow albedo (Miller, 1981). When atmospheric turbidity is high, or the sun is low in the sky, the spectral distribution of solar radiation shifts to the red and infrared portion of the spectrum. Soil and vegetation albedos increase and snow albedo decreases (Kondrotiev, 1973). This variability points out the need to know both the spectral reflectivity of objects and the spectral composition of incident radiation in order to evaluate earth albedos.

Surface and planetary albedos

Two global albedo measurements are of general interest to climatologists: surface and planetary albedos. Surface albedo is

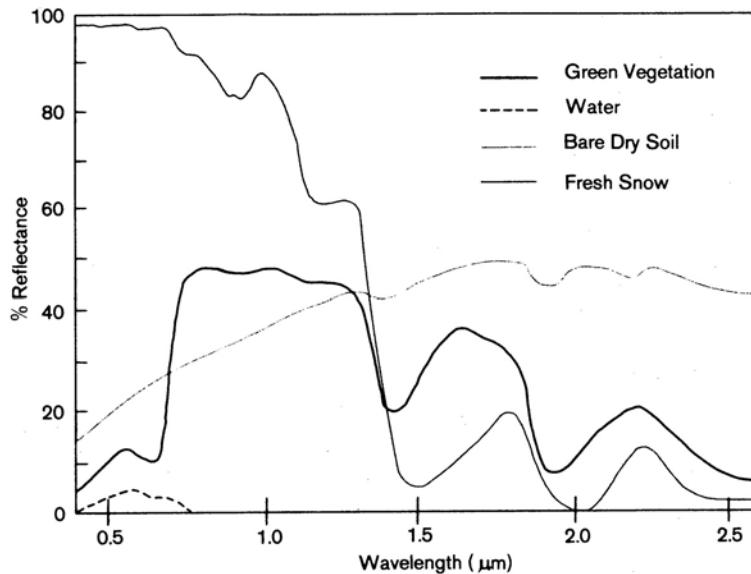

Figure A22 Spectral reflectance of selected Earth surface features.

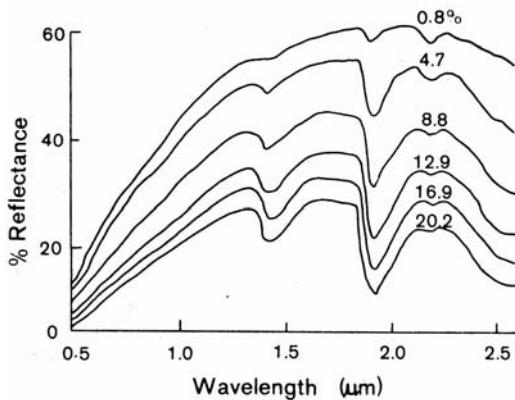

Figure A23 Variations of silty loam soil spectral reflectance as a function of water content (percentage water content shown by each plot) (after Kondrotyev, 1973).

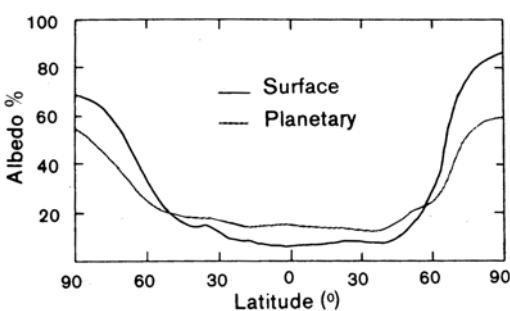

Figure A24 Latitudinal variations in surface and planetary albedo (after Hummel and Reck, 1979).

the ratio of incident to reflected radiation at the interface between the atmosphere and the Earth's land and water areas. Almost 75% of all solar energy absorbed by the Earth is absorbed at this interface; the remainder is absorbed in the atmosphere (Sellers, 1965). Any change in surface albedo will alter climate by significantly changing the amount of solar energy absorbed by the planet. Several studies have evaluated the Earth's surface albedo with resultant estimates ranging between 13% and 17% (Sellers, 1965; Kondrotyev, 1973; Hummel and Reck, 1979; Briegleb and Ramanathan, 1982). This range of results is suggestive of current limitations in knowledge of the distribution and reflectivity of Earth surface features.

Planetary albedo is the ratio between incident and reflected radiation at the top of the atmosphere, also referred to as "Bond" albedo, named after the astronomer who first described this metric. It includes the effects of reflection from the atmosphere, particularly clouds, and surface albedo. Only about 6% of the incident radiation is reflected by scattering in the atmosphere but, on average, 24% of incident radiation is reflected by clouds (Sellers, 1965). Changes in atmospheric turbidity or cloud cover can alter climate by changing the amount of solar radiation that reaches the Earth's surface. Studies of the Earth's planetary albedo have been carried out over the past 60 years (Barrett, 1974). Barrett notes that estimates have progressively decreased from 50% in early studies to current estimates between 30% and 35%, based on satellite estimates. He suggests that this trend is due to improved knowledge of global cloud cover. However, the possibility of inter-annual and longer-term variations in planetary albedo should not be overlooked (Rossow and Zhang, 1995).

Geographic patterns

Both surface and planetary albedos increase with distance from the equator (Figure A24). Surface albedo shows a slight minimum at the equator because of dense evergreen forest and a

secondary minimum at 40°S latitude because of the large extent of open ocean at this latitude. Increases at 25° to 30° north and south result from the presence of subtropical deserts with relatively high albedos (>40%). At higher latitudes the seasonal or permanent occurrence of snow cover and sea ice raise average albedos, which are in excess of 60% in the polar regions. The latitudinal patterns of planetary albedo are less extreme than the surface trends. Two factors affect this difference. Tropical and midlatitude land areas that are vegetated are in latitudes of frequent cloud occurrence. Contrasts between vegetated and desert latitudes are thus less apparent in the planetary figures. In addition, interactions between surface albedo and atmospheric scattering and absorption tend to reduce albedo differences between the tropics and the poles. Where surface albedo is high, the reflected radiation passes back and forth through the atmosphere many times, increasing absorption both at the surface and in the atmosphere. Over regions of low albedo, scattering in the atmosphere increases planetary reflectance when compared to surface albedos (Hummel and Reck, 1979).

Measurements

Traditionally, two pyranometers, one pointed toward the sky, the other toward the surface, have been used to measure albedos. Pyranometers are solar radiation measurement devices that respond thermally to record the amount of radiation incident on the device. They are designed to absorb all wavelengths of solar radiation equally (Sellers, 1965). In the late 1960s, photoelectric detectors, such as silicon cells, became widely used for albedo and spectral reflectance measurements (Dirnhirm, 1968). The advantage of photon detectors is that they respond quickly to changes in incident radiation and thus permit high-resolution measurements, particularly from aircraft and spacecraft (Barrett, 1974; Justice and Townshend, 2002). One limitation of photon detectors is that they are sensitive to restricted spectral ranges. Silicon, for example, senses only wavelengths between 0.5 μm and 1.0 μm. Measurements must be either compensated for in those portions of the solar spectrum not observed, or two or more different detectors must be used. However, ease of use in the field and in aircraft and spacecraft has significantly increased their use for albedo measurements.

Human effects on Earth's albedo

Recently investigators have suggested that human modifications of the Earth's surface, accompanying continued expansion of urbanization, agriculture and forestry, may be altering the planet's albedo. For example, Otterman (1977) showed that overgrazing in desert regions can increase surface albedo by as much as 20%. Charney (1975) estimated that such changes may suppress rainfall, which would enhance the process of "desertification" that is occurring in sub-Saharan Africa. Sagan et al. (1979) proposed that extensive deforestation in tropical rainforests may significantly increase surface albedo and result in major climate changes. Such change may influence local climatic conditions, but global assessment suggests that such human changes to the Earth's land area contribute only slightly to possible global albedo changes (Henderson-Sellers and Gornitz, 1984).

ALEUTIAN LOW

This is a low-pressure area over the Pacific Ocean that reflects the average position of a depression that formed on the western side of the North Pacific, developed into maturity over the Aleutian Islands, and then decayed over North America. It is located in the central part of the North Pacific and is associated with the subpolar low-pressure belt.

The Aleutian Low, in conjunction with its changing relationship with the North Pacific (Hawaiian) High in the eastern part of the Pacific Ocean, is the major feature of the general circulation controlling the weather over parts of North America. It is

a semipermanent “center of action” of persistently lower pressure where barometric pressure of less than 1013 mb (29.92 in) prevails and where higher humidity and relatively higher temperatures for that latitude are common. In an analogous fashion to the Icelandic Low in the North Atlantic, the Aleutian Low is an area of average low pressure that reflects the frequent passage of cyclonic storms that migrate along the polar front from the continents that lie to the west (Akin, 1991). Consequently, the area is very stormy, with frequent strong winds, cloudy conditions, damp weather, and abundant precipitation.

The position of the Aleutian Low does change during the year. Beginning in November and continuing through February, the expanded low averages about 1002 mb (29.59 in). This causes migrating storms to move well into Mediterranean regions to the south more often as winter continues. In March the low diminishes slightly in intensity and migrating storms are less frequent by April. By July the low has virtually disappeared, showing up only as a trough extending from Kamchatka across central Alaska. By September the cycle starts again, as the low begins to form over the Bering Sea, leading to increasing disturbances.

Christoforou and Hameed (1997) studied the location of the Aleutian Low and found its location was highly correlated with mean annual sunspot numbers. When solar activity is at a minimum during its 11-year cycle the Aleutian Low migrates eastward.

ANGULAR MOMENTUM, ANGULAR VELOCITY

An important physical concept appropriate to a rotating globe such as a planet, angular momentum is defined as the moment of the linear momentum of a particle about a point, thus:

$$M = \vec{r} \times m\vec{V}$$

where M is the angular momentum about a point 0, \vec{r} the position vector from 0 to the particle, m the mass of the particle and \vec{V} the velocity.

Angular momentum plays an important role in both the Earth’s rotation and the coupling of the solid earth to the atmosphere. The speed of rotation (angular velocity) of the Earth varies only by small amounts, and these may be related in part to angular momentum lost to or received from the atmosphere. The atmospheric circulation patterns are modified by these energy transfers. The Earth’s angular velocity is the speed of its rotation about the geographic pole, thus its pole of instantaneous rotation, and not with reference to a point in space. The angular velocity is approximately $2\pi/S$ or sidereal day of 86 164.09 seconds, roughly 24 hours, or 15.04106863 seconds of arc per second of time.

As Rossby (1940) explained it, the Earth’s angular momentum can easily be visualized by taking a marble on the end of a string and rotating it on a smooth table. If the string is shortened the rate increases; if lengthened it slows. The speed is inversely proportional to radius, the product of the two remaining constant. This product, the angular momentum per unit mass, is a constant unless energy is added or subtracted (Newton’s Law of Conservation of Momentum, his “first law of motion”).

If part of the atmospheric envelope, rotating with the Earth at the equator at a speed of 465 m/s, moves poleward it will tend to speed up. At latitude 60° the radius (distance from axis of rotation) being reduced to half that at the equator, would indicate that the linear velocity of the Earth’s surface would be reduced to 232 m/s. However, a frictionless atmosphere here (of the same mass, but halved radius) should be accelerated to double its original velocity, thus 930 m/s, but the relative speed would be higher, the Earth’s surface linear velocity here being reduced by 232 m/s, the resultant relative ground speed of the atmosphere being 698 m/s (1560 mph); the direction would be easterly, since the Earth’s sense of rotation is from west to east. The velocity would also be reduced owing to friction, etc. In the upper atmosphere high-velocity easterlies are often observed, but they are far from universal, being replaced by westerlies under the influence of frictional and differential heating, thermodynamic phenomena.

The easterlies have the effect of removing angular momentum from the Earth. If they were the only planetary winds they would cause a gradual deceleration of the Earth. The westerlies, however, compensate and, traveling faster than the Earth, impart angular momentum to it (through friction). The westerlies thus lose angular momentum to the Earth, and they would die out if they had no powerful source of energy. From one or possibly both sides of the westerly belts, large eddies such as cyclones and anticyclones set up by the shears of the westerlies, and in lesser degree by thermodynamic processes, bring in the necessary momentum to keep the westerlies in motion.

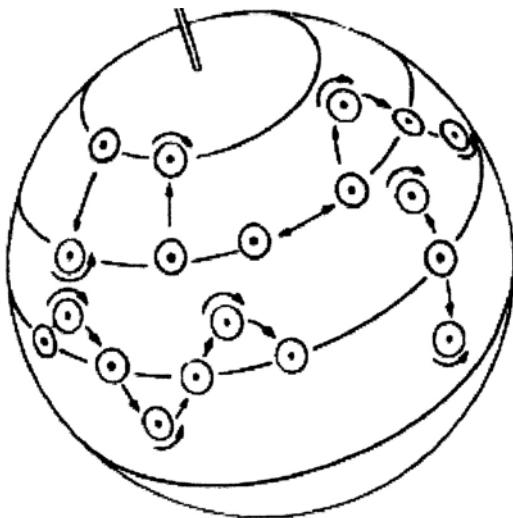

Figure A25 Planetary vorticity: angular momentum tends to be conserved in columns of constant height as they change latitude along different trajectories (from Von Arx, 1962; by permission of Addison-Wesley, Reading, MA).

An additional important principle, illustrated in Figure A25, is the conservation of angular momentum in any parcel of air (or water) as it changes latitude.

ANTARCTIC CLIMATES

Introduction

Climate and the polar regions

Ice plays a critical role in polar climate (Bintanja, 2000). In contrast with lower latitudes, the high albedo and low thermal conductivity of snow cover and ice (sea ice, floating ice shelves, continental ice sheets) have associated negative values of the surface radiation budget (e.g. Nakamura and Oort, 1988). Accordingly, low temperatures occur at the surface and in the free atmosphere in polar regions, and the troposphere has low thickness and tends to be barotropic. The low average temperatures mean a low water-holding capacity of the air, realized as low precipitation amounts annually (i.e. “polar desert”). Because of the atmosphere’s extreme static stability over ice-covered surfaces, clouds and precipitation tend not to be generated *in situ*; rather, they are advected in from lower latitudes by frontal cyclones. This poleward movement of moisture is a consequence of the inflow of energy into polar regions necessitated by the net-radiation deficit. Although these climatic characteristics are common to both polar regions on Earth, there are physical geographic major differences between the Arctic and Antarctic, manifest in their respective climates. Most notably, surface and free-air temperatures, along with cloud amounts, average lower in the Antarctic than the Arctic (Weller, 1982).

The Antarctic versus the Arctic

Whereas the Arctic is a landlocked ocean covered most of the year by sea ice, Antarctica is a polar continent upon which rests a thick ice sheet. The ice sheet rises to over 3000 m in East Antarctica (Figure A26), with a small area (“pole of inaccessibility”) exceeding 4000 m. Moreover, Antarctica is surrounded by the Southern Ocean: the only interruption to the zonal configuration of the continent occurs in the Antarctic Peninsula (AP). The extreme continentality results from the high elevation of the ice sheet and the continent’s isolation from other land masses (Carleton, 1992). In contrast, the Arctic is linked directly with middle latitudes via North America and Eurasia. The greater longitudinal variation of land and sea in boreal regions is expressed as a more meridional average pattern of the tropospheric waves and, accordingly, with enhanced transport of heat and momentum by the waves occurring between middle and high latitudes (van Loon, 1979). Over Antarctica the air is often poorly mixed, especially in austral winter and spring. This promotes a colder circumpolar vortex compared with that in the Arctic, and largely is responsible for the more extensive and intense stratospheric “ozone hole” of southern high latitudes.

Antarctica virtually doubles its own area between the early fall and spring because of the growth of sea ice (Figure A27). This large annual increase in sea ice occurs because, unlike the Arctic Ocean, the equatorward margin of Antarctica is unconstrained by land, and because atmospheric and oceanic mean circulations are relatively zonal (Carleton, 2003a). Interannual variations of Antarctic sea-ice conditions (its latitude extent, ice-water concentration) are most pronounced regionally (Parkinson, 1992), impacting the surface temperatures and precipitation. In addition to its negative feedback with surface

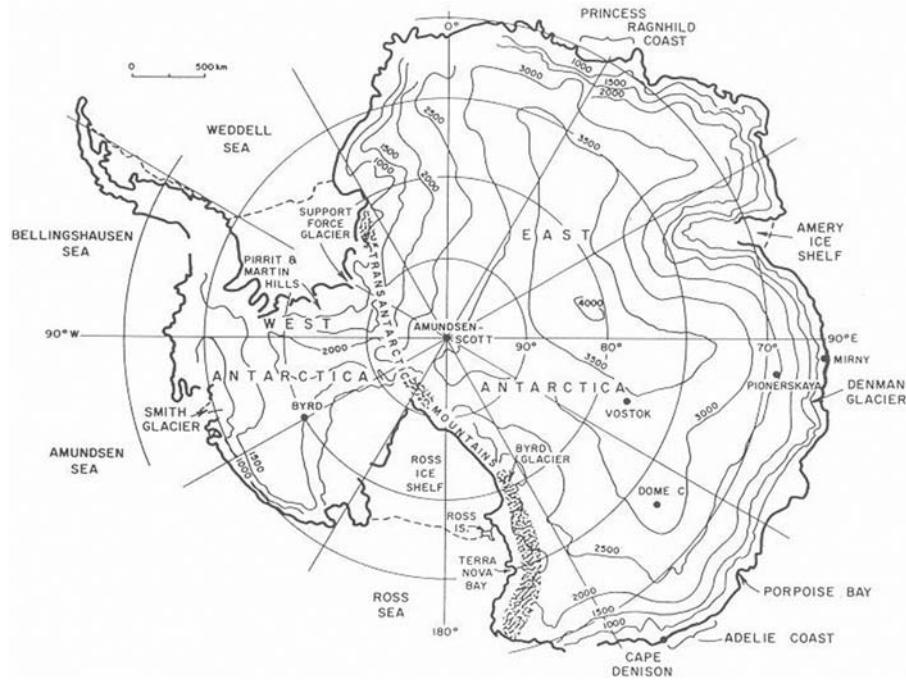

Figure A26 Map of Antarctica showing major physical geographic features (coastline, Antarctic seas, mountain ranges, ice-shelf margins, ice-sheet contours) and locations of selected permanent manned bases (named). (From Parish and Bromwich, 1991.)

temperature, the sea ice extent influences snowfall in coastal areas: the increasing distance between the moisture source (Southern Ocean) and the coast that occurs as sea-ice extent increases during fall and winter, reduces snowfall amounts. Sea ice–climate interactions manifest fluctuations in atmospheric circulation that include shifts in the preferred “storm tracks” of synoptic cyclones, as modulated by lower-frequency climatic teleconnections. The latter involve particularly the “Antarctic Oscillation” (AAO) and El Niño Southern Oscillation (ENSO).

Developments in Antarctic climatology

Major advances have occurred in our understanding of Antarctic meteorology and climatology since the first *Encyclopedia of Climatology*, “Antarctic Climates” item was written 20 years ago. In that time the major developments have been as follows:

1. Improvements in the routine observational network. For the surface, automatic weather stations (AWS) provide data on pressure, temperature and winds, as frequently as every 15 minutes, and their spatial density has increased since 1980, especially in the Ross Sea area. AWS data have been used to improve the representation of 500 hPa height fields over the continent via the atmospheric thickness relationship (Phillpot, 1991); to characterize temperature–sea-ice extent associations locally (Carleton et al., 1998); and to better determine the surface energy balance (Reijmer and Oerlemans, 2002). Satellite retrievals of climate variables additional to those acquired by visible and infrared sensors, include scatterometer-derived near-surface winds over ice-free ocean, ice-sheet altitude and topography from radar altimetry, surface “skin” temperatures and sea ice extent and concentration, including open-water leads and polynyas, from microwave radiometers; stratospheric ozone from atmospheric sounders; and upper-ocean biological activity from shortwave narrow-band sensors. Crucial in these developments has been the establishment of satellite direct-readout facilities on the continent, and the ability to include Antarctic data in global real-time synoptic analyses. Thus, our understanding of Antarctic contemporary climates comes from an array of data sources; some conventional, some remotely sensed, yet with different lengths of record.
2. Advances in numerical modeling of Antarctic climates; not just using atmospheric General Circulation Models (GCM) but also coupled ocean-ice–atmosphere models (e.g. Hall and Visbeck, 2002). In particular, mesoscale meteorological models developed for middle-latitudes are now applied to polar environments (e.g. Polar MM5: Guo et al., 2003). More reliability can be placed in modeling the following features of Antarctic climate: the impacts of changes in sea-ice conditions on atmospheric circulations in the southern extratropics (Raphael, 2003a); the important role of ice-sheet topography and local sources of heat and moisture associated with coastal polynyas, for the surface katabatic winds and cold-air mesoscale cyclone systems (*mesocyclones*) generated in coastal regions of Antarctica (van den Broeke and van Lipzig, 2003); and understanding how the ENSO signal is expressed in Antarctica. These studies confirm that Antarctica interacts actively with lower latitudes, and even may influence climate in parts of the northern hemisphere at certain times of year (Hines and Bromwich, 2002).
3. Development of longer-term archives of daily synoptic analyses for higher southern latitudes, as compiled from operational analyses of the Australian Bureau of Meteorology (ABM) and the European Centre for Medium-Range Weather Forecasts (ECMWF), for studying the circulation climates of higher southern latitudes. More recently, the application of automated techniques for tracking cyclones and anticyclones in these data has greatly extended our understanding of Antarctic-region synoptic climatology (e.g. Simmonds et al., 2003). Reanalysis data sets – meteorological fields generated by an analysis/forecast model that is fixed rather than changing through time, and in which all available data are included – particularly are illuminating Antarctic-region circulation climate (Pezza and Ambrizzi, 2003). Composite studies of synoptic phenomena using reanalysis data have identified the typically occurring circulation environments of mesocyclones, explosively deepening cyclones, and extremely strong wind events (Carleton and Song, 1997; Murphy, 2003). However, reanalysis datasets are not equally reliable for climate change studies: the NCEP–NCAR reanalyses of SLP generally are considered inferior to those of the ERA (ECMWF reanalyses) over southern high latitudes.
4. Dedicated intensive observing periods and special monitoring programs to study Antarctic-region weather and climate. In the mid-1990s a concerted effort to better depict and understand Antarctic synoptic meteorology and climatology was realized with the FROST (First Regional Observing Study of the Troposphere) project (Turner et al., 1999). An outgrowth of FROST was the drive to develop an updated long-term climatology of surface and free-atmosphere conditions for the Antarctic manned stations as part of the SCAR (Scientific Committee for Antarctic Research) READER (Reference Antarctic Data for Environmental Research) project. Stringent quality control of the observation data acquired by the nations which are signatories to the Antarctic Treaty, is permitting the reliable determination of annual and seasonal trends and changes in climate. For longer time scales, recent scientific traverses, particularly the shallow ice cores drilled in West Antarctica as part of ITASE (International Trans-Antarctic Scientific Expedition), are permitting an assessment of climatic variability and changes over about the last two centuries at mesoscale spatial resolutions.
5. Improved determination of the variability (spatial, temporal) of Antarctic surface energy budgets, over both sea ice and continental ice. These have involved shipboard measurements in the sea ice zone, as well as satellite remote sensing (Wendler and Worby, 2001).
6. Refinements in depicting the spatial patterns and temporal variability of variables significant to the ice sheet mass balance (Vaughan et al., 1999); notably, precipitation and the near-surface katabatic winds (Guo et al., 2004).
7. Application of newer analytical and statistical techniques to determining the links between coarse-resolution climate data, such as mapped fields of geopotential height generated from reanalyses or GCM, and local climate conditions (i.e. “downscaling”) (Reusch and Alley, 2002). These methods include artificial neural networks and “self-organizing maps”.
8. Development of satellite-image based “climatologies” of mesocyclones for several genesis key regions around Antarctica. Moreover, there is a realization that these storms

- are important for the snowfall and wind climatologies of coastal areas and embayments. Accordingly, attempts are being made to more accurately forecast these developments.
9. The addition of another 20 years' data has permitted identification of temporal trends and longer-term changes in Antarctic climate (atmospheric variables, sea ice conditions, ocean temperatures). In particular, opposing trends of surface temperature between the AP and the rest of Antarctica have become evident (see "Antarctica and global change", below).
 10. A realization that Antarctica is not isolated from the weather and climate processes of extratropical latitudes, or even the northern hemisphere. Rather, Antarctica is intimately connected with other places via atmospheric teleconnections, primarily the ENSO.
 11. Identification and characterization of the dominant modes of variability (subseasonal, interannual, subdecadal) in the atmospheric circulation of higher southern latitudes, and links with the upper ocean circulation. These modes include particularly the ENSO, but also the AAO, the "Pacific–South America" (PSA) pattern, and an "Antarctic Circumpolar Wave" (ACW) that was discovered in the mid-1990s.
- Accordingly, this revised item emphasizes particularly the above-noted developments in Antarctic climatology.

Antarctica and global climate change

Documenting Antarctic-region climate and its temporal variations has taken on increased urgency in recent decades, in the context of "global change". The following climate trends and changes, and their possible global associations, have spurred the increased monitoring of Antarctic weather, climate, biology, glaciology, and oceanography, particularly using satellites (e.g. Schneider and Steig, 2002).

1. "Global warming". This is likely to be evident earliest in polar regions, owing to "ice–albedo feedback". The latter involves a positive link between reduced snow/ice extent associated with warming, greater absorption of solar radiation by the surface, and continued warming. With respect to Antarctica, the following have been observed: a strong warming trend in the AP over the past several decades (Harangozo et al., 1997), especially in winter (van den Broeke, 2000a), that has been accompanied by reduced sea-ice extent west of the AP; the recent retreat and collapse of ice shelves such as Larsen-B on the eastern AP (Vaughan and Doake, 1996); an observed freshening of the upper ocean in the Ross Sea that suggests increased precipitation and/or melting from the West Antarctic ice sheet (Jacobs et al., 2002); and a subsurface warming concentrated within the Antarctic Circumpolar Current (ACC) (Gille, 2002). GCM studies (e.g. Wu et al., 1999) support a close link between recent climate warming and observed sea ice changes in Antarctica that mostly involve reduced ice–water concentration.
2. Stratospheric ozone depletion over the Antarctic in austral spring is a major contributor to global-scale reductions of ozone. Moreover, interannual variations in high-latitude circulation affect the configuration, spatial extent, intensity, and seasonal persistence of the ozone hole (e.g. Thompson and Solomon, 2002). The increased receipt of ultraviolet radiation

- in higher southern latitudes during spring and summer has deleterious consequences for organisms, including humans (e.g. Jones et al., 1998). In regions of Antarctica where cooling has occurred, a physical link with ozone depletion via the AAO has been proposed (e.g. Sexton, 2001).
3. The observed role of larger-scale atmospheric circulation patterns and their teleconnections for interannual variations and recent changes in climate over extrapolar as well as polar latitudes. These include surface temperature trends and summer melt periods linked to the AAO (Torinesi et al., 2003), and the sensitivity of the Antarctic ice sheet's mass balance to fluctuations in moisture transport, especially in the Pacific sector, where there is a strong ENSO signal (Bromwich et al., 2000).
 4. Since the mid- to late-1970s the change in the dominant Semi-Annual Oscillation (SAO) of climate variables, especially SLP, temperature and precipitation in sub-Antarctic latitudes and coastal Antarctica, has been accompanied by warming in the tropical Pacific and cooling over large areas of the ice sheet (Hurrell and van Loon, 1994). For the same period the ozone hole worsened.
 5. The strong interactions glimpsed between biological productivity in the Southern Ocean, and circulation–climate variations expressed as changes in sea surface temperature (SST), sea ice extent, and zonal wind speed.
 6. The role of Antarctica in long-term global-scale climate changes (glaciations, deglaciations), via its influence on the deep-water ocean circulation. Moreover, contemporary climate processes in the Antarctic appear crucial influences on deep water formation; notably via the polynyas and leads of coastal and sea ice areas generated by strong offshore (katabatic) winds, and by the spin up of polar mesocyclones (see Figure A27). Mesocyclones extract large amounts of energy from the upper ocean, increasing the salinity and density of the water, which then sinks to great depths (Carleton, 1996).

Antarctic climate(s)

No single "Antarctic climate" can be identified (e.g. Bintanja, 2000). Regional ice–atmosphere interactions change markedly with latitude, elevation, season, and exposure to heat and moisture sources (either from open ocean or within the sea ice zone), and with the passage of synoptic systems (Schwerdtfeger, 1984). The seasonal sea ice zone (SSIZ) near maximum extent is considerably further equatorward than the Antarctic Circle, but it remains relatively close to the continent in longitudes south of Australia (Figure A27). The AP frequently exhibits a pattern of climate variability different to that of the rest of Antarctica (Rogers, 1983). The influence of the southern polar region in the global oceanic and climatic environment demands a broad definition, so here "Antarctica" is taken to include the continent and its ice shelves, the SSIZ, and the adjacent ocean area including the ACC (see Figure A26). A discussion of the radiation and energy climates of these higher southern latitudes, and their influence on the atmospheric circulation, is given below in the context of the general circulation, as well as synoptically and subsynoptically. Accordingly, regional variations in these climatic factors are also discussed.

Radiation climates and the energy balance

The radiation balance is the principal climate-causing factor (World Meteorological Organization, 1967) in the Antarctic,

where there are strong seasonal variations in solar radiation as well as variations in elevation and surface characteristics. The high reflectivity of the surface (i.e. surface albedo) means that very little insolation is absorbed; thus keeping surface temperatures low all year. Satellite monitoring (visible, infrared, microwave) provides synoptic information on variables crucial to an accurate determination of the radiation balance, such as the extent, thickness and concentration of sea ice; accurate albedo measurements, and cloudiness. For modeling the surface energy balance, these satellite data augment ground-level observations.

Surface energy balance equation

The energy balance equation for unit horizontal area at Earth's surface is:

$$Q^* = K\downarrow(1-\alpha) + L^* = Q_H + Q_E + Q_G$$

Where $K\downarrow$ = global (direct plus diffuse) solar radiation; α = albedo, or fraction of shortwave reflected; L^* = net longwave radiation ($L\downarrow - L\uparrow$) (where $L\downarrow$ = atmospheric downward and $L\uparrow$ the terrestrial upward); Q_H = turbulent transfer of sensible heat; Q_E = turbulent transfer of latent heat (E = evaporation); Q_G = subsurface heat flux through ice, soil, or water. The conductive flux (Q_G) approximates to zero on an annual basis. Over snow- or ice-covered surfaces the radiative fluxes dominate the turbulent convective terms of Q_H and Q_E . However, over ice-free ocean or areas of low sea-ice concentration or small ice thickness within the pack, the convective terms become important, at least locally.

Solar radiation ($K\downarrow$)

The global radiation ($K\downarrow$) varies from virtually zero in mid-winter south of the Antarctic Circle to values comparable to the highest on Earth over the ice sheet in December and January. The high summer insolation is due to lack of clouds, elevation of the Antarctic plateau, a highly transmissive (low aerosol and water vapor content) atmosphere, 24 hours of daylight, and the occurrence of perihelion. These high values are not reduced much even by periods of cloud cover; a decrease in the direct (clear-sky) component is more or less balanced by an increase in the diffuse radiation.

Annual total received solar radiation is relatively high over the continent, particularly for East Antarctica, but decreases over the pack ice zone to a minimum over the sub-Antarctic oceans. This gradient is due to the increasing cloudiness associated with traveling cyclonic systems and proximity to the Antarctic Circumpolar Trough, ACT (see "Climatic variables; Cloudiness", below).

Albedo

The Antarctic experiences an annual negative net radiation balance largely due to high surface albedo. Albedo values are highest over the permanent snow cover of the continental interior, where around 83% of the incident solar radiation is reflected, and lowest over the ocean (around 11%). Over the coastal sea ice and pack ice zones the albedo is strongly dependent on the presence of meltwater (low α), the presence of snowcover (increases α), and the amount of open water that includes substantial polynyas (Wendler and Worby, 2001). Wendler et al. (1997a) found that midsummer values of albedo for 10/10 ice

cover averaged 59%, but with hourly values increasing to 76% where snow covered. Average values of albedo for 5/10 ice concentration were around 30%.

Although the surface albedo increases generally with latitude, the greater cloudiness over sub-Antarctic oceans modulates the effect of short-term variations in sea-ice concentrations on the planetary albedo. Over the continent, determination of cloud amount from space is difficult and leads to large discrepancies in computed solar radiation budget if not constrained using available surface observations (Hatzianastassiou and Vardavas, 2001). In summer the maximum variation in surface albedo occurs at about latitudes 60–70°S (78%), where it is dominated by the change from open water to ice cover. Seasonally, this constitutes about a 60% change in albedo. Between latitudes 80°S and 90°S the annual range does not exceed 10%.

Net longwave radiation (L^*) and the Antarctic inversion
The net longwave radiation (L^*) at the surface is a function of surface and atmospheric temperatures, and of the downward radiation from clouds, water vapor and aerosols. L^* is uniformly negative at the surface over southern high latitudes in winter. In summer there are large differences between the continent and peripheral oceans (50–60°S), due mainly to cloud cover effects. Increasing cloud cover tends to increase L^* over the ice sheet because $L\downarrow$ becomes more important over high albedo surfaces. Over sea ice, L^* varies due both to cloud amount and the ice–water concentration ($L\uparrow$ is reduced with increasing ice cover, Table A16). Satellite observations of the outgoing longwave radiation at the top of the Antarctic atmosphere show strong negative values in both summer and winter.

The intense radiational cooling and highly transmissive atmosphere produce a persistent low-level temperature inversion that reaches its greatest depth over the higher elevations of the ice sheet, where it is present almost the entire year (Schwerdtfeger, 1984). The inversion is no stronger at the end than at the beginning of the polar night, because an equilibrium is reached between $L\uparrow$ (decreases as surface temperature falls), and $L\downarrow$ from the atmosphere above the inversion layer, which changes relatively little with time. Combined with the slope of the ice surface, the semipermanent inversion is the source of the persistent katabatic winds (Connolley, 1996). A clearly defined time for the occurrence of the inversion maximum temperature is absent in the Antarctic, comprising the "coreless winter". This feature is evident for surface temperatures (T_s) at the Antarctic stations, including the AWS. This is because the rapid radiational cooling begun in the fall is arrested and, in many years, reversed in winter. Changes in the tropospheric longwave

Table A16 Mean outgoing longwave radiation ($L\uparrow$) and surface temperature (T_s) for different Antarctic sea-ice concentrations, from shipboard observations in the period 24 December, 1994 to 6 January, 1995

	Ice concentration in tenths

pattern between early winter and midwinter, and the consequent poleward movement of warmer air, help explain this temperature feature, which comprises part of the Semi-Annual Oscillation (SAO) of SLP and tropospheric height (see “Climatic variables; Temperature”).

Net (all-wave) radiation (Q^*) and energy balance

For the South Pole, Carroll (1982) estimated that 85–90% of the winter deficits of Q^* (i.e. the net “all-wave” radiation, or net shortwave minus net longwave) are made up of sensible heat (Q_H) losses. Table A17 summarizes the energy budget over Adelie Land in East Antarctica, for the period 20 November–22 December 1985, emphasizing the importance of the radiation terms. In the coastal ablation zone, Q^* is positive from late September through late February. Q^* becomes slightly positive over much of the Antarctic interior around the time of maximum solar elevation, due to increased cloud cover and a downward flux of Q_H .

The annual deficit of Q^* necessitates a net influx of energy to Antarctica. This occurs primarily as eddy sensible heat advected by frontal cyclone systems migrating into high latitudes. Because the amplitudes of southern hemisphere planetary waves are reduced, on average, compared with their northern hemisphere counterparts, the waves themselves transport relatively little sensible heat into the Antarctic. Instead, the remainder of the heat transport is carried out by the ocean, whereby divergence (convergence) of air in the near-surface wind field occurs on the western (eastern) side of a standing tropospheric trough, promoting upwelling of cold (downwelling of warm) water.

Turbulent exchange and the role of sea ice in the energy balance

Seasonal and interannual variations in sea ice conditions (areal extent, ice–water concentration, presence/absence of snow cover, ice-edge latitude) profoundly influence the surface energy budget and climate. The sea ice cover modulates the oceanic fluxes of heat to the atmosphere, and thereby its own thickness (Wu et al., 2001). The average thickness of Antarctic sea ice is around 1 m or so in late winter, except where deformation occurs and it reaches thicknesses of up to 4 m. During the 1990s, which was broadly representative of the longer period 1978–2000, a trend to increased Antarctic sea–ice extent accompanied reduced ice–water concentration.

Close to the continent the sea ice tends to have higher concentration and a longer seasonal duration than further out. Moreover, when sea ice is advected equatorward (poleward) by winds and the ocean circulation, it undergoes divergence (convergence), which leads to increasing ice extent and decreasing ice concentration (decreasing ice extent and increasing ice concentration). These associations are evident particularly in the major embayments, notably the Weddell Sea, and on interannual time scales (Carleton, 1988; Turner et al., 2002b). Anomalies of this type appear related to the AAO and the ENSO. Additionally, the presence of low ice-concentration areas and open-water leads and polynyas can significantly influence the local to regional-scale climate (e.g. as increased cloud cover and precipitation). This occurs owing to the enhanced oceanic heat losses to the atmosphere as Q_H and Q_E , especially in winter. Then these fluxes can be at least one order of magnitude greater than those of adjacent areas of higher sea ice concentration.

Table A18 summarizes the radiation and energy fluxes for a ship transect through variable sea ice conditions in Antarctic longitudes of the Tasman Sea during summer (Wendler et al., 1997a). In addition to showing the very strong contribution of the radiative fluxes to the surface energy balance, and of the ocean as a heat sink, these results reveal that the fluxes of Q_H and Q_E are of approximately similar magnitude but opposite sign: Q_H is a source of energy to the surface, Q_E is a sink. In late winter, as sea ice concentration decreases below about 50%, the convective fluxes change relatively little compared with those from open ocean (Worby and Allison, 1991).

Climatic variables

Temperature

Setting the surface energy balance to zero determines the equilibrium T_s . Mean winter T_s of -60°C to -70°C occurs on the highest areas of the ice sheet. Maps of mean T_s (Figure A28) indicate that the cold pole is displaced into East Antarctica, both in January and July (Borisov and Dolganov, 1982). There is a general decrease of temperature with latitude, especially evident in the AP. Considerable interannual variability of

Table A18 Summary of radiation and energy fluxes (W m^{-2}) through the Antarctic sea ice for the period 24 December, 1994 to 6 January, 1995 (variable ice concentrations). Note the dominance of the radiative fluxes. As in Table A17, the fluxes are positive (negative) toward (away from) the surface. Q_B = ocean or ice heat flux or phase changes

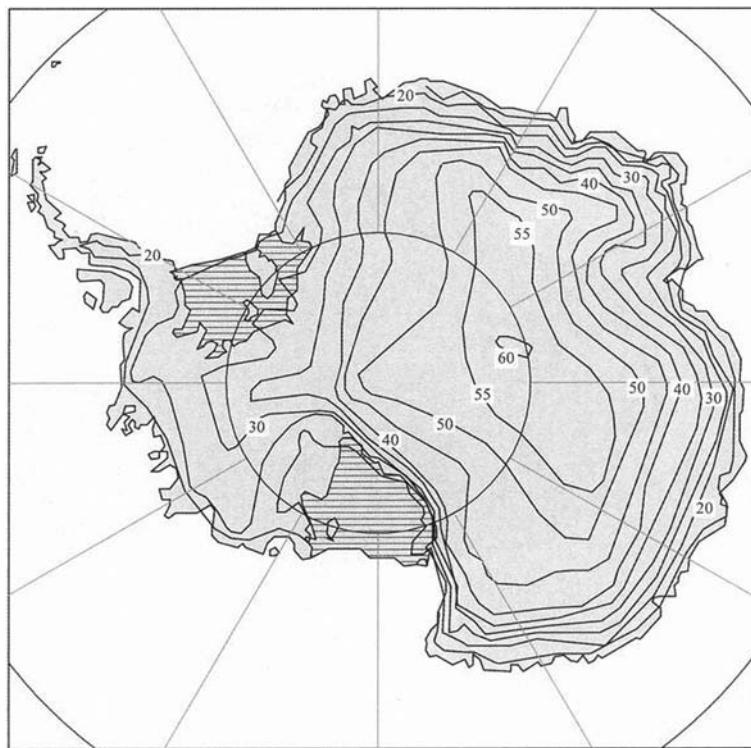

Figure A28 Map showing mean annual near-surface temperature field for Antarctica, synthesized from surface observations; isotherms in degrees below 0°C. (From Guo et al., 2004.)

T_s occurs, notably along the western AP and for stations south of the ACC ($60\text{--}70^\circ\text{S}$) because of their position within the SSIZ (the temperature gradient in the latter zone increases to above $1^\circ\text{C}/1^\circ$ latitude in winter, compared with about $0.6^\circ\text{C}/1^\circ$ latitude between 30°S and 60°S). Some of the interannual variability of temperature is related to ENSO (Schneider and Steig, 2002). SST gradients are steepest in the vicinity of the ACC, comprising an Ocean Polar Front (OPF), but strong thermal gradients also border the continent, particularly in winter. On average the meridional strong gradients of temperature near the surface disappear in the mid-troposphere (van Loon et al., 1972).

Trends in Antarctic temperatures are evident over the past several decades. Although the sign and magnitude of recent temperature trends differ somewhat by study and the method of spatially extrapolating the sparse data (cf. Doran et al., 2002; Turner et al., 2002b), a strong warming of the AP region (winter on western side, summer on eastern side) is evident in many studies. The winter warming has been accompanied by decreases in sea ice extent and reduced concentration to the westward, suggesting the importance of ice–ocean–air positive feedbacks. Synoptically, warm (cold) winters in the AP are associated with a greater (reduced) frequency of northerly wind components as the Amundsen–Bellingshausen Sea mean low pressure intensifies (weakens). These SLP patterns also resemble those connected with the tropical ENSO and its teleconnection to higher southern latitudes occurring via the Pacific–South America (PSA) pattern (see “Circulation variations and climatic teleconnections; The El Niño Southern Oscillation (ENSO) in Antarctica”).

In contrast to the recent warming of the AP, a cooling over much of the continent has coincided with lowering pressures in the ACT, strengthening westerlies over sub-Antarctic latitudes, and greater sea ice extent on average. These are associated with a trend toward more positive values of the AAO.

The dominant SAO in the annual march of temperature – and related changes in wind, pressure, geopotential height and precipitation – over sub-Antarctic latitudes and coastal Antarctica, produces gradient maxima in the equinoctial (March, September) months. The SAO results primarily from the tropospheric radiative imbalances between middle and high latitudes, which are at a maximum around the equinoxes. Also, a SAO has been detected in the latitude of the speed maximum of the ACC (Large and van Loon, 1989).

The atmospheric SAO is involved in the annual patterns of sea ice freeze-up and melt (Enomoto and Ohmura, 1990), as well as ice–water concentration (Watkins and Simmonds, 1999), via its interactions with the latitude location of the ACT and associated patterns of easterly (westerly) low-level winds occurring to the south (north) of this feature. In summer and early fall, when the ACT lies equatorward of the ice edge, easterly winds produce convergence of the pack, resulting in little increase in ice area despite the lowering surface temperatures. However, as the ACT shifts poleward of the ice edge in March, westerly winds to the north encourage ice divergence and a relatively rapid expansion of the pack through the winter and early spring. In December and January the ACT again lies north of the ice edge, which has melted back as temperatures have risen. The associated easterly winds encourage compaction of the ice pack and its retreat to higher latitudes.

There has been a climate change in the SAO since the mid-1970s to late 1970s (Hurrell and van Loon, 1994; Simmonds and Jones, 1998), involving primarily a shift in the springtime phase from September and early October into November. This change has coincided with strengthened latitude gradients of temperature originating mostly from a warming in the tropical Pacific, possibly associated with more frequent El Niño events (Mo, 2000); reduced sea-ice extent in the Amundsen–Bellingshausen seas (van den Broeke, 2000b), but significant cooling in coastal East Antarctica in early winter (van den Broeke, 2000a). At least part of the increased severity of the ozone hole over the past two decades likely is related to the longer isolation of the southern circumpolar vortex in austral spring, accompanying this change in the SAO.

Cloudiness

Satellite-observed cloud cover is at a maximum (80–100%) over ocean higher latitudes adjacent to the pack ice zone, varies little with the season, and is due to traveling cyclonic storms (see “Synoptic processes; Synoptic cyclone activity”, below). Manned observing station data indicate a cloudiness minimum over the interior plateau (Figure A29 Borisenkov and Dolganov, 1982), especially in midwinter (less than about 25%), and generally low seasonal variability. Maximum cloud cover variability occurs at Antarctic coastal stations located between these two zones (van Loon et al., 1972), arising from higher rates of alternation of high- and low-pressure systems. The contribution of lower cloud to the total cloud amount reaches a maximum

over coastal regions and the pack ice zone (cyclonic), and a minimum over interior East Antarctica where subsidence of air dominates. In recent decades, cloudiness in the spring and summer seasons has increased by about 15–20% at the South Pole. These increases appear to be associated with changes in the high-latitude circulation.

Precipitation

Snowfall dominates precipitation in the Antarctic. However, the contribution of clear-sky precipitation (e.g. “diamond dust”) and blowing snow to the ice sheet mass balance, increases in importance over the higher, colder and dryer regions of the interior (Giovinetto et al., 1990). The mass balance is the result of precipitation, evaporation, direct deposition (rime, frost), drifting, and runoff from melting at low elevations (Figure A30). Snow drift represents a net loss from the continent to the coastal sea ice zone. Although our confidence in measurements of Antarctic continental T_s and pressure is reasonably high, it remains low for precipitation. This results from a lack of data and the difficulty of separating real precipitation from drifting snow, especially in katabatic wind-prone areas. Accordingly, indirect estimates of Antarctic precipitation have been more forthcoming. These compute the net surface mass balance as $P - E$, where P = precipitation and E = sublimation, from moisture fluxes directed toward the continent. Recently, model calculations of precipitation have been undertaken. The decrease of precipitable water, relative humidity, and precipitation with increasing latitude, together with increasing distance from the Southern Ocean moisture

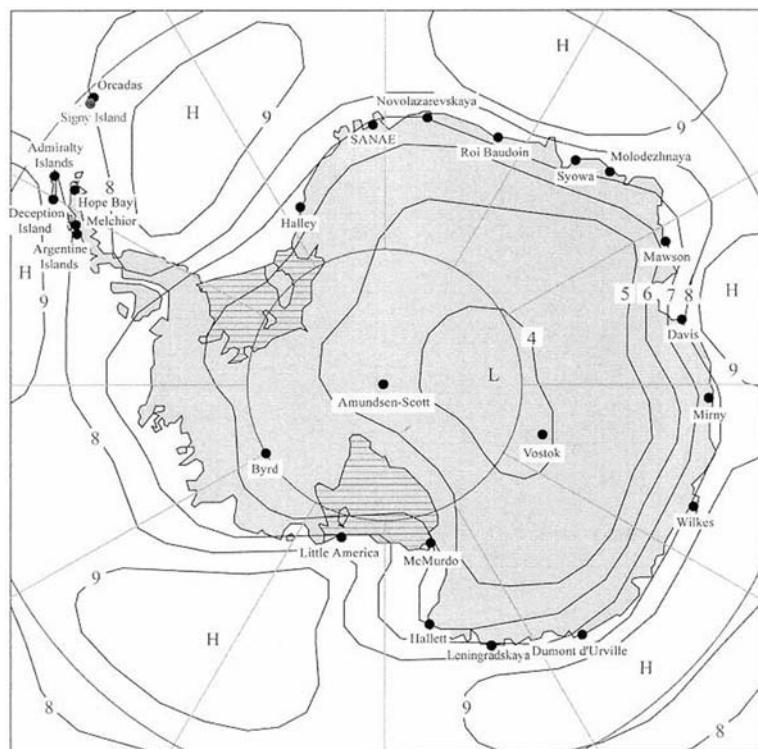

Figure A29 Map showing mean annual total cloud cover from station observations (dots show observation sites used for the compilation); cloud cover isopleths in tenths. (From Guo et al., 2004.)

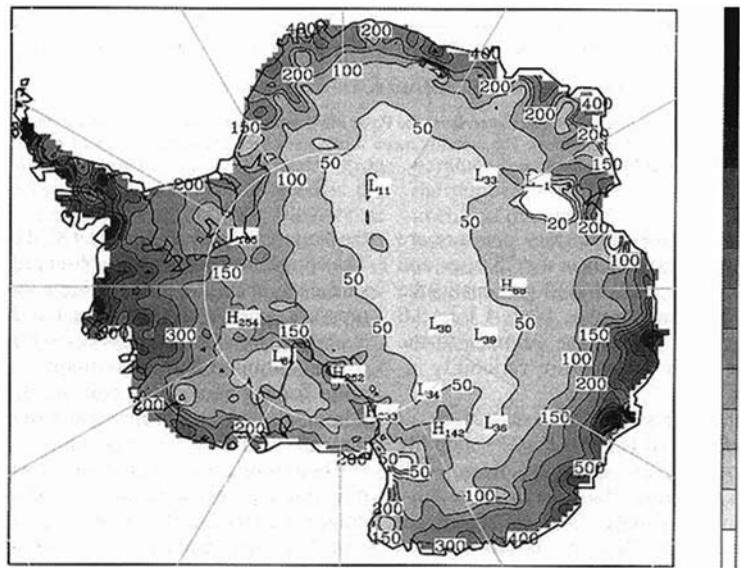

Figure A30 Map showing long-term accumulation distribution; units of mm yr^{-1} . (From Guo et al., 2004.)

source, means that annual precipitation on the high plateau is less than about 2 cm yr^{-1} water equivalent. This increases by up to at least 2 orders of magnitude at the coast (Figure A30). The lower elevations of West Antarctica facilitate moisture transport into the interior, mostly by synoptic cyclones.

Interannual variations of coastal precipitation are high, in response to high variability of cyclonic activity, especially along the western AP where they manifest fluctuations in the intensity of the Amundsen–Bellingshausen mean low pressure. The latter has an ENSO component (Guo et al., 2004). There has been a statistically significant upward trend in precipitation averaged over the continent between 1979 and 1999, although weakly downward trends are evident regionally and in the interior.

Surface winds

The surface wind is a persistent katabatic (downslope) flow that is gravitational and thermal in origin, relatively shallow (100–200 m deep), and essentially decoupled from the synoptic gradient flow above. It dominates the annual wind speed and direction at many stations in West Antarctica and coastal East Antarctica (Borisenkova and Dolganov, 1982; Figure A31). At Cape Denison the mean annual windspeed exceeds 20 m s^{-1} , which is the strongest on Earth close to sea level (Wendler et al., 1997b). Extremely high wind speeds can persist for weeks or even a month or two, especially in winter. In summer, solar radiation absorption reduces the katabatic effect (van den Broeke and van Lipzig, 2003). Katabatic winds are important because they produce snowdrift and enhance coastal polynyas and sea ice production (Adolphs and Wendler, 1995), thereby affecting the surface mass and energy budgets. Also, katabatic winds promote mesoscale cyclogenesis in confluence areas near the coast (e.g. Heinemann, 1990; Bromwich, 1991; see Figure A27). Streten (1968) found that katabatic winds are best developed in coastal regions with little synoptic cyclone activity, but with generally lower pressure located to the eastward. However, individual synoptic events may enhance the katabatic

winds at certain coastal locations. Modeling suggests that synoptic forcing may not be important in determining these winds over interior East Antarctica. There, they can be explained adequately from consideration of the topography (i.e. channeling effect) and the intensity of the wintertime inversion (Connolley, 1996). The katabatic winds are a critical component of the atmosphere's meridional circulation for southern higher latitudes and are linked to the intensity of the circumpolar vortex in the mid- to upper-troposphere. Katabatic winds may even participate in high latitude–tropical interactions on subseasonal time scales (Yasunari and Kodama, 1993).

Winds on the eastern side of the AP and the western Weddell Sea comprise a strong and persistent southwest to southerly flow, or *barrier wind* (see Figure A27). This wind is important for advecting ice equatorward into the westerly wind belt, thereby maintaining lower air temperatures in the southern South Atlantic than at comparable latitudes in the southeast Pacific (Schwerdtfeger, 1975, 1979). The barrier wind results from very cold and stable air that moves westward over the Weddell Sea, is dammed up against the eastern side of the AP, and sets up a thermal gradient similar to that forcing the katabatic wind. This explanation does not require the presence of a semipermanent low pressure in the Weddell, although such a feature often exists and may enhance the barrier wind (Figure A32). Interannual fluctuations in the intensity of the Weddell Sea low, some of which are ENSO-related (Yuan and Martinson, 2001), are strongly evident in the sea ice conditions of the embayment (Turner et al., 2002a).

Large-scale atmospheric circulation

Mean surface pressure and 500 hPa height fields

The essential features of the atmospheric circulation around the Antarctic have been known since at least the International Geophysical Year (IGY) of 1957–1958 (e.g. Lamb, 1959; van Loon et al., 1972). Mean monthly height, temperature, and wind

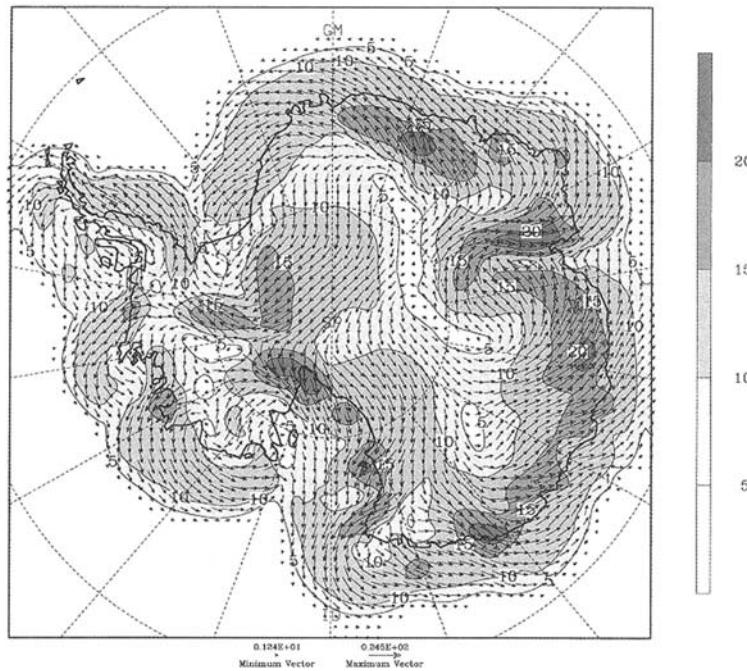

Figure A31 Antarctic near-surface winds for winter; units of m s^{-1} . (From Guo et al., 2004.)

fields at different tropospheric levels are available in atlas form (see van Loon et al., 1972), and have been summarized by Schwerdtfeger (1984). Synoptic and dynamic climatologies of the higher latitude circulation derived from the ABM, ECMWF, and other datasets, largely confirm the IGY studies, although greater detail is now known for previously data-void ocean areas (the South Pacific). In addition, much more is known of the circulation variability on interannual and decadal time scales.

The dominant features of the SLP field of southern high latitudes are a thermal anticyclone over the continent (Figures A32 and A33), although this feature is somewhat artificial owing to the method of reducing pressures to sea level. An almost continuous belt of low pressure (the ACT) around the continent and pack ice zone has well-defined centers located near the major Antarctic embayments, and also off Wilkes Land in East Antarctica (Figure A33a,b). The Amundsen–Bellingshausen mean low (ASL) comprises a “pole of maximum variability” in the SLP field (Connolley, 1997). Modeling experiments suggest that the strong interannual variability of the ASL is explained by the displacement of Antarctica’s highest elevation areas toward the Indian Ocean (Lachlan-Cope et al., 2001).

The mean lows of the ACT are the summation of individual synoptic cyclones moving in from middle latitudes (Figure A32), and represent areas of stagnation and cyclolysis (Carleton, 1979; Simmonds et al., 2003). However, recent satellite-based studies show that these “cyclone graveyards” are often active sites for mesoscale cyclones forming in cold-air outbreaks just to the westward (e.g. Carleton and Song, 1997). The SLP has lowered over Antarctica since the mid-1970s to late 1970s as the surface and troposphere has cooled. This trend comprises part of the AAO teleconnection pattern.

Although the ACT undergoes little variation in intensity between summer and winter (Figure A33a,b), its latitudinal position changes markedly in connection with the SAO: more equatorward in the solstitial (January, July) months, and closer to Antarctica in the equinoctial (March, September) months. Also, the broad zonality of the Antarctic mean circulation undergoes quite marked meridionality on individual (daily) analyses, especially in the South Pacific. High-pressure ridges frequently interrupt the ACT (see Taljaard, in van Loon et al., 1972). Favoured longitudes for ridges are in East Antarctica between 0–15°E, 50–60°E, and 140–150°E. The last location particularly is important in blocking events, which typically are more prevalent during ENSO warm phases (i.e. El Niño) (Marques and Rao, 2000).

In the free atmosphere the Antarctic is dominated by a circumpolar westerly vortex that expands equatorward in winter. Lowest heights (and layer thicknesses, or mean temperatures) occur over the ice sheet, and there is evidence that the intensity of this feature is coupled to the katabatic winds. On average the whole vortex is displaced slightly toward the Indian Ocean sector, or wave number 1 pattern. However, a three-wave pattern of tropospheric troughs and ridges also often occurs (Figure A32), especially during blocking events, with a trough over each of the three major ocean basins (e.g. Kiladis and Mo, 1998). In contrast to their counterparts in the northern hemisphere, the tropospheric waves have low amplitude and their positions do not change much from season to season. Interannual variations of wave number 1 occur preferentially toward either the Australian region or the Falkland Islands, with accompanying large variations in sea-ice conditions in the Scotia Sea (Carleton, 1989). This mode of variability is described by a Trans-Polar Index (TPI), which is based on the SLP anomalies at Hobart and Stanley (Pittock, 1984). However, the negative

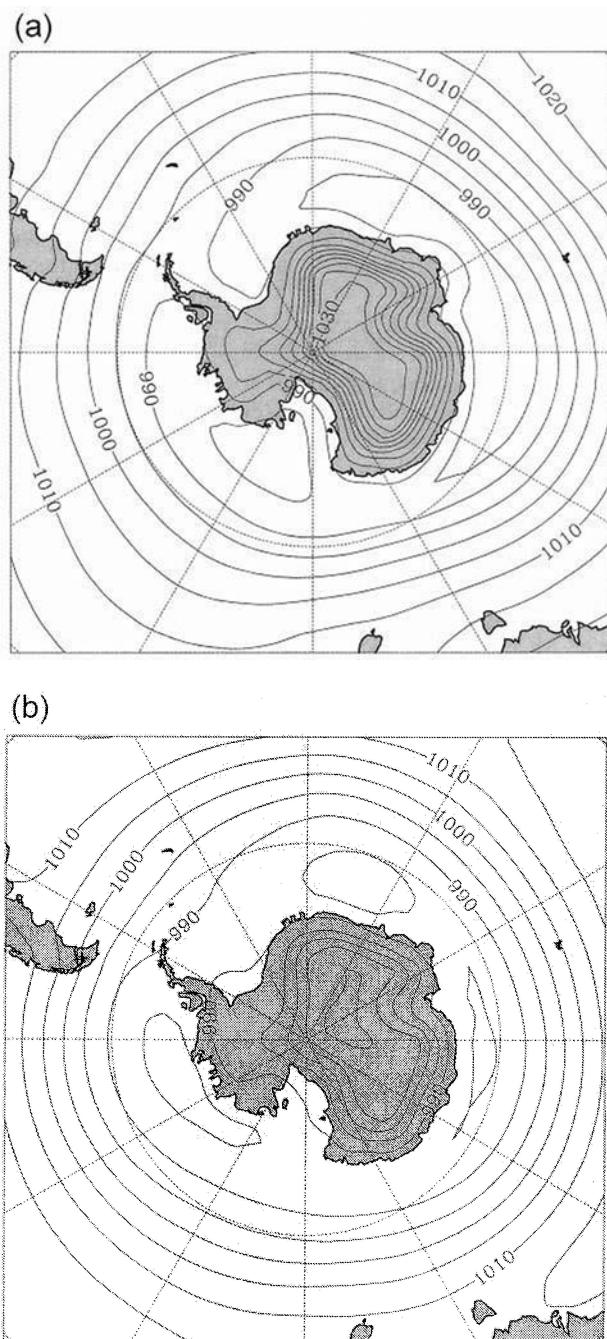

Figure A33 Mean sea level pressure (SLP, contour interval of 5 hPa) derived from NCEP-NCAR reanalyses for (a) winter, June through August, of 1979–1999; and (b) summer, December through February, of 1980–2000. (From Simmonds et al., 2003.)

relationship of SLP between these two places is not stable in the long term (Carleton, 1989). Temporal changes in the tropospheric waves are confirmed from NCEP-NCAR reanalyses (Raphael, 2003b), showing that the largest changes have occurred since about 1975 in the southern late fall through early spring, and from the Indian Ocean eastward to the Weddell Sea.

Zonal circulation

In accordance with the limited summer-winter variation in the wave pattern (see “Mean surface pressure and 500 hPa height fields”, above), there is little seasonal change in the intensity of the zonal westerlies at 500 hPa in middle and high latitudes (Trenberth, 1979). However, there is marked interannual variability, especially in the Pacific sector, where it is dominated by the ENSO – westerly zonal winds in adjacent broad latitude zones vary out-of-phase, or so-called “split jet” flow (Bals-Elsholz et al., 2001). During ENSO warm events the STJ (PFJ) tends to be stronger (weaker) (Figure A34); but in cold, or La Niña events, the STJ (PFJ) is weaker (stronger). These variations modify the momentum and heat transports, as well as storm tracks, over southern middle and higher latitudes. However, it is important to note that there is considerable variability of the above-noted patterns within a given phase of ENSO, especially the El Niño events.

Synoptic indexes long have been used to characterize the zonal atmospheric circulation in the southern extratropics (e.g. the TPI). These are constructed using SLP observations for station pairs across widely separated latitudes (zonal index) or

longitudes (meridional index). Indexes of this type capture the SAO in near-surface SLP, and confirm the recent change in the AAO to a more positive (i.e. increased zonality) mode. The increased strength of the southern westerlies that occurs between fall and spring occurs concurrently with the expansion of the sea ice (Ackley, 1981); also, greater zonal wind variability tends to accompany increased variability of the ice. Similarly, between-year regional variations of the ice near maximum extent accompany changes in the zonal index which, in turn, are related to patterns of higher latitude cyclonic activity and the teleconnection patterns of AAO and ENSO (Carleton, 1989; Renwick, 2002).

Synoptic processes

Air masses and air streams

The Antarctic ice sheet is the source region for extremely cold, dry and stable Antarctic continental (cA) air year round (Wendland and McDonald, 1986). It is recognized as inversion air only over the continent and ice shelves because it transforms

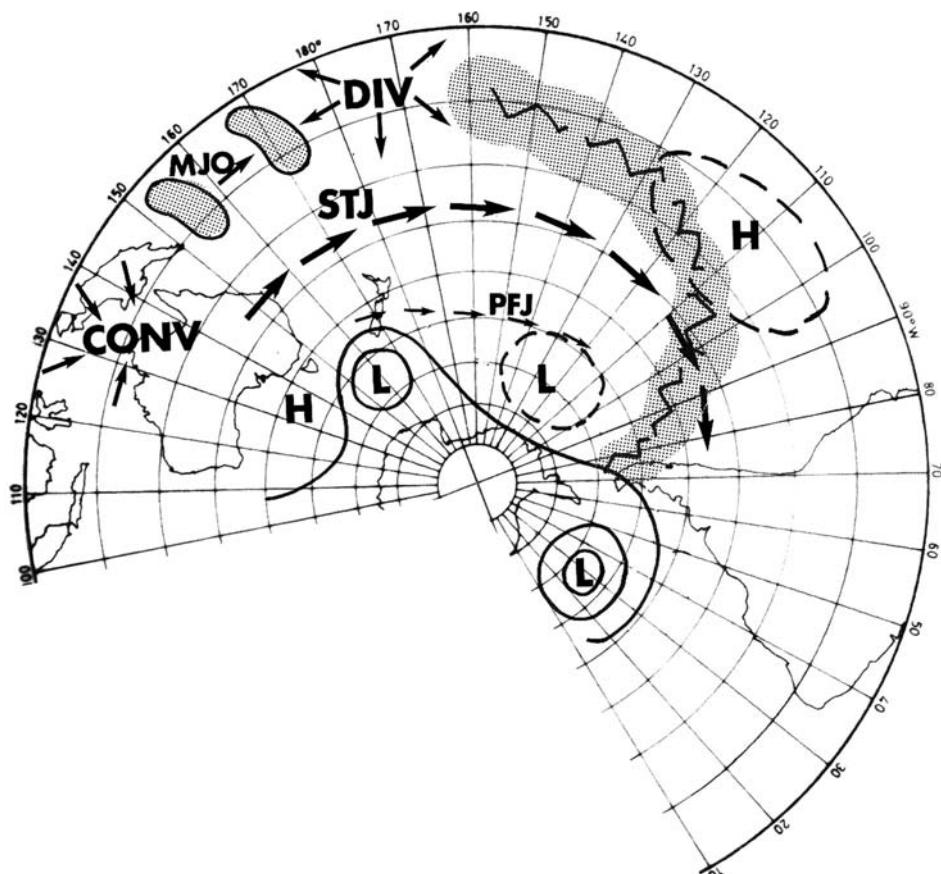

Figure A34 Schematic showing the dominant changes in mid- to upper-tropospheric circulation over the Pacific and southwest Atlantic sectors that accompany a warm (El Niño) event. Features over lower latitudes (MJO: Madden-Julian Oscillation, SPCB: South Pacific Cloud Band) mostly are representative of the summer season. Those over middle and higher latitudes (STJ, PFJ, pressure/height anomalies) apply to the winter season 4–8 months earlier. The solid (dashed) lines indicate that the represented feature is stronger (weaker) during El Niño than in La Niña, for the respective season. (From Carleton, 2003a.)

Source: After Taljaard, in van Loon et al. (1972).

strongly during equatorward excursions (Andreas and Makshtas, 1985). Taljaard (in van Loon et al., 1972) identified a transitional airmass (Antarctic maritime, mA) over the pack ice which is present only during winter. It is slightly warmer and less stable than cA (Table A19), but at times may be indistinguishable from that airmass.

Polar maritime (mP) air – sometimes also known as Southern maritime (mS) – dominates the middle and higher-latitude oceans that are ice free. Developed partly over the marked SST gradients of the OPF, mP air exhibits south–north variations in temperature and moisture (Table A19), being strongly destabilized on moving equatorward. Thus, the OPF is the site for many higher-latitude polar mesocyclone (“polar low”) systems observed in satellite imagery and a high frequency of lower-level (“boundary-layer”) fronts (Carleton, 1995). Modification of mP air also occurs when it returns poleward, typically in advance of frontal cyclones. In this case the air stabilizes and may penetrate far into the interior of Antarctica via the Pacific sector of West Antarctica.

Climatic fronts

The climatic frontal zones (and, hence, major cyclone tracks) of the southern hemisphere (see Figure A32) show a close association with the OPF at middle and high latitudes (Baker, 1979). These polar fronts are manifest as tropospheric thickness gradient maxima (TGM) in association with middle- and high-latitude jet streams (Taljaard, in van Loon et al., 1972). In summer there is some correspondence between the 1000–500 hPa TGM and the summer pack ice margin, implying frontal activity. In winter the higher-latitude frontal frequency maxima occur equatorward of the sea ice margin in the South Pacific, but there are no corresponding bands of TGM at this latitude owing to higher rates of alternation of high- and low-pressure systems

(Taljaard, in van Loon et al., 1972). Instead, a well-defined TGM in the 1000–500 hPa layer lies poleward of the ice border along 65–70°S. This has been considered evidence of a secondary Antarctic (as opposed to Polar) Front (see Figure A27). In East Antarctica, TGM in the 500–300 hPa layer may correspond to an Antarctic Jet related to the topography of the ice sheet, as identified during the IGY and subsequently modeled (Mechoso, 1980). Interestingly, there has been little research on the climatology of atmospheric fronts over southern high latitudes in recent years. However, useful insights can be gleaned from satellite passive microwave retrievals of cloud water, column-integrated water vapor, and precipitation over ice-free ocean, as well as the summary maps of extratropical cyclone tracks derived using automatic tracking of systems in digital analyses.

Synoptically, fronts penetrating Antarctica often lose their identity on ascending the ice sheet, although they may temporarily disrupt the strong surface inversion. Warm fronts advancing southward ahead of mP or mA air provide overrunning precipitation, and frequently are involved in warming episodes associated with the coreless winter.

Synoptic cyclone activity

Automated cyclone-tracking routines applied to digital SLP data (Simmonds and Keay, 2000a,b) largely confirm the mean patterns of extratropical cyclones determined in the earlier satellite-based (cloud vortex) and IGY climatologies for the Antarctic and sub-Antarctic (Carleton, 1979; Figure A32). However, they add information on the variability (frequency, spatial locations) of these systems and also their characteristic intensities. Over the Southern Ocean, including the SSIZ, the circulation is dominantly cyclonic all year (see “Large-scale atmospheric circulation; Mean surface pressure and 500 hPa height fields”, above), the mean pattern involving cyclogenesis

over middle latitudes of the western South Atlantic, Indian Ocean, and mid-Pacific (Carleton, 1979). Synoptic cyclones bring clouds, precipitation and strong winds to coastal Antarctica. The maturity and dissipation (cyclolysis) of these systems occur at successively higher latitudes along well-defined climatic tracks that merge in the ACT. These “storm tracks” are evident as cloud bands in satellite VIS/IR imagery. They are also retrievable from digital daily analyses as zones of high variance of the v-wind (south–north) component and geopotential height, but low variance in the u-wind (west–east) component (Trenberth, 1987). However, there are some differences in the locations of storm tracks derived in this manner and those obtained from tracking cyclone systems (Jones and Simmonds, 1993). Relatively few lows invade interior East Antarctica, whereas many enter West Antarctica from the South Pacific. The latter region particularly shows an interannual variation in cyclone frequencies related to ENSO (Carleton and Song, 2000). Moreover, a trend to decreased (increased) cyclone frequencies over the sub-Antarctic (Antarctic) seas for the period 1960–1999 is consistent with numerical modeling studies employing anthropogenic forcings (Fyfe, 2003). These imply a poleward migration of the zone of maximum baroclinity under global warming. However, this change may depend, at least partly, on the intensity class of cyclone studied (Pezza and Ambrizzi, 2003).

Similar to earlier studies for the northern hemisphere, explosively deepening cyclones (“bombs”) have been identified and studied for the southern extratropics. Those occurring closer to Antarctica have much in common with some “polar lows”, in terms of their large-scale synoptic environments (cf. Carleton and Song, 1997, 2000; Simmonds et al., 2003).

The time-averaged centers of cyclolysis within the ACT are located just eastward of the longitudes of maximum variation of sea-ice extent; Carleton and Fitch, 1993; Yuan et al., 1999; cf. Figures A27 and A34). Therefore, the longitudinal frequency of depression centers influences ice distribution and advance/retreat patterns via temperature and dynamical (wind-induced) advection (Cavalieri and Parkinson, 1981). On average there is no clear connection between Antarctic sea ice extent and cyclone tracks, although closer associations can be found for certain time periods and regions (Yuan et al., 1999).

Mesoscale cyclone and “polar low” activity

High-resolution meteorological satellite imagery has shown that mesoscale cyclones, or polar-air mesocyclones (approximate length scales 100–800 km), occur frequently in Antarctic and sub-Antarctic latitudes (Carleton, 1992, 2003b). The improved detection of these systems likely is involved in a statistically significant recent increase in extratropical cyclone frequencies over the southern hemisphere that is not matched by significant changes in SLP (Sinclair et al., 1997). Mesocyclones comprise two main cloud-vortex types: inverted comma-shaped “polar lows”, dominated by positive vorticity advection associated with short waves and jet stream maxima; and spiral-shaped (multi-banded) systems generated mostly by strong sea–air interactions of heat and moisture (Carleton, 1995, 1996). One zone of mesocyclone high incidence is located near the winter/spring sea-ice margin, especially in the South Pacific sector (see Figure A27). There, streams of cA or mA air are strongly destabilized in the vicinity of the ice edge and OPF. These storms often track east or northeast through Drake Passage to decay in the Weddell Sea area (Carleton and Song, 1997). The

other major zone of meso-cyclogenesis is close to the Antarctic coastline and over the ice shelves; near the confluence areas for the katabatic winds (see Figure A27). There, “vortex stretching” as air descends the steep slope of the ice sheet, enhances cyclonic vorticity. Also, some mesocyclones develop in association with coastal polynyas because of the oceanic large heat losses to the atmosphere. These near-coastal mesocyclones may lack a cloud signature, being detectable only in the AWS data, or be composed mostly of low-level clouds.

The zonally averaged meso-cyclogenesis seems to be greatest in March and September, associated with the SAO (Carleton and Song, 1997). A number of regional-scale “synoptic climatologies” of mesocyclones in the Antarctic have been developed for time periods of varying length; for the Ross Sea, Marie Byrd Land and the Siple Coast, the Bellingshausen and Amundsen seas, and the Weddell Sea (refer to section 2.2.3 in Carleton, 2003b; also Carleton and Carpenter, 1990; Carrasco et al., 2003). In the Bellingshausen–Amundsen seas, strong differences in the ENSO-related SLP and SST anomalies (SSTA) for the southern winters 1988 and 1989 were reflected in major changes in mesocyclone activity (Carleton and Song, 2000). Mesocyclones were more (less) frequent in this sector in 1989 (1988), associated with decreasing (static) SSTA during the respective May to September periods.

Circulation variations and climatic teleconnections

Climate fluctuations in the Antarctic and sub-Antarctic occur interannually (i.e. climate variations), decadally (climate trends), and multidecadally (climate changes). Interannual variations primarily involve teleconnections to the tropical Pacific ENSO, which is, globally, the dominant coupled ocean–atmosphere interaction mode. On decadal time scales, Antarctic-region circulation–climate variations are most closely connected with an Antarctic Circumpolar Wave (ACW) of extratropical coupled anomalies of SST, upper-ocean salinity, SLP, meridional winds, and sea ice. At times the ACW may be linked to, and modulated by, the ENSO. Recent climate changes in the Antarctic, particularly as revealed in the retreat and collapse of ice shelves, and the ongoing warming of the western AP, may be evidence of “global warming”. However, a more immediate explanation for these climate changes derives from long-term shifts in the atmospheric circulation; primarily, the zonally varying mode or Antarctic Oscillation (AAO).

The El Niño Southern Oscillation (ENSO) in Antarctica The climate teleconnections to the ENSO phenomenon also are evident in Antarctica, especially in the Pacific sector (Kwok and Comiso, 2002). Interestingly, the pressure changes that occur over southern higher latitudes in the lead-up to an El Niño may be at least as large as those in the tropics, and often precede the changes there. (In an El Niño, tropical convection shifts eastward from the “maritime continent” to the central tropical Pacific, in association with the area of highest SST.) The associated weakening of the South Pacific subtropical high, a key “center of action” in ENSO, permits the semi-permanent South Pacific Convergence Zone (SPCZ) to move eastward (Figure A34). The SPCZ is a major trough ahead of which energy and moisture are advected rapidly southeastwards into extratropical latitudes. Consequently, its forward side is evident in satellite imagery as a quasi-meridional band of deep clouds that often energizes cyclonic circulations transiting the Pacific

sector of the Southern Ocean. During El Niño the strengthened latitudinal pressure and temperature gradient resulting from the higher SST in the tropical central Pacific, helps intensify the STJ in that sector. At the same time the PFJ tends to weaken. These synoptic interactions are evident on monthly time scales as a standing wave train pattern of alternating anomalies linking the South Pacific and South Atlantic sectors, or so-called Pacific–South America (PSA) pattern (e.g. Mo, 2000). The PSA is reminiscent of the North Pacific PNA pattern, although the pressure/height anomalies generally are of lower magnitude. The PSA pattern during composite El Niño events is shown in Figure A34. Note particularly the out-of-phase relationship of the pressure anomalies between the Bellingshausen–Amundsen sector (Weddell Sea), where SLP anomalies are positive (negative). Similarly, this relationship is evident as out-of-phase anomalies of temperature and sea-ice extent. Thus, El Niño events tend to produce colder conditions, more frequent southerly winds and greater sea-ice extent east of the AP.

The out-of-phase temperature and related pressure anomaly pattern between the seas west and east of the AP comprise an Antarctic Dipole Index (ADP), which correlates well with tropical Pacific SST and surface air temperature, as well as the Antarctic sea ice edge (Yuan and Martinson, 2001). Thus, the ADP appears to link interannual climate variability in the Antarctic seas with the ENSO pattern. The signal is particularly strong in La Niña events, for which it may have some predictive value.

Over most of Antarctica, El Niño events tend to be accompanied by colder conditions than normal and negative anomalies of surface pressure (Smith and Stearns, 1993). The cooling of the troposphere helps intensify the katabatic winds, leading to stronger wind speeds near the coast; at least, as occurred during the major El Niño of 1982–1983. Accordingly, sea ice may be more extensive in those regions while it is reduced in others, such as the Ross Sea.

During La Niña, or ENSO “cold events”, the regional pattern of coupled anomalies in pressure, meridional winds, temperature and sea ice over the Southern Ocean are more or less opposite those for El Niño (Sinclair et al., 1997). In the Pacific sector, La Niñas typically are expressed as a strengthened Amundsen Sea low and associated stronger PFJ (a weaker STJ), and a weaker Weddell Sea low (Yuan et al., 2001). Accordingly, the temperature anomalies along the western AP are mostly negative in La Niña, with greater sea-ice extent, in contrast to the eastern side of the peninsula.

As noted for climate variations in other parts of the world, the ENSO teleconnection is not stable through time. In the Pacific sector of West Antarctica a change in the relationship between ENSO and the poleward flux of moisture evidently occurred around 1991; from strongly positive before that time to significantly negative afterward. This change impacted regional precipitation amounts.

The Antarctic Circumpolar Wave (ACW)

Unlike the ENSO climate signal in Antarctica, the subdecadal ACW appears primarily to be of southern extratropical origin, although it likely interacts with the ENSO as a “slow teleconnection” (Peterson and White, 1998). In the atmosphere the ACW is a propagating wave number 2 pattern that makes a complete circuit about Antarctica in about 8 years (4 years per wave). It differs from the ADP, which is a quasistationary wave,

although the two may interact in the Amundsen–Weddell Sea sectors (Yuan and Martinson, 2001). Because the western (eastern) sides of a trough are characterized by opposite anomalies of meridional wind and temperature, the patterns of upwelling and downwelling in the ocean – important for sea temperature and salinity differences – and of sea-ice extent, also are opposite across the wave (Motoi et al., 1998). East of a trough and west of a surface high pressure, the northerly winds advect mild air southward, leading to downwelling and decreased near-surface salinity, and a general retreat of the sea-ice extent. Conversely, west of a trough and east of a surface high pressure, the southerly winds advect cold air equatorward, producing upwelling and increased salinity, and advancing sea ice. Thus, the ACW in the upper ocean is evident as a slowly migrating (to the eastward) suite of anomalies that maintain their identity across seasons and through the different regions of the Southern Ocean. Interestingly, a number of modeling studies have successfully simulated an ACW-like phenomenon, yet its period and even wave number can be different from those evident in the data (e.g. Motoi et al., 1998). Similarly, the analysis of datasets for the periods before and after that analysed by Peterson and White (1998) suggests that the ACW is not always a prominent teleconnection (Kidson, 1999). This lack of temporal stability is reminiscent of the Antarctic teleconnection to ENSO.

The Antarctic Oscillation (AAO) and recent climate changes

The AAO, also known as the zonally varying mode, southern annular mode, and high-latitude mode, comprises the first EOF (empirical orthogonal function in a principal components analysis) of SLP and tropospheric height over southern middle and higher latitudes (Rogers and van Loon, 1982; Kidson, 1999). An intensification of the mean pressure centers respectively over middle latitudes and Antarctica results in stronger geostrophic westerly winds in the sub-Antarctic and PFJ, or the positive phase of AAO. Conversely, a weakening of the pressure meridional difference reduces the westerlies and PFJ, or negative phase of AAO. After the 1970s, the trend of the AAO has been one of increasing “positive polarity”, partly linked to rising SST in the tropical Pacific and more frequent El Niño events. The stronger westerlies bring in relatively mild and moist air to the western side of the AP, providing at least a partial explanation for the observed winter warming and reduced sea ice there. During the same period the intensification of the polar vortex over the continent accompanied downward trends of temperature there, and reduced surface melt in the summer (Torinesi et al., 2003). Stronger westerlies in the AAO positive mode tend to be associated with a zonally averaged greater extent of the sea ice (Hall and Visbeck, 2002).

Although it is most marked in the troposphere, the AAO has links with the stratosphere, and may modulate the shape and intensity of the annually occurring Antarctic ozone hole (Thompson et al., 2000). In general, greater cooling over Antarctica accompanying positive AAO, better isolates stratospheric air from that in middle latitudes, permitting the formation of more polar stratospheric clouds upon which chlorine compounds accumulate, thereby accelerating the breakdown of ozone during austral springtime (Sexton, 2001). Thus, recent Antarctic-region climate changes involving human activities may be linked to changes in frequency of “natural” teleconnection patterns.

APPLIED CLIMATOLOGY

Applied climatology has been the foundation upon which the world's weather-sensitive activities and infrastructure have been developed. Applications of climate data and information have likely contributed more to the development of most nations than any other function of the atmospheric sciences. Today weather forecasts are very useful and important but these only became available in the twentieth century, more than 150 years after applied climatology had been in service to the nation.

What is applied climatology? The answer may seem obvious, but the definition of applied climatology is elusive for several reasons. Activities falling under the umbrella of applied climatology are spread among many disciplines. The activities also have interfaces with many parts of the atmospheric sciences, forming a myriad number of interactions. The field is truly interdisciplinary, embracing climatologists and those of other disciplines including hydrology, agriculture, engineering, and business. This breadth of the field and its evolution over time make the history of applied climatology interesting.

Over 50 years ago, leaders in the field defined applied climatology as the scientific analysis of climate data in light of a useful application for an operational purpose (Landsberg and Jacobs, 1951). A recently published glossary of meteorological terms indicates that applied climatology includes agricultural climatology, aviation climatology, bioclimatology, industrial climatology, and others (AMS, 2000).

My interpretation is that applied climatology describes, defines, interprets, and explains the relationships between climate conditions and countless weather-sensitive activities. For example, if viewed in a business sense, applied climatology would embrace interactions with marketing, sales, customer services, research support, and the delivery arm for climatological data and information. The diversity of the field is one of its hallmarks.

Applied climatology does not include fundamental, basic studies of the climate system, but it does embrace causation as a functional part of explaining climatic relationships to other phenomena. For example, a climatological study of rainfall effects on streamflow may include an explanation of the atmospheric factors influencing the rainfall variability between days, months, or years.

The field of applied climatology has evolved over the past 60 years, into interactive groups embracing three functional areas. First is the inner core of applied climatology – focusing on instruments and data. Functions include data collection, transmission, quality assessment, archival, its representativeness in space and time, and access to it.

Functions found in the second group relate to the interpretation and generation of climate information generally based on interactions with users. Activities include statistical and physical analyses, performance of special interpretive studies, and generation of information (published or computer-based). Within the atmospheric sciences, applied climatology extends well into the areas of dynamic climatology, instrumentation, and climate data. Applied climatological research develops the informational products for the users, studies the climate–sector relationships, develops statistical techniques to express climate information effectively, contributes to weather data collection efforts, and develops databases to fulfill its mission. Today

these functions are handled by state climatologists, university-based scientists, and staffs at regional climate centers, the National Climatic Data Center, the Climate Prediction Center, and the private sector that addresses climate services.

The third group consists of users of applied climatology products, and is easily the largest group. Users include scientists in many disciplines and decision makers in business and government. Effective relationships between applied climatologists and users require a two-way interaction to share needs and information. Applications of climate information fall into four classes: (1) design of structures and planning activities, (2) assessments of current and past conditions including evaluation of extreme events, (3) study of the relationships between weather–climate conditions and those in other parts of the physical and socioeconomic worlds, and (4) operation of weather-sensitive systems that employ climatic information in making decisions.

History

Applied climatology, as one sector of today's world of atmospheric sciences, was the first atmospheric sciences activity to serve humankind, and applied climatology remains a most successful contributor to the nation's well-being.

Persons such as Thomas Jefferson were among the nation's early users of climate information. Jefferson planned farming operations around local climate conditions and applied climate information in the equipment he designed and used and in building construction (Martin, 1952). Crop selection, construction styles, and building placement in the eighteenth century reflected awareness of climate conditions and their effects.

The beginning of weather observations, both privately and at military forts, helped further applications of climate data. The expansion and organization of the nation's weather data collection system, and science in general, occurred during the nineteenth century.

Early leaders in the emerging field of meteorology, such as James Espy and Elias Loomis, recognized regional differences in the nation's climate and identified how these differences created profoundly different effects on human endeavors (Fleming, 1990). A key scientist of the century, Joseph Henry, made invaluable studies in applied climatology, and in the 1850s analyzed the impacts of climate on US agriculture of the time. Koeppen (1885) and other scientists began associating climate conditions with various land uses and plant environments as a means to define climate regions in each continent.

Further growth in the understanding of climate interactions with various physical systems, such as water resources, had to await the systematic collection of data on climate as well as weather-sensitive conditions. As the nation entered the twentieth century data collection had been in progress sufficiently long to allow new, more definitive studies of how climate impacted activities. For example, Thiessen was a civil engineer who in 1912 defined how climate conditions were to be used in engineering designs. Famed hydrologist Robert Horton made basic discoveries regarding the components of the hydrologic cycle, and unraveled the complexities of climate–hydrology conditions of the Great Lakes in the 1920s (Horton, 1927). Early key studies of effects of climate on human health and behavior included those of C.F. Brooks (1925).

A national priority of the nineteenth century was to enhance agricultural production, and this led to the establishment of the US Weather Bureau in 1888, as part of the Department of

Agriculture (Whitnah, 1961). Establishment of experimental farms around the nation ultimately produced the data needed to make definitive studies of how various components of the climate affected each crop, as well as livestock. Wallace (1920) made strides by developing the first climate–crop yield models. Thornthwaite (1937) pioneered modeling of the hydrologic system so as to derive measures of evapotranspiration and soil moisture and their effects on both plants and crops.

By 1940 many of the fundamental relationships between climate conditions and other physical systems had been sufficiently delineated to allow highly effective designs of structures, selections of regionally appropriate crop varieties, and wise management of water resource systems in the varying climatic zones of the nation (Landsberg, 1946). The pressures of World War II for climate data and expertise brought forth a new dimension to applied climatology (Jacobs, 1947). For example, studies focused on severe weather conditions such as tornadoes and hail, and their effects on crops, property, and human life (Flora, 1953). A flood of publications within the realm of applied climatology appeared during the 1940s and 1950s (Landsberg and Jacobs, 1951). This explosion of research and information generation was also tied to the creation of computers during World War II and use of punch cards as a means of digitizing historical weather data. By 1948 a national center housing all historical climate data had been established. The National Climatic Data Center (NCDC) staff began generating a myriad of publications giving potential users access to information never before widely available (Changnon, 1995).

Ever-improving computers and digitized data allowed major achievements in modeling of climate effects such as hydrologic models that related various climatic variables to streamflow behavior (Linsley et al., 1958). Heavy rainfall design information, critical to planning and designs to manage flooding, was generated (Hershfield, 1961; Huff, 1986). A highly useful national drought index was devised (Palmer, 1965), and sophisticated climate–crop yield models appeared, allowing accurate predictions of yield outcomes well before harvest (Thompson, 1964). Other studies addressed another important sector of applied climatology – the economic and environmental impacts of all forms of climate (Maunder, 1970; McQuigg, 1974). Major advances in statistical techniques for applied climate analysis occurred (Conrad and Pollack, 1944; Court, 1949). An area of applied climatology that has evolved over the past 100 years concerns urban climates and other human-induced changes to the landscape leading to altered local and regional climates (Landsberg, 1956; Changnon, 1973; Oke, 1973). The impacts of these changes on the physical world and socioeconomic sectors have also been assessed (Changnon, 1984; Hare, 1985) with climate guidance to urban planners (Changnon, 1979). Finally, textbooks that addressed applied climatology appeared (Oliver, 1973, 1981; Thompson and Perry, 1997), serving to enhance training and attention to the field.

By 1970 applied climatology had moved to a new level of recognition and ever-higher value to the user community. Atmospheric scientists within the field turned their attention to improvements to: weather-sensing instruments, data quality and its archival, access of data and climate information, and generation of user-friendly climate products.

The golden age

The era since about 1970 has seen a series of scientific and technological changes that have vastly enhanced the field of

applied climatology. Coupled with these advances have been national and global economic conditions that acted to increase the demand for climate products. The golden age of applied climatology had begun.

The agricultural economy became global, and with this expansion came huge economic pressures. American firms searched for every activity that would give them an advantage. One of these was use of climate predictions. Firms that had previously ignored use of uncertain climate outlooks now shifted and became users. Other business sectors also became global, and the net effect was more use of climate data and information.

Another factor enhancing wide interest and use of climate information comprised major global climate anomalies of the 1970s and early 1980s and their severe impacts (Kates, 1980; Panel, 1981). This included the devastating Sahel drought, the record cold winters of 1976–1980 in the US, and the droughts of 1980, 1983, and 1988. Climate, and the problems it created, including escalation of federal relief payment for weather–climate disasters, attracted the attention of the federal government, and Congress passed the National Climate Program Act in 1978. This program fostered new climate institutions, enhanced applied research, and funded new data collection–transmission systems. However, at the federal level the program became overshadowed in the late 1980s by the rapidly expanding national climate change endeavors. Concerns over a climate change related to global warming became the new thrust enveloping most of the atmospheric sciences. An era of numerous weather extremes and large global losses during the 1990s has led applied climatologists to pursue climatological assessments (Changnon, 1999a,b). Some have assessed whether these increasing losses were due to the start of a climate change due to global warming, to increasing societal vulnerability to climate (Changnon et al., 2000), and/or to inadequate government policies (Changnon and Easterling, 2000). Recent major urban droughts in the US initiated new societal problems, indicating that the future of water supplies for major urban areas looks questionable (Changnon, 2000).

Development during the 1960s and 1970s of reasonably inexpensive computer systems capable of handling large volumes of climate data was another key factor in the recent growth of applied climatology. The systems allowed continual updates of information, and the development and delivery of near real-time climate information, coupled with wide use of PCs. Everyone could access a wealth of climate information quickly and at low cost (Kunkel et al., 1990). This enhanced use of climate information has helped create greater awareness of the value of applied climatology.

The above-mentioned fast access was facilitated by another critical step forward – the development of inexpensive means to quickly collect data, and to transmit climate data and information. This included satellites and the Internet. These allowed real-time transmittal of data and quick access to it, a huge step forward (Changnon and Kunkel, 1999). Closely coupled with this advance were the establishment of new climate service/research centers, which had been fostered by the National Climate Program (Changnon et al., 1990), as well as the growth of private sector providers of climate information (Vogelstein, 1998). The development of these new institutions with expertise and systems to serve the needs of users of climate data and information led to other advances in applied climatology.

Interdisciplinary research of climatologists and other physical and social scientists increased, and this led to a new level of

sophisticated climate-effect models (crops, water, transportation, etc.). Further, these models, when fed with real-time data, allowed their use in operational settings. Thus, near real-time estimates of current and projected climate effects were generated for decision makers. These activities moved forward in the right arenas based on assessments of user needs that began during the 1970s, a form of market analysis for climate products (Changnon et al., 1988; Changnon, 1992).

Since the 1970s the nation and world have seen an increase in society's sensitivity to climate conditions and especially extremes. Population growth, coupled with demographic changes and wealth, have created greater vulnerability and hence higher costs from climate anomalies. These impacts in the US have further promoted the growth in the use of climate data and information to more effectively react, manage, and compete (Stern and Easterling, 1999). Climate information has taken on greater value. One reflection of this in the business world has been the development and use of "weather derivatives" during the 1990s, a means of insuring against climatological risk (Zeng, 2000). One company offers coverage for a fixed price against a climate outcome, say a cold winter, that a utility fears economically. If the cold winter occurs, the coverage firm pays the other for its losses, but if the cold winter does not occur, the coverage firm retains the original payment. Such risks are assessed using climate data.

One of the applied climate products long sought by weather-sensitive entities has been accurate long-term climate predictions. The past 15 years have seen major advances in climate prediction quality, related to a greater understanding of the climate system such as the effects of El Niño on the nation's climate (Kousky and Bell, 2000). Government predictions have improved, both in accuracy and formats needed by users (Changnon et al., 1995). Private firms now work more closely with firms to interpret predictions to meet specific corporate needs.

As stated, applied climatology has moved into its golden age in service to society. In a recent book Thompson and Perry (1997) provide a broad, all-encompassing view of the world of applied climatology. They and 27 other applied climatologists prepared chapters on wide-ranging topics such as climate effects on tourism, glaciers, fisheries, and air pollution. Hobbs (1997), in a sweeping assessment of applied climatology, points to the growing awareness of applied climatology and increasing use of climate information.

However, not all things are occurring at an optimum level. Some problems still face the field. Ironically, teaching of applied climatology is too limited and often not done at many colleges and universities. To be effective, quality instruction in applied climatology requires interdisciplinary training and experience (Changnon, 1995).

A second concern relates to the adequacy of weather instrumentation and data collection. Since the structure of weather data collection endeavors in the US is still dominated by the needs of forecasters, there are continuing problems with sustaining adequate spatial sampling of climate conditions and with the use of instruments that allow continuity with historical data (NRC, 1998). For example, the automated surface observation system installed during the 1990s for measuring many weather conditions at nation's first-order weather stations has led to alterations in the quality of certain data.

As noted above, the use of climate data and information has grown rapidly in the past 30 years, but sampling reveals many potential users are still not served and often unaware of

applications (Changnon and Changnon, 2003). An outreach effort by government agencies involved in climate services and by private sector partners is needed to educate and demonstrate how to use climate information and the potential values apt to be realized from usage to manage climate risks.

There is no systematic collection of data on the impacts of climate extremes, and a national effort to begin such data collection is needed (NRC, 1999). Uncertainty over impacts under a changing future climate due to global warming is a current dilemma and one that will continue. Hare (1985) first noted the need to consider impacts of future climate change. Some have predicted future climate conditions exceed extremes sampled in the past 100 years, making use of existing climate-impact regression models as predictors of future impacts invalid. The implications of future climate changes remain a major challenge for applied climatologists. This is reflected in a recent book about applied climatology which includes four chapters addressing potential impacts of future climate change (Thompson and Perry, 1997).

Resolution of these four issues – better training, stabilization of weather measurements, better information on climate impacts, and effects of global warming induced climate change – needs to be accomplished to realize the full potential of applied climatology. Regardless, applied climatology is the oldest atmospheric sciences activity in service to society, and its most successful.

ARCHEOCLIMATOLOGY

The term archeoclimatology was coined by Reid A. and Robert U. Bryson, about 1990, to designate a particular approach to the estimation of past climates on the time and spatial scales appropriate for the use of archeologists (Bryson and Bryson, 1994). Because cultures change on less than the millennial scale, and because people live in relatively restricted areas, whatever data or model is used must be nearly site-specific and of high time-resolution. Ideally the method should be rather economical, since archaeology tends to be funded at a low level.

This subspecialty of paleoclimatology is largely concerned with bringing together various sources of estimation of past climates, models and proxy estimates from field studies, to provide the most consistent estimates of the past climatic environment at particular places and times. The study of proxy records has been well advanced by various other Earth and biological sciences, so archeoclimatology thus far has been concerned with climatic models designed with this particular end in sight rather than on studies of the atmosphere itself.

The definition of climate

The way a segment of the world is studied depends on how the topic is defined relative to the expertise of the scientist and the historical precedents of the scientist's discipline as much as on rational analysis. This may lead to definitions and biases that affect the study of the topic.

The usual definition of climate according to meteorologists is approximately that given in the *Glossary of Meteorology* (Huschke, 1959). Here climate is defined by reference to C.S. Durst, a meteorologist, as "The synthesis of the weather". Huschke then goes on: "More rigorously, the climate of a specified area is represented by the statistical collective of its

weather conditions during a specified interval of time (usually several decades)."

Geographers tend to use a similar definition, witness Trewartha's "Climate...refers to a more enduring regime of the atmosphere; it is an abstract concept. It represents a composite of the day-to-day weather conditions, and of the atmospheric elements, within a specified area over a long period of time" (Trewartha and Horn, 1980). (How one can use facts, figures and equations to study an "abstract concept" is more than a little puzzling.) Lamb uses a similar definition of climate: "Climate is the sum total of the weather experienced at a place in the course of the year and over the years" (Lamb, 1972).

Viewing climate as essentially a summation of the weather has profound implications for the development of a body of climatological theory. Indeed, the preceding sentence might evoke disagreement from many atmospheric scientists for the common definition of climate indicates that there is no distinct body of theory separate from that of the weather, except perhaps statistical theory. With this viewpoint one might disagree, based on a quite different view of the relation of climate and weather.

The relation of climate and weather

An experienced meteorologist can identify the atmospheric circulation pattern on a weather map immediately as to whether it represents a summer pattern or a winter pattern. Usually the identification of the season can be even closer. The reason the array of weather patterns characteristic of a season differs from the array of another season is that the climate differs from season to season. This statement, of course, does not make sense if the climate is the summation of the weather. It does make sense if the thermodynamic status of the Earth-atmosphere-hydrosphere-cryosphere system *determines* the array of possible (and necessary) weather patterns. This status, which changes with time and season, *along with* the associated weather patterns, constitutes the climate.

The basis of the present discussion, and the research of which it is an elaboration, is that the climate is a consequence of external controls on the atmosphere-hydrosphere-cryosphere system. These "boundary conditions" force the state of the climate system, which in turn produces and requires sets of weather complexes, which differ as the climate differs from one time to another. For example, the climatic state thought of as summer has a different array of associated weather patterns than does the climatic state called winter (Bryson, 1997).

Modeling the climate on this basis utilizes what is here called a macrophysical approach. Relationships of large-scale nature are used, such as the Rossby long-wave equations, the thermal wind relationship, or the Z-criterion derived from the work of Smagorinsky (1963). The model on which archeoclimatology is based required first a model of global glacial volume, from which the glaciated area could be calculated and the ice albedo effect estimated (Bryson and Goodman, 1986). A hemispheric temperature model was then possible using the so-called Milankovitch-type variations in solar irradiance as modulated by volcanic aerosols (Bryson, 1988). This section of the overall model is essentially a "heat budget model" but with improved treatment of the volcanic modulation.

Going from hemispheric or global models to regional models requires that some broad-scale relationships be used. For example, one knows that the westerlies must become stronger with height up to about 10 km because the Earth is colder at the poles than at the equator, and the rate of increase is proportional

to the magnitude of the south–north temperature gradient. Since equatorial temperatures change relatively little even from glacial to non-glacial times, the average hemispheric temperature and the temperature gradient must both depend primarily on high-latitude temperatures.

Assuming that the zonal component of the wind at 500 mb is proportional to the meridional temperature gradient, this concept was applied to North Africa, using the “Z-criterion” to calculate the latitude of the subtropical anticyclone and the latitude of the jet axis at 500 mb (Bryson, 1992). Empirical values of the appropriate gradients were derived from the inter-monthly variation, including the relation between the latitude of the anticyclone and the latitude of the intertropical convergence (ITC). Ilesanmi’s model (1971) relating position of the ITC to rainfall south of it could then be used to estimate the rainfall in the Sahel at two- or five-century intervals for the late Pleistocene and Holocene. The match with palaeolimnological and archaeological field data was excellent. Ilesanmi’s model is an example of the kind of synoptic climatology that constitutes the final calculation of the local climatic effect from the large-scale features of the atmospheric circulation.

The hierarchical steps and the fundamental assumptions

Step 1: Model glacier volume and area

Examination of the geological evidence tells us that the volume of glacier changes very slightly in the southern hemisphere from glacial to interglacial, and that most of the Pleistocene northern hemisphere glacier was in North America, with a large part of the rest being in northwestern Europe.

Synoptic climatology tells us that the snowiest winters in the major North American glacier accumulation areas are mild winters. Logic and experience tell us that snow melts slower in a cool, cloudy wastage season.

Assumption 1

Assume that the seasonal temperature of the hemisphere is related to the amount of radiation received and absorbed near the surface by the hemisphere in that season. (And secondarily, that the winter temperatures in the ice accumulation area of North America are essentially always well below freezing, even as now.)

It follows that accumulation rate minus wastage rate will be inversely related to the radiation seasonality of the hemisphere.

It also follows that the difference of these two rates is also a rate, so that this net accumulation rate must be integrated to simulate the total glacier volume at any particular time (arbitrary units).

The northern hemisphere irradiance seasonality may be computed using the “Milankovitch” periodicities in the usual Fourier series form, which may be readily integrated. This series contains no high-frequency terms (Bryson and Goodman, 1986).

Assumption 2

Assume that volcanic aerosol is the major source of modulation of the incoming radiation in ancient times.

Volcanic eruption chronologies may be extended back to about 30 000 years, however, using radiocarbon-dated eruptions. Using historically observed eruptions, Goodman was able to show that

most of the variance of the observed aerosol loading can be explained by the volcanic record (Goodman, 1984).

Using the radiocarbon-dated volcanic eruption chronology it is possible to construct a proxy record of volcanic aerosol that extends back at least 30 000 years. This may be used to modulate the radiation for the integrated Milankovitch-based glacier volume modeling, and thus introduce higher-frequency terms into the glacier model.

The result of this modulation and the introduction of higher-frequency terms is a simulation in arbitrary units of glacial volume that follows the known geological record quite well, including such short-term features as the “Younger Dryas”, and Neo-Glaciation. The arbitrary units may be readily calibrated into standard volume units by scaling (Bryson, 1988).

Step 2: Model hemispheric seasonal temperatures

Assumption 1

Assume that the largest source of variation in hemispheric albedo is due to variation in ice and snow cover.

Estimates of glacial volume from step 1 may be converted to glaciated area using the relationship developed by Moran and Bryson for typical glacial profiles (Moran and Bryson, 1969).

Measurements of typical albedos clearly indicate the dominance of ice as the source of variation in time for the total range of albedo for the other surfaces is less than even the range within various forms of ice cover (Kung et al., 1964).

Assumption 2

Assume equivalent opaque cloud cover. With the definition of equivalent opaque cloud cover developed by Dittberner and Bryson, the cloud amount drops out of the heat budget equations *but only for climatic scales* (Bryson and Dittberner, 1976).

Assumption 3

Assume that, throughout most of geological history, carbon dioxide and water vapor content of the atmosphere have been dependent variables, dependent on the temperature, and as a first approximation linearly so (Bryson, 1988).

Step 3: Model monthly hemispheric temperature, evaporation, and net radiation

Using the Lettau climatonomic method of obtaining a mutually consistent set of monthly surface heat budget components monthly temperatures may be obtained (Lettau and Lettau, 1975; Lettau, 1977, 1984).

Step 4: Calculate the position of the “centers of action” (large-scale features such as the subtropical anticyclones and the jet stream)

Assumption 1

Assume that the latitude of dynamic instability of the westerlies as calculated by Smagorinsky is a valid estimate of the latitude of the subtropical anticyclones. That this is valid was first suggested by Flohn, who used the term “Z-criterion”. Tests with modern data give abundant evidence that the assumption is valid even regionally, and gives very close estimates (Flohn, 1965; Smagorinsky, 1963).

The Z-criterion calculation requires only the large-scale meridional and vertical temperature gradients.

Assumption 2

Assume that, since equatorial temperatures hardly vary during the course of the year and in time, that the meridional temperature gradient is a function of the mean hemispheric temperature and that the vertical temperature gradient is a function of season. These relationships may be determined empirically using modern data.

Assumption 3

Assume that the latitude of the jet stream is closely related to the outer edge of the westerlies as calculated with the Z-criterion (Bryson, 1992).

It has been shown that the latitude of the intertropical convergence is closely related to the latitude of the related subtropical high(s) (Bryson, 1973).

At this point one may have calculated the monthly latitude of the subtropical anticyclones, latitude of the jet stream and position of the intertropical convergence for each sector of the hemisphere for as far into the past as the volcanic aerosol record and Milankovitch calculations allow, and at intervals of centuries dictated by the quality of the volcanic record.

Step 5: Calculate local climate history from output of the above steps

At this stage, knowing the mean locations of the major anticyclones, mean latitude of the jet stream, and mean latitude of the intertropical convergence, sector by sector and month by month, one may use the well-established techniques of synoptic climatology to calculate the mean monthly local values of temperature, precipitation, rainfall frequency, potential evapotranspiration, etc. at one's station of interest.

For example, one might want to calculate the past precipitation amount for a location in the midwestern United States, such as Madison, Wisconsin. It is well known that tropical air from the North Atlantic cyclone brings warm-season rain when it is far north, but this is not a linear relationship. It is also known that the cyclonic storms associated with the storm track represented by the jet stream position bring the maximum rains of spring and early fall, and lesser amounts in winter. Other times, especially in winter, air from the Pacific anticyclone streams across the country, usually suppressing the rains in Madison. The problem then is to say how the mean monthly precipitation at Madison responds to the position of these circulation features. The synoptic climatology approach to this problem is empirical. By examination of the relationship of the precipitation at Madison to these circulation elements within the instrumental period, one can establish a quantitative relationship, which is

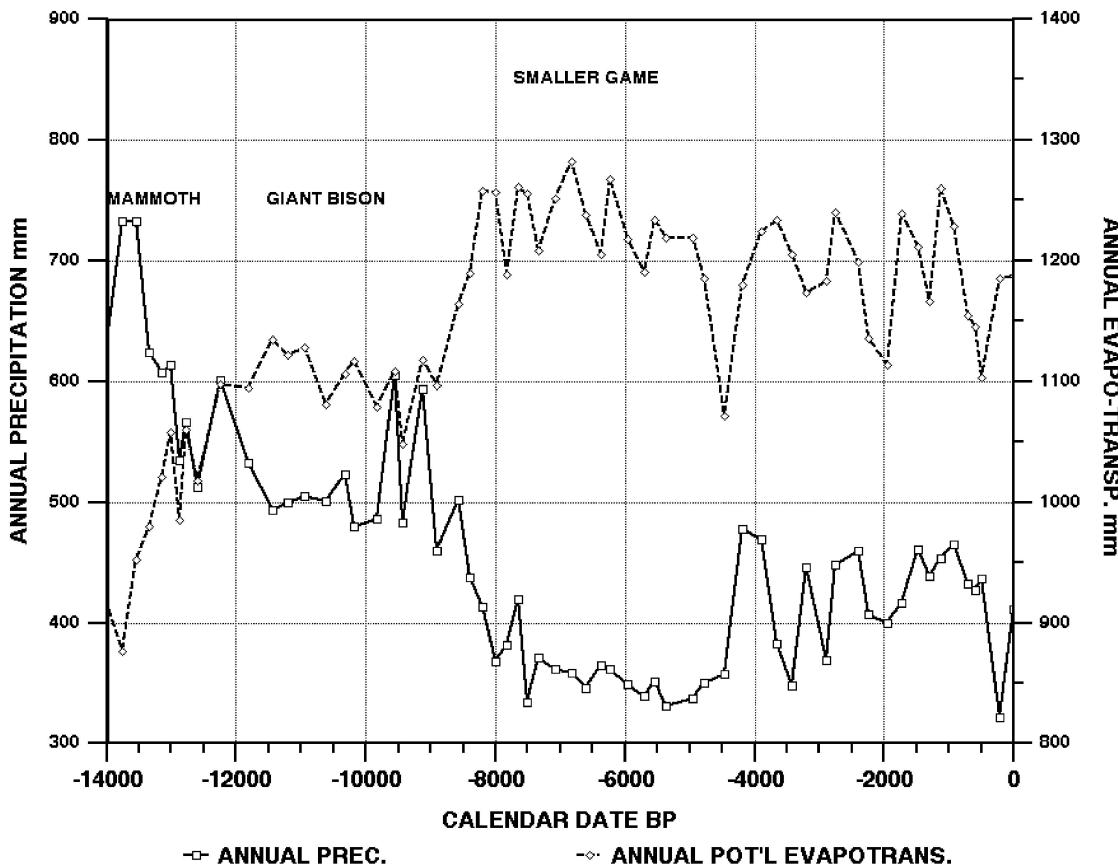

Figure A35 Modeled water supply history for Portales, New Mexico.

assumed to apply as far back as the general geographic pattern of waters and topography is relatively constant.

One virtue of the synoptic climatology approach is that the local and regional topography, etc. is implicitly included in the precipitation, temperature, etc. values that have been observed. For example, the data from Milwaukee, 75 miles east of Madison, differ from the data for Madison, in part because Milwaukee is on the shore of a great lake, and thus the relationship of the precipitation there to the large-scale circulation features would contain, implicitly, the effect of its location.

We can then say that the archeoclimatic model for North American precipitation at a particular place consists of the latitudes of the oceanic anticyclones, the jet stream and the intertropical convergence as inputs, and the calibrated response of the local mean values of the precipitation at that place as the output. Since the circulation features have been calculated far into the past, we can assume that the calibration was the same then, and calculate the local past climate. As a first approximation non-linear regression is used for calibration. Lacking a long series of observed values of all the needed data, the annual march of monthly positions of the circulation elements and of the precipitation are used, and in over 2000 trial cases seems to be an adequate first approximation.

The position of the intertropical convergence is used, even for northern locations, because it is related to the insertion of very moist air into the westerlies, sometimes in tropical cyclones, and hence is related to the precipitation even at higher latitudes.

On the other hand, the positions of the polar anticyclones are omitted because they are more dependent on topography and errors of pressure reduction to sea level than they are to dynamics

of the atmosphere, and the latitude of the jet stream gives the outer limit of polar air.

Example 1: North America

Eastern New Mexico has been of particular interest to archeologists because it is a well-known locale for early big-game hunters in North America. These included hunters of mammoth and giant bison, the Clovis and Folsom cultures. Clovis, New Mexico, is the type locality for the distinctive projectile point of the Clovis people, a form found over a vast area of North America. The archeoclimatic model of the past climate of nearby Portales, NM yielded the next two graphs (Figures A35 and A36) of the precipitation, potential evapotranspiration and temperature history of the locale.

The graph of precipitation shows the high precipitation and lower evapotranspiration of latest Pleistocene time necessary to produce the rather lush vegetation required to support mammoths. This situation changes rapidly after the "Younger Dryas" peak precipitation to a quite different situation by 10 500 years before the present, and the typical big game changed to bison. With the advent of the Middle Holocene, after 8000 radiocarbon years ago, the environment only supports smaller game, and indigenous cultures no longer hunt big game. This pattern seems to agree with the field evidence.

Example 2: The Mediterranean

In 1965 Rhys Carpenter, a distinguished scholar of ancient Greece, proposed that the famous and very important Kingdom based at Mycenae, in the Peloponnesus, had

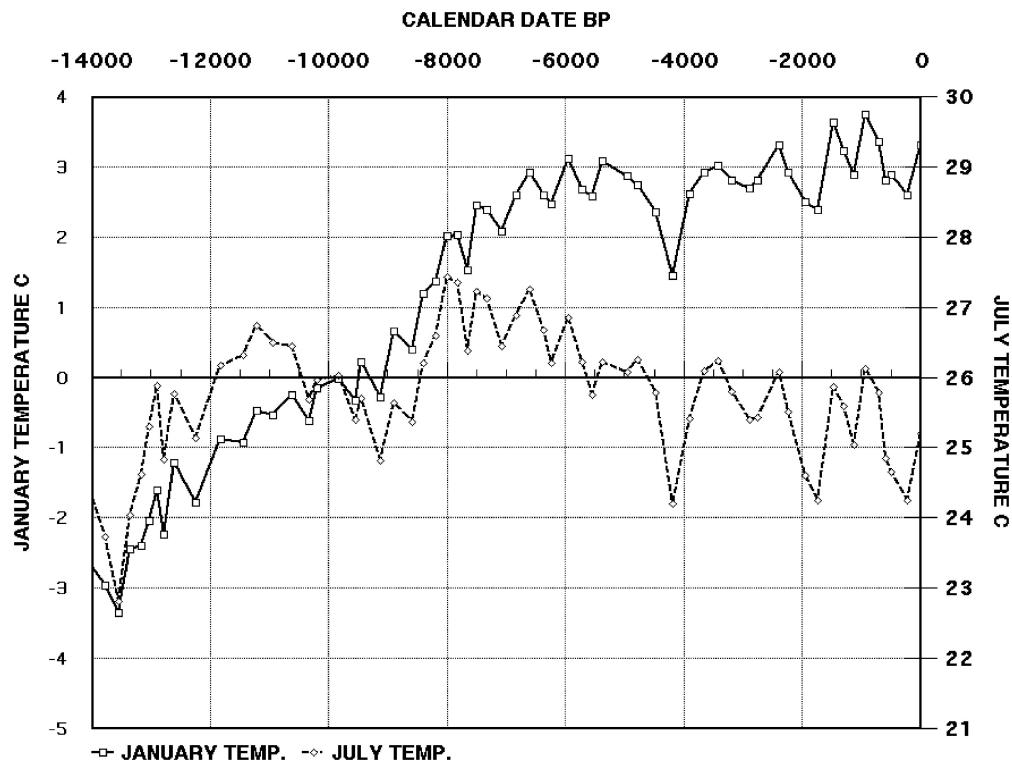

Figure A36 Modeled temperature history for Portales, New Mexico.

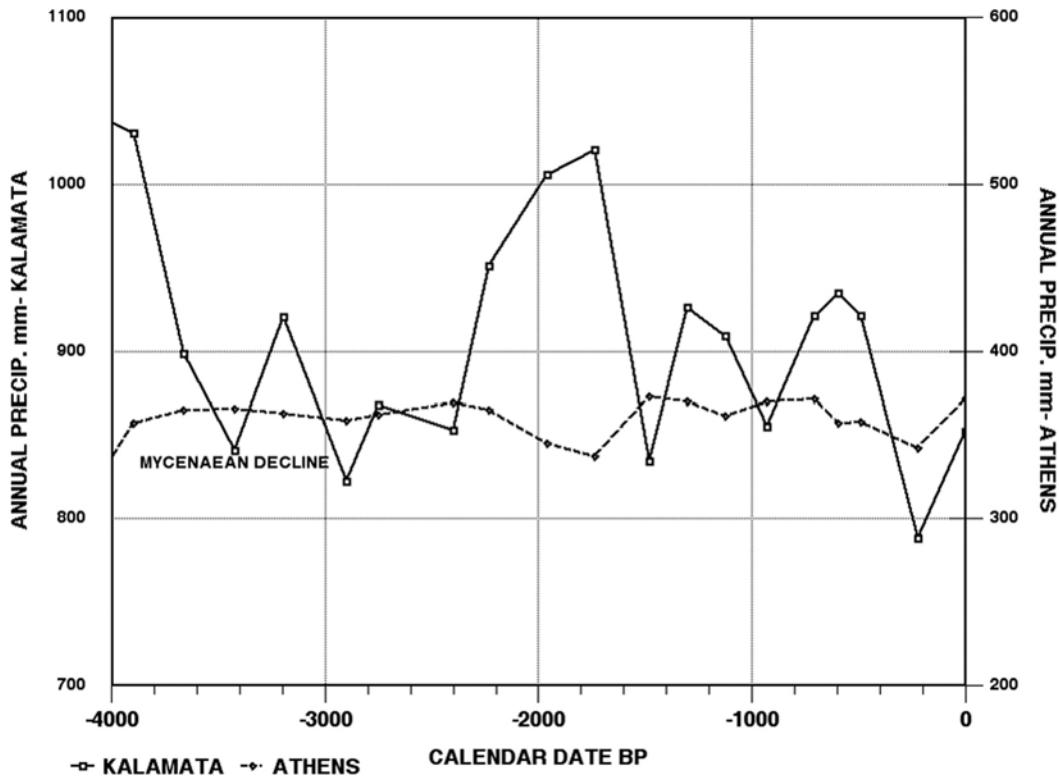

Figure A37 Modeled precipitation history for Peloponnesus (Kalamata) and Attica (Athens).

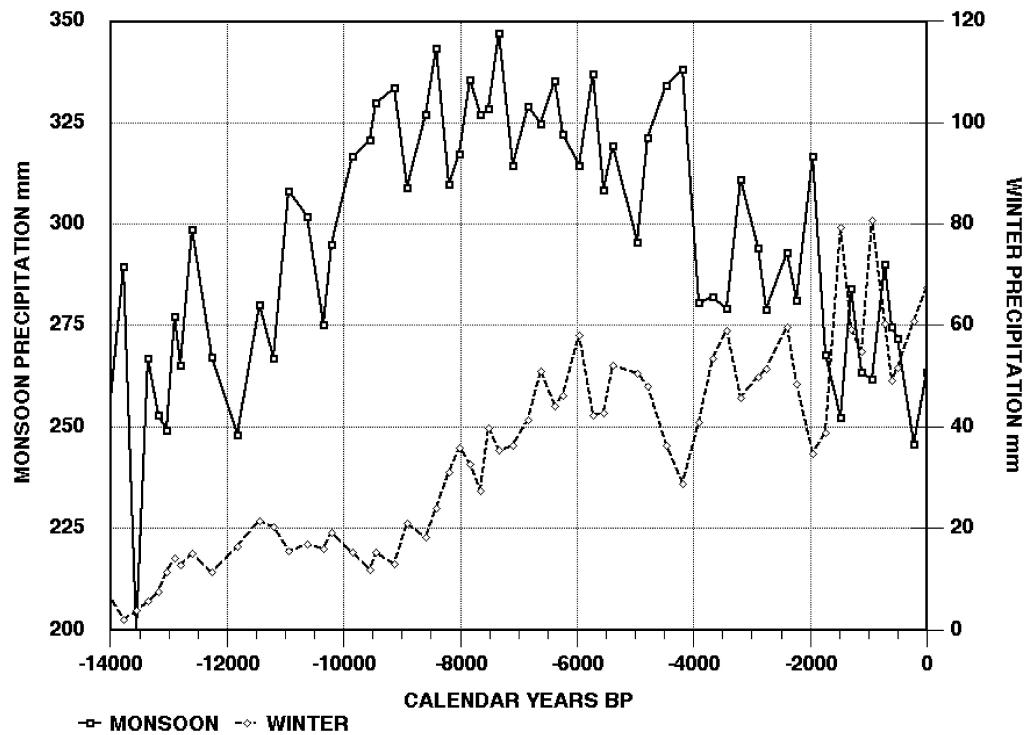

Figure A38 Modeled precipitation history for Harappa.

declined and had been abandoned due to a prolonged drought (1966). He proposed that the drought had been localized to regions by the terrain so that, while it affected the Peloponnesus, it did not affect the Attic Plain (Athens area). Using the archeoclimatic model we may compare the modeled history of these two neighboring areas to see whether such a pattern can be detected. Figure A37 shows the modeled history of precipitation for these two places.

This figure also shows the modeled precipitation for Kalamata in the southern Peloponnesus and for Athens on the Attic plain. Mycenae itself was nearer to Athens than Kalamata.

Some studies showed that Carpenter's drought hypothesis represented a possible, and even probable, pattern (Bryson et al., 1974). Archeoclimatic modeling also supports the hypothesis, and suggests that when the Peloponnesus became dry ca 1200 BCE, the Attic Plain did indeed not have a corresponding drought, even though the actual precipitation was usually less.

Example 3: Asia

In northwestern India and Pakistan, in an area now desert or semiarid, the extensive agriculture-based Indus culture existed between about 5500 and 3500 radiocarbon years ago. Studies of pollen in the northwestern Indian desert suggested that the termination of this culture was associated with a decrease in rainfall (Singh et al., 1974; Bryson and Swain, 1981). Figure A38, which shows the rainfall near Harappa, a major city of the Indus culture in the Indus valley, also suggests that there was a rapid change toward lower rainfall about 3500 years ago.

Cultural Climatology

ARCHITECTURE AND CLIMATE

There are dramatic new building forms emerging around the world that have been generated by a growing understanding of climate and its importance to sustainability. From England to the US, from Malaysia to Malta, emerging architecture demonstrates the power of sun, wind, light, moisture and diurnal swing to generate innovative building forms, material detailing and systems integration for sustainability.

In an era of rediscovery, a growing number of architects and engineers begin their design efforts with regional climate graphics, study indigenous responses to climate, use climate-driven computer simulation tools for design development and specifications, and celebrate climatic variability through unique architectural results. These professionals will increasingly need accessible and consistent climate data worldwide, field testing of regional performance of climate-responsive buildings, regional design guidelines, and design simulation and modeling tools. The opportunities for improving environmental quality and reducing environmental costs could transform land-use and community development, building design and renovation, as well as speed the introduction of new materials and technologies – celebrating regional climates and sustainability in the pursuit of environmental security.

Climate change and architecture

In the face of climate change, surprisingly few global leaders have identified buildings and land-use as critical factors. Yet increasing levels of floods, hurricanes, quakes, and natural disasters are most clearly manifested in loss of property. Similarly, pollution, inversions, and warming are driven by combined forces of climate and building decision making. Even growing concerns about chemical and biological attack, and strategies for energy security, will only be addressed by a better understanding of climate and the built environment. International emphasis on avoiding environmental failure and improving environmental security must be fully tied to a rich understanding of regional climates, to ensure individual comfort and health, organizational effectiveness, and environmental sustainability.

Interface between climate and building performance

Total building performance

Today's design challenge is to "balance the high tech and the natural tech" to simultaneously ensure all building performance mandates – thermal comfort, acoustic comfort, visual comfort, air quality, spatial quality, and building integrity – for individual, organizational and environmental effectiveness.

To comprehend the breadth of this challenge it is important to begin with a complete definition of the building performance to be met assiduously by building policy makers, programmers, architects, engineers, contractors, owners, and managers.

First, there has been a fundamental mandate over the centuries for building-enclosure integrity, that is, protection from environmental degradation through moisture, temperature, air movement, radiation, chemical and biological attack, and environmental disasters (such as fires, floods, and earthquakes). Established by concerns for health, safety, welfare, resource management (energy, money), and image, the requirements for building integrity can be stated as limits of acceptable degradation and debilitation.

Second, there are a series of mandates relating to interior occupancy requirements (human, animal, plant, artifact, machine) and the elemental parameters of comfort, that is, thermal comfort, acoustic comfort, visual comfort, air quality, and functional comfort. Table A20 lists performance mandates of primary concern to the building industry, with admittedly lopsided emphasis given to building integrity (protection from degradation, debilitation, and devastation) reflecting the industry's focus on building failures in this area.

Limits of acceptability

Each building performance mandate has a "comfort zone" that establishes the limits of acceptability for the type of occupancy concerned. These limits, often translated into standards and codes, budgets and guidelines, are established by the physiological, psychological, sociological, and economic requirements of a nation and its citizenry. The limits must be established in each country for the range of building functions and the range of occupancy types (human, artifact, plant, animal).

In regard to human occupancy, physiological requirements aim to ensure the health and safety of the building occupants, sheltering basic bodily functions from wear or destruction over time, against such conditions as fire, building collapse, poisonous

fumes, high and low temperatures, and poor light. Psychological requirements aim to support individual mental health through appropriate provisions for privacy, interaction, access to the natural environment, clarity, status, change, and so forth. Sociological requirements (also referred to as sociocultural requirements) aim to support the effectiveness of the organization and the well-being of the community, relating the needs of the individual to those of the collective, including rising expectations for environmental quality. Finally, economic requirements

aim to allocate resources – energy, water, land, air, materials – in the most efficient manner in the overall goal to serve user needs.

Although the distinction between climate and weather data is of major significance in the study of meteorology, the needs of the building industry span the range of *descriptive* climate data and *predictive* forecasted data without lucid differentiation. Consequently, both climate and weather data will be discussed under the broader term *climate*, with descriptive data referring to the long-term climate conditions and predictive or forecasted data referring to weather conditions.

Climate and thermal comfort

The climate database requirements for ensuring thermal comfort in buildings continues to be of great importance. Descriptive summaries of average temperatures are needed to estimate annual heat loss and heat gain, in order to establish building energy budgets. Record and extreme temperature conditions must be known to predict peak heat losses and gains, and to determine the size of mechanical conditioning equipment required in a given building. Forecasts of daily temperature and temperature swings must be given for setting mechanical system operating schedules and relieving day-night and seasonal conditioning imbalances. In addition, records of coincident wet-bulb temperatures or humidity conditions must be incorporated into air-conditioning system design, while predictive data will determine the level of humidification or desiccation needed. Annual, monthly, and typical-day solar data aids in estimating both solar heating contribution in winter and solar overheating potential in summer, with design responses to lower annual operating budgets and to allow the use of smaller mechanical conditioning equipment. Predictive solar data allow building operators to anticipate building thermal imbalances and to maximize the use of free heat. Finally, descriptive summaries of wind direction and speed, particularly coincident with temperature and humidity conditions, enable designers to prevent serious winter infiltration through vulnerable building components and to maximize the potential for natural ventilation.

The widespread shift to deeper section buildings that began in the mid-1970s, with less perimeter and more core, a move intended to reduce “climate-driven” conditioning loads, has instead dramatically compromised natural conditioning of buildings. Today, many commercial buildings have become so massive in plan and/or maintain such significant internal loads (from lights, equipment, and people) that energy costs include both high cooling loads in the core, as well as climate-related cooling and heating loads at the perimeter. The EU-funded PROBE studies identified 40–60% higher conditioning loads in newer commercial buildings than traditional, thinner buildings with identical functions (Bordass and Leaman, 2001).

Even in buildings that cannot take advantage of passive conditioning (daylighting, natural ventilation, solar heating, time lag cooling, etc.) attention to climate conditions is still critical for building energy conservation (Figure A39). Heating and cooling equipment size and consequent capital costs are set by peak heat loss and gain conditions, both of which are established at the perimeter. Annual heating and cooling costs (and associated personnel costs) are often significantly escalated by heating and cooling system “battles,” resulting from the attempt to respond to daily shifts in temperature, sunshine, and wind infiltration in perimeter spaces. Energy reliability and utility rates are often set by peak demand, a condition that results from

core internal loads being aggravated by poor climatic design at the perimeter (solar overheated roofs and facades in summer, cold air infiltration in winter). Finally, significant energy savings can be generated by conditioning buildings with fresh outside air through the use of the economizer cycle (passive conditioning with some energy cost). In the future we will need to shift away from massive, core-dominated buildings in order to provide thermal comfort through strategic combinations of passive conditioning and energy conservation, set climate by climate, as well as to reinstate the physiological and psychological “healthiness” of access to the natural environment.

Climate and lighting comfort

A significant descriptive and predictive database on sky cover conditions, daylight hours, and the quantity of direct, diffuse, and reflected radiation is needed for effective lighting and day-lighting design. Artificial lighting effectiveness depends on absence of glare (caused most frequently by direct and diffuse sunshine), presence of adequate contrast to prevent eyestrain, and a controlled mix of wavelengths to provide effective color rendition. On the other hand, individual productivity, energy conservation, and a measurable amount of visual delight is achieved with effective daylighting. In the US more than 10% of all national energy use is for electric lighting in buildings, and most of that during the daytime (DOE/EIA 2002). A predominant number of new sustainable buildings, such as those achieving LEEDJ certification (US Green Building Council), clearly demonstrate that daylight can cost-effectively provide both ambient lighting for general way-finding and task lighting for the range of visual tasks in buildings. The use of daylight can offer major energy savings as well as improved health, productivity, and morale. Daylight, and all the climatic variables associated with daylight, also have the unique ability to provide “kinetic feedback” that gives the user a critical sense of time, place, and dynamic excitement (contributing to the emerging field of biophilia).

Climate and air quality

Wind speed and direction, relative humidity, and atmospheric composition are instrumental in maintaining or improving air quality within and around buildings. Interior pollution migration in large buildings is determined by variation in building pressurization and temperatures, which, in turn, depend on wind direction, wind speed, temperature differentials and possible solar-induced air flows. Controlling indoor pollution migration will also be critical to reducing chemical and biological risk. Anticipating pollution migration from neighboring sites also depends on the climate database, while avoiding pollution buildup in cities, commonly caused by temperature inversions, depends on access to a combination of wind, temperature, and atmospheric composition data sets. Moisture conditions also play a major role in building air quality. Requirements for humidification and dehumidification, linked to absolute and relative humidity conditions, remain one of the major conditioning challenges in building construction and operation. Water management, from driving rain and melting snow, and moisture management from infiltration and condensation on cold surfaces, is critical to avoiding long-term air quality risks from mold and mildew – demanding knowledge of climate data, weather events, and the interpretive power of building physics.

Figure A39 Atop a 100-year-old building, the dynamic enclosure of the Intelligent Workplace™ at Carnegie Mellon University uses sunlight and natural ventilation to achieve an 80% reduction in heating, cooling and lighting loads of typical office buildings.

Figure A40 The glazed superstructure over the office space of Moncenis in Essen moderates the northern German climate to be more like Tuscany.

Climate and spatial comfort

One of the central activities of urban planners and building designers – the layout of spaces and functions for accessibility, way-finding, and effective use – also depends on climate data if the best use of the building site is to be ensured. Entering and exiting a building comfortably and safely depends on the designer's and operator's comprehension of local wind conditions, combined with occurrences of snow, rain, and ice. Servicing the building with water, electricity, and other transported goods also depends on reliable data of the averages and extremes of temperature, snow, ice, rain, and wind.

Moreover, planning for effective use of outdoor spaces and indoor–outdoor movement during comfortable periods, requires a full understanding of coincident climate conditions. In the design of outdoor spaces at least three microclimates can be created by the building itself: outdoor comfort without sun or wind; outdoor comfort with sun but without wind (extending the comfortable period into early spring and late fall); and outdoor comfort with wind but without sun (extending the comfortable period into the heat of the summer). In the past 10 years, architects and engineers have pursued a new generation of atrium spaces with passively moderated climates to support significant programmatic needs. Double envelopes have been developed for a number of landmark buildings in Europe, with modulated climate zones in the 1–5 meters between the inside and outside glazing. In one of the most dramatic projects the building's programmed spaces are laid out in a village configuration within a highly dynamic, climate-responsive glazed superstructure that moderates the northern German climate to be more like Tuscany (Figure A40). With knowledge of regional and local climate data, building designers can extend the use of outdoor spaces, enrich indoor–outdoor movement, create modified climates in buffer and atria spaces, and provide building occupants with the delight of daily, seasonal, and annual climate variability and manageability.

Climate and building integrity

The final and perhaps most touted area of overlap between climate and architecture is the contribution of climatic forces to building degradation, debilitation, and destruction.

Humidity and precipitation contribute most heavily to these three failures in building integrity. Streaking, corrosion, efflorescence, and decay start as unsightly signs of age. With time this degradation leads to more serious debilitation, the inability to keep out the rain or to provide thermal comfort. However, at the point when the humidity, rain, snow, or ice begins to endanger structural integrity (through excessive loading, for example), the partial or complete reconstruction of the building may be inevitable. Wind and sun conditions also contribute to the loss of building integrity. Information about wind speed and direction and commensurate atmospheric conditions is needed to prevent corrosion (from sand and wind, for example), lifting, shear failure, cracking, and the popping in or out of claddings due to pressure differentials. Data on seasonal and daily solar intensity and position warn against potential fading, cracking, breaking due to expansion, or corroding due to dryness.

Each of these climatic stresses – precipitation, wind and sun – is aggravated by extreme temperatures or major temperature swings in a short period of time. The movement of the sun on extremely cold days and the action of changing solar gain values cause the greatest stress in materials and component assemblies. The combination of snow and freezing rain can cause the extreme structural loading that leads to failure. Consequently, descriptive and predictive database requirements for the prevention of building degradation, debilitation, and destruction are unique. In addition to predictive data as to climatic disasters (hurricanes, floods, tornadoes, and earthquakes), descriptive data on recent and repeated coincident climate conditions (average and extreme) are also needed. Finally, builders must track daily forecasts to ensure that potential material and component failures, leading to degradation, debilitation, or destruction, are not sealed into the building during the construction phase.

Rationale for action

These six performance mandates for buildings – thermal, acoustic, visual, air quality, spatial and building integrity – outline the breadth of the interchange needed between builders and climatologists. However, the rationale for action depends on the physiological, psychological, sociological, and economic limits society is willing to establish for *each* of the performance mandates. For a majority of developed nations these limits translate into five reasons for action.

Increasing environmental contact

Increasing environmental contact for passive conditioning was traditionally a prominent design criterion, but this climate-responsive design expertise was lost with the advent of air conditioning and the ability to mechanically condition year-round. With year-round conditioning, previously uninhabitable regions could be rapidly developed – especially desert and tropical regions. Designers could ensure comfort in any climate, with any building materials, packaged into any building image. However, the psychological unacceptability of this homogeneous and sealed-in approach to architecture has grown, despite its inherent development benefits. Indeed, pedestrianization (making outdoor spaces and facades more suitable for pedestrians), daylighting, natural ventilation, and outdoor space utilization have become novel foci for emerging design theory. It is on this basis that the newest rationale for climate data in building design is introduced – the desire to increase environmental contact.

Increasing environmental comfort

Even though the architectural and engineering community tout human comfort, the use of regional and local climate data to design for increasing environmental comfort within and around buildings has not been a primary step. The majority of urban planners, building designers, contractors, and managers rely heavily on deep, sealed buildings with mechanical conditioning to artificially provide thermal comfort, lighting comfort, and air quality. Indeed, little has been done to mitigate the liabilities of climate (cold wind infiltration and cold mean radiant temperatures in winter, glare and solar overheating in summer) or to use the assets of climate (solar gain and daylighting in winter, natural ventilation in summer) to provide a balanced environment as a basis for mechanical system design and operation. Yet thermal, visual and indoor air quality concerns have actually grown during this time due to an over-reliance on advanced technologies in sealed buildings that are oblivious to climate and energy consumption. Moreover, building energy consumption has also grown, for simultaneous heating and cooling,

increased fan and pump energy, electric lighting during the daytime, and for ensuring adequate ventilation to purge indoor pollutants. The economic motivation for *energy conservation* is what puts emphasis on this second rationale for introducing climate data – to naturally increase environmental comfort within and around buildings.

Reducing environmental failure

The third rationale for action, reducing environmental failure, is well established in the building industry. Whether triggered by the desire to keep up appearances (psychological limits of acceptability) or by the need to prevent failure and consequent risk to life (physiological limits of acceptability), data on extreme climate conditions have become a part of most building design codes. Today, design for the safety and security of building occupants, in the face of earthquakes, hurricanes, tornadoes, and heavy snow loads, ensures that extreme climate conditions are well documented in the codes. It is the joint responsibility of the architectural, engineering and construction community and the climatologist to establish whether these data are of the appropriate amount and in the appropriate form to adequately ensure both the psychological and physiological limits of acceptable environmental stress on building integrity.

Reducing environmental costs

Reducing environmental costs is a fourth argument for including climate data in the building decision-making process. This rationale for action promotes the value of all resources: money, labor, materials, air, water, and energy in the face of carelessness and abuse. The introduction of climatic facts and thresholds into analyses of the renewability of air, water, soil, energy, and capital-intensive building materials has the potential to significantly reduce the environmental costs (from leaky roofs to pollution build-up) imposed by building development (see Table A21). Growing concerns about climate change, pollution build-up, water shortages and depleting resources should significantly

Table A21 Environmental costs of poor planning and design decision making

^a Billions of dollars.

boost the demand by the design community for climate data. It is important for the meteorological community to anticipate these demands and create interpretive databases on the vulnerability of regions and local ecosystems in relation to air, water, soil, natural energies, and material resources.

Increasing environmental security

In a parallel effort, it is important for the meteorological community to create interpretive databases on the opportunities of regions and local ecosystems to replenish air, water, soil, natural energies, and material resources. With growing international attention on energy and water security, the meteorological community has a major opportunity to emphasize the importance of sun, wind, hydrothermal and other data in the design and retrofit of buildings and communities. The best protection from chemical and biological attack within a building's mechanical system may be replacing central systems with natural conditioning. The best protection from brownouts and blackouts may be the effective use of solar electric, thermal and daylighting energies. The importance of climate data to environmental security – both reducing vulnerability and providing sustainable resources – cannot be overstated.

Climatic data and building decision making

Given these five rationales for action – to increase environmental contact, comfort, and security while decreasing environmental failure and costs – climate data form an essential resource for the building industry. By focusing on the steps in the building decision-making process, these data can be introduced in a form conducive to action. Table A22 outlines the decisions made in the early stages of planning and design and the eventual operational decisions that must be made in building construction and management.

Table A22 Building decision making

Energy and environmental costs over time

Climate and land-use/town planning

Land-use development involves decisions concerning building density, spacing, height, collective massing, and functional mix. Land-use decision-making has a direct impact on air quality, pollution, thermal build-up, runoff and flooding potential, and water quality and availability, as well as changes in wind and sunlight conditions. Consequently, an understanding of a region's climatic profile and thresholds for concern are critical to the effective planning and design of building communities.

If regional and local wind conditions are to provide natural ventilation for thermal comfort, reduce pollution build-up, and improve use of outdoor spaces, then prevailing wind speeds and directions, as well as microclimate variations, must be known. Average and extreme wind conditions must also be addressed if liabilities are to be mitigated, including thermal discomfort through infiltration, acoustic discomfort through noise transportation, poor air quality through pollution transportation, and building degradation and destructive failure. Early design decisions regarding building density, massing, and functional mix dictate the availability or mitigation of regional wind conditions at the building microclimate level. According to Landsberg (1976):

The major effect of urban areas on the wind circulation is a result of the increased roughness introduced by the building complexes. These induce many smaller and larger eddies which swirl around in the city. The arrangement of streets and avenues will cause channeling of the wind. The results may then be that strong currents flow through one set of streets, while relative calm prevails in the streets at right angles. The eddy currents that are caused by the buildings, especially the tall ones, can lead to very high wind gusts at street level. They can be so strong that it becomes difficult to walk on pavements and to open doors unless special protective overhangs are included in the design.

Sun conditions are equally affected by land-use decisions. If the benefits of solar heating, daylighting, and outdoor space utilization are to be realized, regional sunlight conditions and microclimate modifications must be optimized through careful control of density, height, and collective massing (Knowles, 1994). If the liabilities of solar overheating, thermal inversions causing poor air quality, and ultraviolet building degradation are to be reduced, regional sun position, intensity, variability, and potential microclimate shifts must be fully incorporated into site planning decisions.

Without a regional comprehension of overheated, underheated, and comfortable climate conditions, land-use decisions as to density, massing, and functional mix can aggravate a region's disadvantages, while losing the opportunity to make use of its climatic advantages. Still today, urban planning takes little advantage of the comfortable season for natural thermal conditioning or outdoor space utilization. In fact, town planning often shortens the natural season by poor manipulation of natural wind and sun conditions. Landsberg (1976) states that "on a local scale, the formation of an area of higher temperatures compared with rural environs is generally the first obvious manifestation of settlements, and can be directly related to the building density." Heat islands, which result from the complex actions of urban pollution, solar and heat build-up, and poor air flow, can be anticipated with climate information. In addition to increased thermal discomfort and reduced access to outdoor spaces, our poor understanding of regional temperature conditions and corresponding wind,

sun, and humidity conditions leads to unsightly building degradation, unacceptable debilitation (inability to provide shelter), and, eventually, unsafe destruction.

Finally, regional humidity and precipitation data are needed in the effective planning of urban density, spacing, building height, and collective massing. To the designer's advantage, low humidity allows for effective evaporative cooling to provide thermal comfort and reduced conditioning costs. Design for the utilization of precipitation can provide for our water needs and improve air quality as well as reduce degradation of buildings due to pollution. However, comprehension of the serious liability presented by regional humidity and precipitation is also critical. Extreme humidity can be the major cost in conditioning for thermal comfort and air quality, as well as growing concerns about the health consequences of mold and mildew. While average precipitation contributes to building degradation and debilitation over time, extremes in precipitation, aggravated by extreme wind conditions, constitute the greatest cause for building and infrastructure debilitation and destructive failure.

Climate and building design

Although many design decisions regarding massing and orientation, organization of spaces, enclosure design, opening

design, and systems integration are made without the benefit of regional and microclimate data, the importance of climatic conditions to thermal and lighting comfort, air quality, and building integrity (versus degradation and destruction) cannot be understated. Table A23 clarifies the advantages and disadvantages of various climatic forces on building performance as well as the building design decisions that are consequently affected.

Records of average wind speeds and directions are necessary if natural ventilation is to be provided, dictating appropriate building orientation, spatial organization, opening design, and systems integration. The liability of wind to thermal comfort, air quality, and building integrity must also be considered, demanding that building massing, organization, enclosure detailing, and opening design minimize the unacceptable wind forces around and through the building. Today, the most advanced architectural/engineering teams use computational fluid dynamic tools (CFD) to create innovative naturally ventilated buildings and even power-generating wind turbine designs integral with the building design (Hamzah et al., 2001).

The natural conditioning benefits of sunshine for solar heating, daylighting, and outdoor space utilization require a working knowledge of seasonal and daily sun position and intensity, along with their implications for building massing and orientation,

Table A23 Climate and building design decision making

	Massing and orientation	Spatial organization	Enclosure design	Opening design	Systems integration

organization of spaces, opening design, and system integration. Average and extreme solar and sky conditions must also be considered by designers if solar overheating in summer, glare causing lighting discomfort, and building degradation are to be reduced. Today, the most advanced architectural/engineering teams use daylighting and solar thermal simulation tools to maximize passive solar heating, daylighting and power generation utilizing buildings rooftops and facades.

When temperature conditions offer significant periods of natural comfort, with or without the assistance of sunshine for warmth or wind for cooling, the massing of a building and its potential for indoor-to-outdoor movement through the appropriate organization of spaces and displacement of openings should be significantly affected. Often, however, the design of the building's mechanical system is not integrated effectively with climatic data, thereby eliminating the advantage of this natural conditioning potential. Today, the most advanced architectural/engineering teams use hour-by-hour simulation tools to design thermal mass and thermal distribution strategies – such as core-to-perimeter, E-S-W-N, and day to night load balancing systems to take advantage of diurnal energies in specific climates.

Knowledge of regional humidity conditions allows the designer to take advantage of evaporative cooling for thermal comfort and air quality, reducing the conditioning liability of excessively dry climates through careful opening design and systems integration. In humid climates the minimization of moisture build-up and the effective use of ventilation and solar "drying" or desiccant systems places equal demands on enclosure design and systems integration. Spatial comfort, including the ability to enter or exit a building and the usableness of outdoor spaces, is assured through an understanding of average and extreme rain, snow, and ice conditions, along with coincident wind and temperature data. Full knowledge of these coincident climatic liabilities is also necessary to prevent all three threats to building integrity: degradation; debilitation to such a degree that the building no longer provides comfort or shelter; and destructive failure. Tveit (1970) presents an illustrative discussion:

Water may be brought into porous materials as liquid or as vapour. The driving force may originate from differences in hydrostatic pressure, osmotic pressure, vapour pressure, as well as from free surface energy. Considering rain penetration into building structures, this would be caused by (1) capillary action due to free surface energy; (2) kinetic energy of rain drops or water streams; (3) hydrostatic pressure due to gravity or to wind pressure on water films or menisci; or (4) air flow through the structures. The ability of a building structure to dry out and keep dry generally depends on the successful design in every detail of the building and its various structural components and draining systems above or under the ground as well as on certain physical properties of the applied materials and workmanship, all in relation to the ambient climate. Some of these principles are related to the design and construction of certain building components and are in exposed areas frequently reflected in a characteristic of local design and building practice.

Consequently, increased understanding of regional and local climatic assets, their combinations, and manageability could change significantly the present-day isolationist or "sealed box" tendencies of building designers. Setting regional priorities among these climatic assets and liabilities to ensure long-term thermal comfort, lighting comfort, air quality, spatial comfort, and building integrity, is the genius of climate-responsive building design. The regionalization of architecture is not a return to

the past but a reconfirmation of the natural forces and resulting material availabilities that make survival and comfort in each location unique. The all-glass building in hot and humid Houston, the flat roof in rainy England, the pedestal building in windy Chicago all attempt to deny the very climate in which they sit. Today, armed with a full understanding of a building's climate and consequent microclimate, design priorities can be set that maximize the benefits of the various climate assets for natural conditioning while minimizing the liabilities – a delicate balance that will ensure building quality over time.

Climate and building construction

The building construction industry has several responsibilities that depend greatly on climate data. Worker comfort in relation to precipitation, hot or cold temperatures, biting or dehydrating winds, excessive solar gain, serious humidity and pollution conditions as well as protection against the stresses of heat stroke and frost bite, require that project managers keep a close watch on daily and hourly weather forecasts. The safety of the worker requires knowledge of climate conditions – wind speeds in high-rise construction, snow and ice conditions on various ground surfaces, excessive overheating or freezing of building materials as well as components that must be handled or walked on. The seriousness of these responsibilities, and the corresponding need for predictive weather information, is already an innate part of the standards and liability laws of the construction industry. However, material stress resulting from adverse climatic conditions (average, coincident, and extreme) is less enshrined in the working standards of the construction industry. Not only do extreme temperature, humidity, precipitation, wind, and sun conditions greatly affect the integrity of building materials, components, and assemblies on the job site, but historic average conditions also indicate the feasibility of using particular materials and assemblies in various climates. Without a working knowledge of the impact of average and extreme climate conditions on building integrity, the unsightly degradation of buildings, the debilitation of buildings to an extent where they no longer provide comfort or shelter, and the destructive failure of buildings will be initiated from the laying of the first foundation.

Balancing these climatic variables that dictate worker comfort and safety as well as material stress over time, against other construction variables such as worker availability, material delivery, financing, and occupancy schedules form the basis of operational planning on the construction site. However, because of the lack of descriptive and predictive climate data in a form readily usable by the construction industry, only sketchy climate information is used in construction planning, despite long-term implications of precise climate data for the performance of components and systems.

Climate and building management: maintenance, operation and use

The daily operation and use of a building for occupant comfort require data on present and near-term anticipated climate conditions. To provide thermal and visual comfort for the occupants, as well as the air quality they need, building operators (or automated operating systems) require information on outdoor temperature, humidity, and sun conditions. Energy load balancing from north to south, from day to night, and from season to season to reduce peak demands and annual energy costs requires descriptive average and extreme climate data, in addition to 24-hour weather forecasts. Table A24 shows that over 50% of

Table A24 Winnipeg office building: annual load breakdown and climate dependencies

	kWh/sq ft/ year	Operating dollars 1981	Climate impact annuals	Climate negotiable capital costs ^a
Process electricity (kitchen, power, computers)	4.0	22 000	—	No
Electric conditioning				
Lights	5.0	28 000	10 000 ^b	Yes
Fans for air quality ^c	2.0	11 000	—	No
Fans for “core”/cooling				
Lights ^d	1.2	6600	2000	Yes
Equipment ^e	1.8	10 000	—	No
Fans for perimeter cooling	1.0			
Air conditioning for perimeter ^f	2.0	16 000	16 000	Yes

the annual operating costs in a 300 000 square-foot office building in Winnipeg, Canada, depend on outdoor climate. These operating costs, and the occupant comfort that is associated with them, generate the demand for on-site weather monitoring equipment today. The innovative use of such equipment can yield tremendous improvement in the understanding of occupancy comfort and stress that is directly affected by climate and related building decision making.

Occupant safety, given adverse weather conditions and long-term building degradation due to these conditions, also constitutes a major demand for climate information. Wind, rain, snow, and ice can make certain parking areas, pedestrian areas, and entries unsafe. Material expansion and contraction, caused by swinging temperatures, fluctuating humidities, and sunshine, can make various building components unsafe to walk on or under. Material corrosion and degradation due to moisture migration and rain penetration can lead to building failures that are dangerous to occupants and passers-by. Disasters such as hurricanes, floods, tornadoes, or snowfalls followed by freezing rain can cause total building collapse, a phenomenon that should be anticipated in building design and upheld through building maintenance. Consequently, 24-hour and weekly forecasts are needed by building managers to anticipate building stress and occupant safety risks. Long-term historic data are needed to establish annual maintenance budgets for each building, while short-term historic data will compel building managers to undertake preventive maintenance programs for building materials and assemblies that have been under unexpected, but recorded, stress.

The image of the building – of interest to the occupants, the owner, and the community at large – is also a major factor in building maintenance programs. Before the building is occupied, the climatic liabilities of the region and site can be mitigated with careful planning, design, detailing, and construction.

However, after the building is occupied, the stresses placed on the building fabric and site by climate will require continuous cycles of maintenance. Preventive maintenance, like preventive medicine, can slow the degradation of buildings and potentially prevent debilitation to the point where the building no longer provides comfort or shelter. For example, anticipating excessive rainfall, gutters can be cleared out and drainage channels opened, preventing the major roof leak that eventually demands millions of dollars of repair. In many countries, records of major snowfalls become mandates for maintenance crews to clear roofs, preventing excessive structural loading and eventual failure. Material and product manufacturers often establish preventive maintenance programs, given a range of average climate conditions. Table A25 lists the weather mechanisms that contribute to stone decay; factors that can be translated directly into building maintenance programs (Tombach, 1982). Eventually, these maintenance schedules, as well as the reactive maintenance required in the aftermath of major climatic events, will be computerized along with the descriptive, predictive, and historic climate data that necessitate the activities, providing each building owner with a specific climate-responsive maintenance program.

Methods of intervention

There is little question that the availability of climatic data is far greater than their use. Indeed, the willingness of climatologists to be of service to the building community is far greater than the demand for their services. Several theories have been advanced as to why this is so. John Page (1970) writes:

“When an applied science is not applied in practice, it is always valuable to inquire why this situation should persist in spite of a host of apparently good scientific reasons why the situation should be otherwise. The aviation services use the

meteorological networks without persuasion, why not the architects, town planners, and civil engineers? There would seem to be three fundamental reasons for rejecting scientific information in any practical field of human activity: (1) the information provided is considered irrelevant by the potential user; (2) the information provided in the form presented is considered inapplicable by the potential user; and (3) the information provided is considered incomprehensible by the potential user. The first question implies a lack of understanding of the problem by the scientific worker, the third question a lack of understanding by the designer of the problem, and the second question shows a lack of communication between the two.

John Eberhard of the National Academy of Sciences (1986) adds:

The resistance to change is a natural, and probably necessary, instinct in all people and consequently in human institutions. The organizations and institutions associated with the building industries of the United States are no exception – in fact they appear more resistant to change than many other sectors of the economy. One major indicator, and also contributor, to this lack of innovation is the relatively low volume of research and development. While industries such as electronics and aircraft are spending more than 20 percent of their revenue on R&D, all indications are that the industries of building spend less than one percent on Research and Development – in fact if quality control and product testing

to meet government regulations is subtracted from the so-called R&D budgets of building industry organizations, the budget left to devote to new ideas and new knowledge is probably very small indeed.

These weaknesses in information transfer and in applied research are compounded by the unfamiliarity of the climatologist with the exact nature of individual building decisions and the uncertainty of the planner, designer, engineer, contractor, and building manager as to what climatology has to offer. Despite this overall lack of familiarity there are several concrete steps that can be taken to improve the contribution of climate data in the building decision-making process: accessible climate databases; climate data information packaging; algorithm development and information processing; model testing; field case studies and documentation; and advanced computer simulation tools.

Important climatic variables

For effective decision making in the early stages of land-use planning and building design and in the later stages of construction and building management, the building community needs a considerable quantity of average and extreme temperature, humidity, atmospheric content, wind, sun, and precipitation data. In the majority of industrialized nations this database exists to

such an extent that data collection needs are insignificant in comparison to the needs for applied data packaging and processing in relation to the building sciences. The efforts of the European Community to consolidate solar and other climate databases for EC members in the publicly accessible web site – SoDa (2002) – will greatly enhance decision making in those climates.

However, there is a major gap in two areas of data collection and presentation: the availability of information on complex, coincident climate conditions often critical to building performance; and the development of micrometeorology. Lacy (1972) writes:

Although in many multi-variate problems, an analysis of the simultaneous occurrence of various elements is usually required, there are others in which the sequence in which events occur is important. Ultra-violet radiation will only react with a material if the material has already been wetted by dew or rain. Frost will only damage porous materials if they have been wetted by rain a sufficiently short time before the frost occurs, so that there has been insufficient time for water loss by evaporation. Condensation of water on structures can be caused if a prolonged cold spell is followed rapidly by a mild one, so that the atmospheric dew-point rises more rapidly than the temperature of surfaces which have been chilled during the cold spell. In such cases the conventional statistical analyses of weather elements may be useless, and it is necessary to study the actual weather situations which cause such problems, and estimate their frequency of recurrence.

Only coincident climate data can ascertain the availability of wind when the temperatures are warm enough to merit natural ventilation, or the direction and speed of wind when it is raining to ensure appropriate enclosure detailing and opening design.

Equally important is the development of microclimate databases or scientific methods for the prediction of microclimates on specific building sites. Building design decision making will

rely on whatever sketchy microclimatic databases exist, until the predictive science of micrometeorology is developed. Finally, the industrialized nations should be committed to establishing climate databases for the developing world as well, if climate responsive community and building design, construction and operation is to be achieved world-wide for environmental safety, comfort and security.

Information packaging and climate graphics

Graphic interpretations of climate data are critical for professionals to understand the variations and coincident conditions that should significantly impact building and community design. From the early work of the H.E. Landsberg for the AIA (1950), the Olgay brothers (1963), Loftness (1982), Brown and Dekary (2001), and a host of recent leading international designers (e.g. Short, Foster, Yeang) a commitment to graphically communicating climatic forces is key to climate-responsive design.

Based on the assumption that the greatest amount of information is learned in the doing, a how-to publication, *Climate/Energy Graphics*, was written by Loftness (1982) for the World Meteorological Organization. Loftness outlines 15 graphic exercises that can be completed by meteorologists, technicians, engineers, or architects using data from local weather stations. As shown in Figures A41 and A42, available climate data should be used to generate climate graphics and result in a summary translation with written design guidelines to ensure the climate-responsive design of building massing and orientation, spatial organization, enclosure and opening design, and systems integration (Figure A43).

Algorithms and climate information processing

To get beyond the elementary knowledge concerning regional and local climates that can be achieved through climate graphics, it is necessary to develop an understanding of the fundamental algorithms that relate climate to building success and failure. Boer (1970), in an article outlining a training and education syllabus, stipulates:

Knowledge of the interaction between meteorological parameters and/or processes and building activities, of single structures and built-up areas, is an essential prerequisite for a functioning information system of building meteorology.

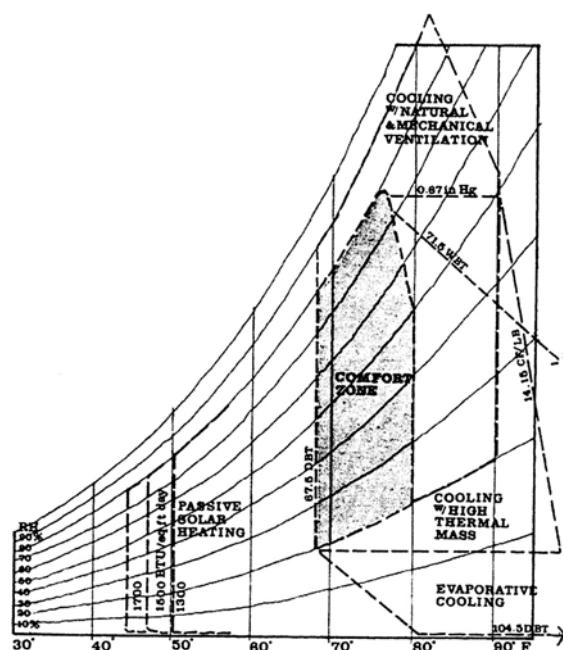

Figure A41 Evaluating passive conditioning potential (from Loftness, 1982).

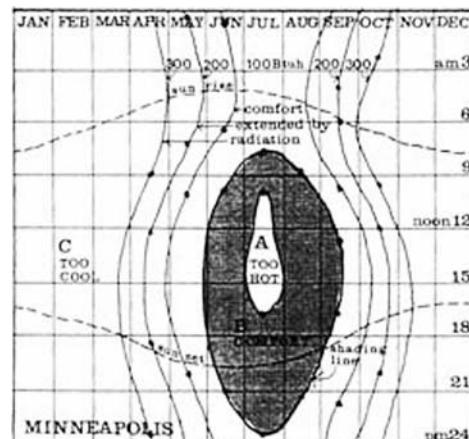

Figure A42 Climate design priorities for Minneapolis, Minnesota (from Loftness, 1982, based on Olgay, 1963).

	RANK	A Bldg. & Landscaping	B Building Grouping	C Bldg. Shape & Configuration	D Bldg. Orientation	E Building Organization	F Envelope/ Enclosure Design	G Envelope/ Opening Design	H Systems Integration

COMFORTABLE									
Use ASSET	4	Provide open spaces for winter, spring & Autumn uses					Provide connections w/ outside for winter, spring & autumn uses		

Figure A43 Developing design strategies from climate priorities (Charleston, from Loftness 1982).

The algorithms that explain the interaction between meteorological parameters and design decision making can be as simple as the snow loading that leads to failure of various structural systems and as complex as the relationship of town planning decisions to the alteration of regional wind patterns. While computational tools such as DOE 2.2 support the integration of on-line climate databases into energy-effective design decision making, there are numerous performance simulation challenges that remain, including the potential impact of time-lag, of radiant cooling, and the hygrothermal performance of materials and assemblies. In his book *Climate Considerations in Building and Urban Design* (1998), Baruch Givoni documents the importance of algorithms to describe the effect of mass in buildings with continuous ventilation, nocturnal ventilation, and night-time radiant exchange (Figure A44). In practice, Dr. Givoni continues to explore innovative cooling strategies using combined forces of wind, thermal stratification, and evaporative cooling, to create, for example, the dramatic Ashower cooling towers that captured the imagination of all who attended the 1992 World Expo in Seville, Spain (see Figure A45).

Laboratory and field case studies and documentation

Field studies of innovative indigenous and advanced buildings in a range of climates could aid in the development of performance algorithms linking climate and architecture, to enable designers to understand the regional appropriateness of climate-responsive design innovations. A range of diagnostic tools, equipment, and procedures should be further developed to determine the overall performance of building materials, assemblies and integrated systems in the full range of climates. According to Markus and Morris (1980):

Historical studies of vernacular buildings are helping in the development of a new kind of planning and architectural theory – concerned not with monumental planning and design, but with the pattern of cities, settlements, and buildings as expressive of the structural relationship between technological, social, symbolic and natural forces – that is, a cultural theory of form. This theory attempts to unravel the meaning of patterns found in primitive and vernacular creations of the past and, by studying the processes and forms of still active authentic societies, to draw conclusions for design today.

Until now, field instrumentation has generally focused on the evaluation of building degradation, debilitation, and destruction. Indeed, there are no comprehensive approaches to evaluating the performance of materials, buildings or land-use alternatives in a range of climates for universities or professionals to decisively study indigenous and innovative climate-responsive architecture.

On the other hand, climate testing of scale models set in average and extreme wind or sun conditions has been pursued by a small number of designers for major projects or climatically challenging projects. Model wind testing is used on some large projects to visualize pedestrian safety and comfort, the integrity of cladding and structure against degradation or destruction, the viability of natural ventilation, and the predictability of pollution migration. Model sun/daylight testing is used to illuminate the solar availability in public spaces, the effectiveness of shading devices, the potential of solar heating, and daylight penetration. However, scale model testing could go much further. Model wind/snow testing could clarify the build-up of snow on roads, airports, building entries, roofs, and

in recreational areas such as ski resorts. Model rain testing could be undertaken to demonstrate watersheds, storm runoff and site drainage effectiveness and the consequent impact on communities and regions.

Both laboratory and field studies of climate-responsive building materials, assemblies and integrated systems are critically needed for designers to regionally increase environmental contact, comfort, and security while decreasing environmental failure and costs. There should be a concerted effort to completely document field studies of both indigenous climate-responsive buildings and communities and recent innovations in a range of climates to inform the entire building community, from building owners to material suppliers, of the significance of climate in building decision making.

Advanced computer simulation tools

The computer plays a more active role in land-use planning and building design, construction, and management today, with climate data integral to performance simulation. However, more laboratory and field case studies linking the performance of materials, assemblies and integrated systems to regional climate conditions will help to mainstream the use of simulation tools in design and construction. When an adequate number of building climatological algorithms and descriptive case studies can be simplified into computer-simulation packages, the demand for climate data in building decision making will be clearly established. The environmental costs of inappropriate land-use and building and their corresponding change in soil, vegetation, and topography should be too graphic to ignore. The loss of environmental comfort through poor building orientation, organization, and opening design should be quickly simulated and alternatives chosen. The environmental stress placed on building materials in the face of anticipated and recorded climate conditions should be avoided through computerized construction management programs. Material manufacturers should be able to establish regional performance priorities and preventive maintenance schedules suited to the unique history of climate conditions surrounding the project. The acceptable averages and threshold of coincident climate conditions should be automatically processed through the algorithms of physiological, psychological, and economic comfort to continuously guide decision making in building design, construction, and use.

Although no attempt is made to establish which of these methods of intervention will generate the greatest impact – data packaging, data processing through algorithms, field studies, model testing, or computer simulation – each of them will reap results. Each method of intervention “describes historical and more recent notions of buildings as shelters; i.e., structures which intervene by acting as barriers and as responsive filters between the natural and urban environment, and the range of environments required for human activity” (Markus and Morris, 1980).

Urban Climatology

ARCTIC CLIMATES

The Arctic is the northern hemisphere heat sink that establishes latitudinal pressure gradients which drive the general circulation of the atmosphere. The Arctic typically conjures up mental images of a region dominated by extreme cold, snow cover and floating sea ice; but Arctic climates are quite diverse, both by season and region. This diversity reflects the pronounced seasonal cycle in solar radiation receipts, regional aspects of the atmospheric circulation and the contrasting thermal properties of different surface types. The most formal definition of the Arctic is the region north of the Arctic circle, approximately 66.5°N. At this latitude the sun does not rise above the horizon at the winter solstice and does not fall below the horizon at the summer solstice. However, climate conditions of Arctic “flavor” can be found south of the Arctic Circle, while surprisingly mild winter temperatures extend well north in the Atlantic sector. Other definitions of the Arctic include the region north of the 0°C mean annual isotherm, and the region north of the tree line.

Key physical features

The geography of the Arctic is in striking contrast to its southern counterpart. The Antarctic is characterized by a continental ice sheet surrounded by ocean. By comparison, most of the area north of latitude 70°N is occupied by the Arctic Ocean, which apart from the sector between about 20°E and 20°W longitude is almost entirely surrounded by land. The most striking feature of the Arctic Ocean is its floating sea ice cover. Total northern hemisphere sea ice extent ranges from about 14.8 million square kilometers in March to roughly half that value in September (Figure A46). Typical ice thicknesses in the Arctic Ocean are 1–5 m. The sea ice cover is not a solid slab, but contains roughly linear openings, known as leads, and more irregular areas of open water, termed polynyas. The ice cover is in near-constant motion due to winds and ocean currents. Snow cover overlies the sea ice and surrounding land for most of the year. Maximum snow depths range widely, especially on local scales, but values of 30–80 cm are typical.

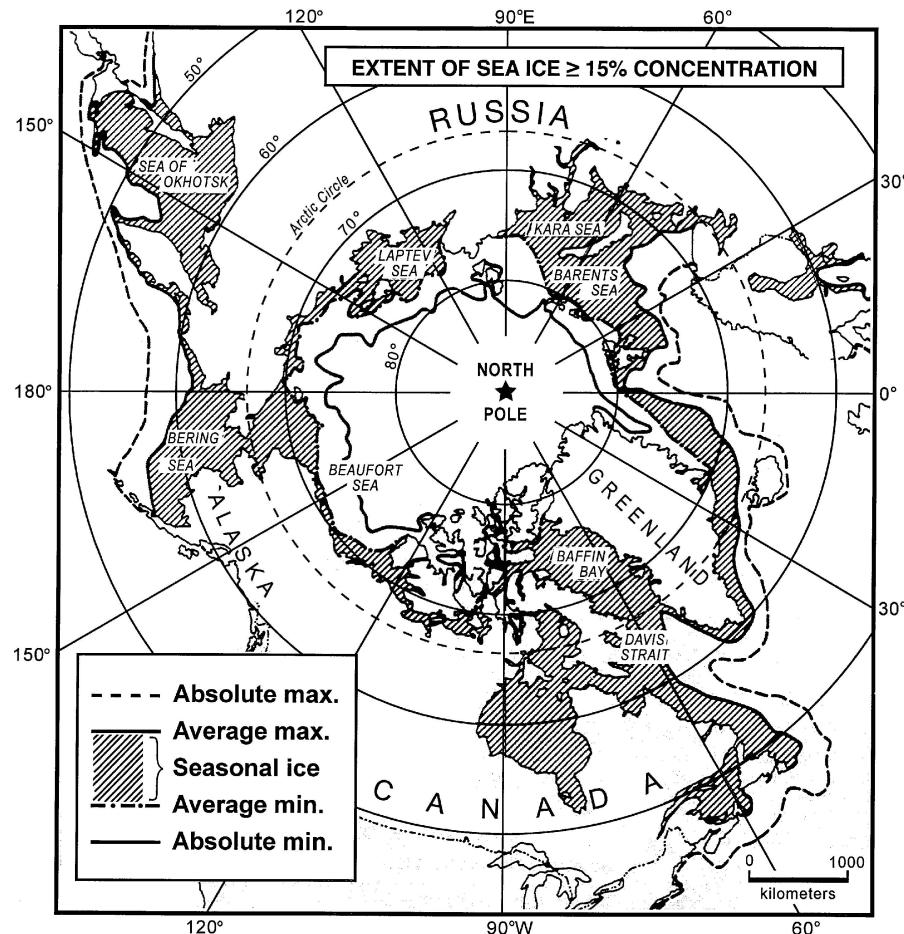

Figure A46 Geography of the Arctic region and limits of sea ice (adapted from Barry, 1983).

Apart from the Greenland ice sheet, which contains about 7.5 m of global sea level equivalent, ice caps and glaciers are primarily limited to the mountainous parts of the Siberian and Canadian Arctic Archipelagos, Svalbard and Iceland. However, most of the Arctic lands are underlain by perennially frozen ground, known as permafrost. The upper part of the ground in permafrost regions, termed the active layer, freezes and thaws seasonally, generally to depths of 100–200 cm. Permafrost acts as an impermeable barrier, which keeps moisture near the surface. Hence, many areas with poor drainage are covered by shallow thaw lakes in summer. In areas with more pronounced drainage, permafrost fosters rapid channeling of snow melt and precipitation into streams and river channels.

Much of the land surface is characterized as tundra. The most extreme and generally northernmost tundra landscape, polar desert, often has less than 5% vegetation cover. In lower latitudes, tundra commonly includes shrub vegetation of birch and willow, together with sedges and grasses. Vegetation covers 80–100% of the surface. At lower latitudes there is a forest-tundra transition, or ecotone, south of which is found the boreal forest.

Atmospheric circulation

The primary feature of the northern high-latitude mid-tropospheric circulation is the polar vortex, which in winter (Figure A47a) has major troughs over eastern North America and east-

ern Asia, a weaker trough over western Eurasia, and a strong ridge over western North America. The lowest winter pressure heights are located over northern Canada. These features are related to orography, land-ocean distribution and radiative forcing. The mean winter circulation at sea level (Figure A47b) is dominated by three “centers of action”: (1) the Icelandic Low off the southeast coast of Greenland; (2) the Aleutian Low in the North Pacific basin; (3) the Siberian High over east-central Eurasia. The Icelandic and Aleutian lows are complex features. In the most fundamental sense they reflect position downstream of the major mid-tropospheric stationary troughs where cyclone activity is favored (they are hence part of the primary North Atlantic and East Asian cyclone tracks, respectively) and thermal effects of the relatively warm underlying ocean. The Icelandic Low is part of a broad area of low pressure extending into the Barents and Kara seas. This manifests open ocean waters and the penetration of cyclones (with associated strong horizontal heat and moisture transports) well into the Arctic Ocean. The Siberian High is a cold, shallow feature, driven largely by radiative cooling to space.

The polar vortex during summer is weaker and more symmetric (Figure A48a). The sea level Icelandic and Aleutian Lows essentially disappear and the Siberian High is replaced by a broad region of low pressure (Figure A48b). Mean low pressure is also found near the pole. Cyclone activity increases over land. Reflecting the mean low pressure, a summer cyclone

maximum is also found over the central Arctic Ocean. This is largely due to the migration of cyclones generated over Eurasia and along the weakened North Atlantic track. Serreze (1995) provides further reading.

Surface air temperature

Figure A49 shows patterns of mean surface air temperature (at approximately the 2-m level) for the four mid-season months. January means near the North Pole are -32 to -33°C . The coldest conditions are found in northeastern Siberia in association with the winter Siberian High. Mean values of below

-40°C are found in January. Locally, in valleys, temperatures are lower. Verkhoyansk, located along the Yana River valley at 67°N , is notorious for its extreme winter cold. The highest winter temperatures are found in the Atlantic sector. Building from previous discussion, this manifests warm, open water and horizontal transports of sensible and latent heat associated with the North Atlantic cyclone track. Over the ice-covered Arctic Ocean, leads and polynyas permit locally strong vertical heat fluxes from the ocean to the atmosphere. This prevents winter temperatures over the central Arctic Ocean from reaching the extremes observed in Siberia.

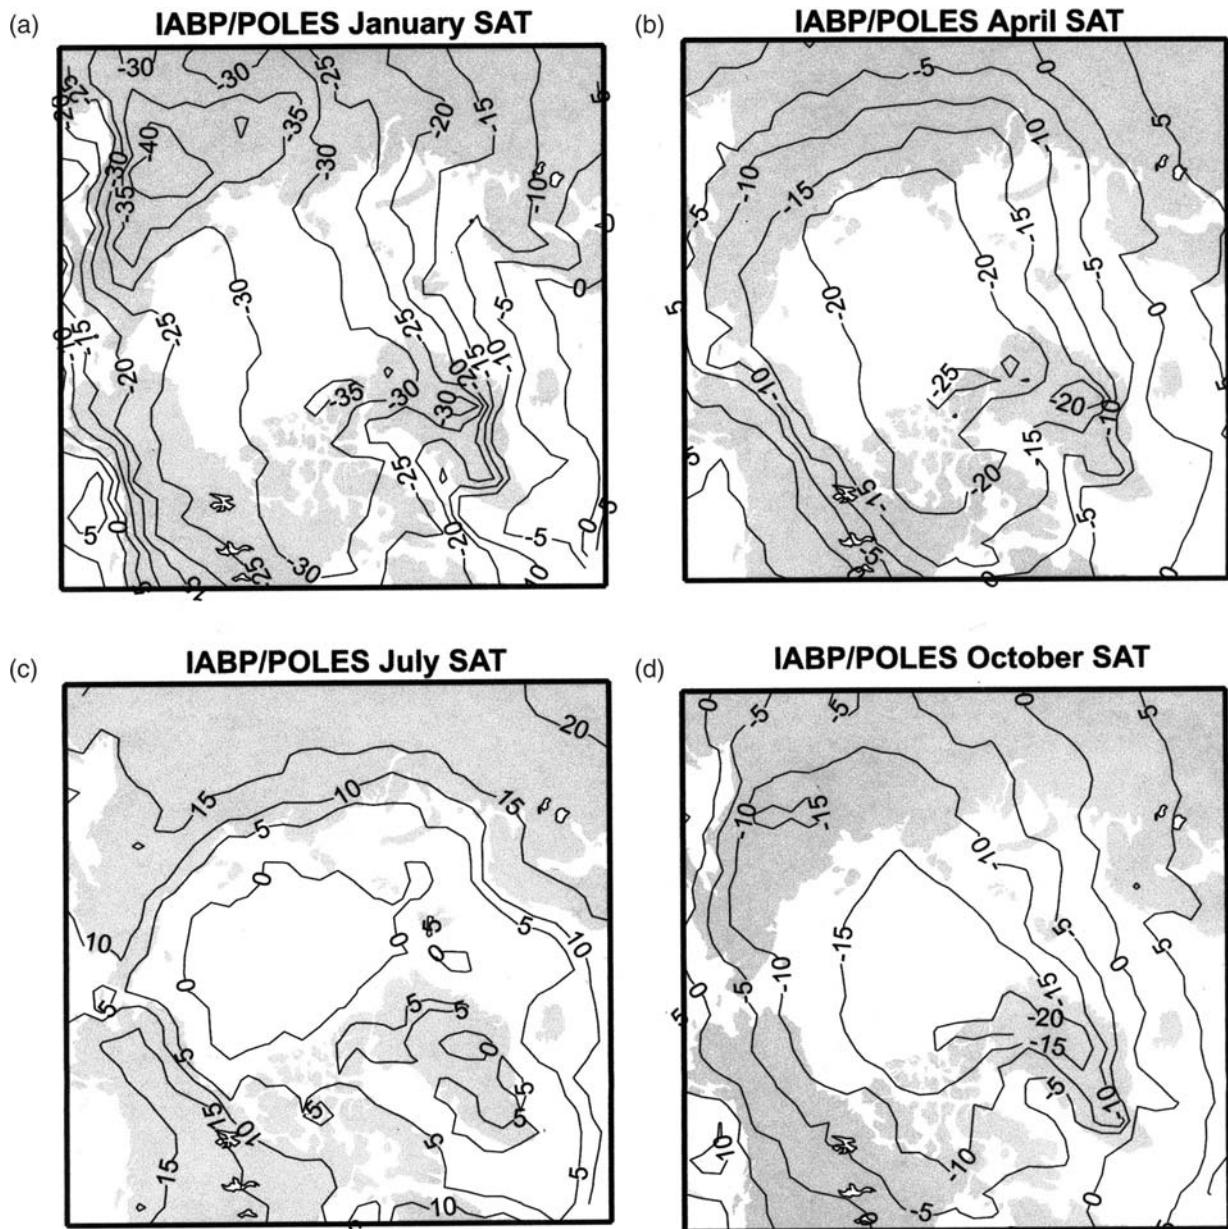

Figure A49 Mean surface air temperature ($^{\circ}\text{C}$) for: (a) January; (b) April; (c) July; (d) October, based on the University of Washington International Arctic Buoy Programme/Polar Exchange at the Sea Surface (IABP/POLES) data set (updated and adapted from Rigor et al., 2000).

By April the Siberian temperature minimum has disappeared. The lowest temperatures are found over the Arctic Ocean and the Canadian Arctic Archipelago. Temperatures rise to the melting point over the coasts by the end of May and over most of the central Arctic Ocean by mid-June. The melt season over the central pack ice is about 60 days long. Summer temperatures over the central Arctic Ocean are constrained to hover near freezing point due to the presence of the melting sea ice cover. Because of strong differential heating between the Arctic Ocean and snow-free land, summer sees a sharp temperature gradient along the Eurasian and Alaskan coasts. Inland Arctic temperatures for July range from 10°C to 15°C. The sharp coastal gradient is not observed along the Canadian Arctic Archipelago due to the many ice-covered channels separating the islands.

A notable aspect of the Arctic environment is the presence of strong low-level temperature inversions (increasing temperature with height) during winter. These surface or near-surface-based features generally extend to about 1200 m during January–March, with a temperature difference from the inversion base to top of typically 11–12°C (Serreze et al., 1992). The inversion layer tends to be maintained by a radiative equilibrium associated with the different longwave emissivities of the surface (nearly a blackbody) and of the temperature maximum layer aloft, with northward heat advection balancing the outward radiation loss to space (Overland and Guest, 1991). Especially strong winter inversions are found inland in northwest Canada and eastern Siberia in inter-montane basins and valleys (e.g. at Verkhoyansk). In summer the Arctic is characterized by weaker, elevated inversions.

Precipitation

Mean annual precipitation totals across the Arctic (Figure A50a) vary by a factor of 20. The lowest annual totals of less than 100 mm are found over the northern Canadian Arctic Archipelago. Over the central Arctic Ocean the mean totals are around 250 mm. The largest annual amounts, locally exceeding 2000 mm, are found over the Atlantic sector. There is a strong seasonality in precipitation, illustrated by the January (Figure A50b) and July (Figure A50c) fields. The high annual totals in the Atlantic sector are largely driven by winter precipitation. This is a response to the strong Icelandic Low and North Atlantic cyclone track in this season. By contrast, most land areas and the central Arctic Ocean exhibit a summer maximum and winter minimum in precipitation. The winter minimum manifests the low moisture-holding capacity of the cold air in these regions and the relative infrequency of cyclone activity. The summer maximum over land areas is strongly associated with surface evaporation and more frequent cyclone activity. Convective precipitation is common over Alaska and Eurasia. The summer maximum for the central Arctic Ocean also manifests the summer cyclone maximum for this region.

Cloud cover

The Arctic is a cloudy place. Winter cloud fractions range from 40% to 70%, greatest over the Atlantic side where cyclone activity is frequent. Total cloud fractions rise to 70–90% in summer. Over the central Arctic Ocean there is a rapid increase between April and May, driven primarily by an increase in

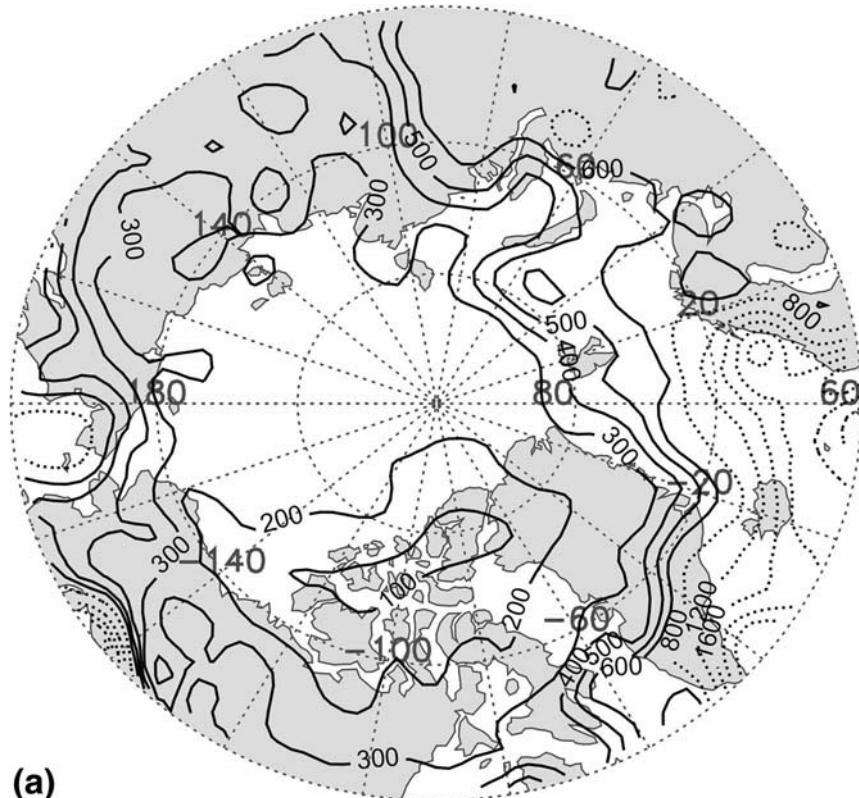

Figure A50 (Continued)

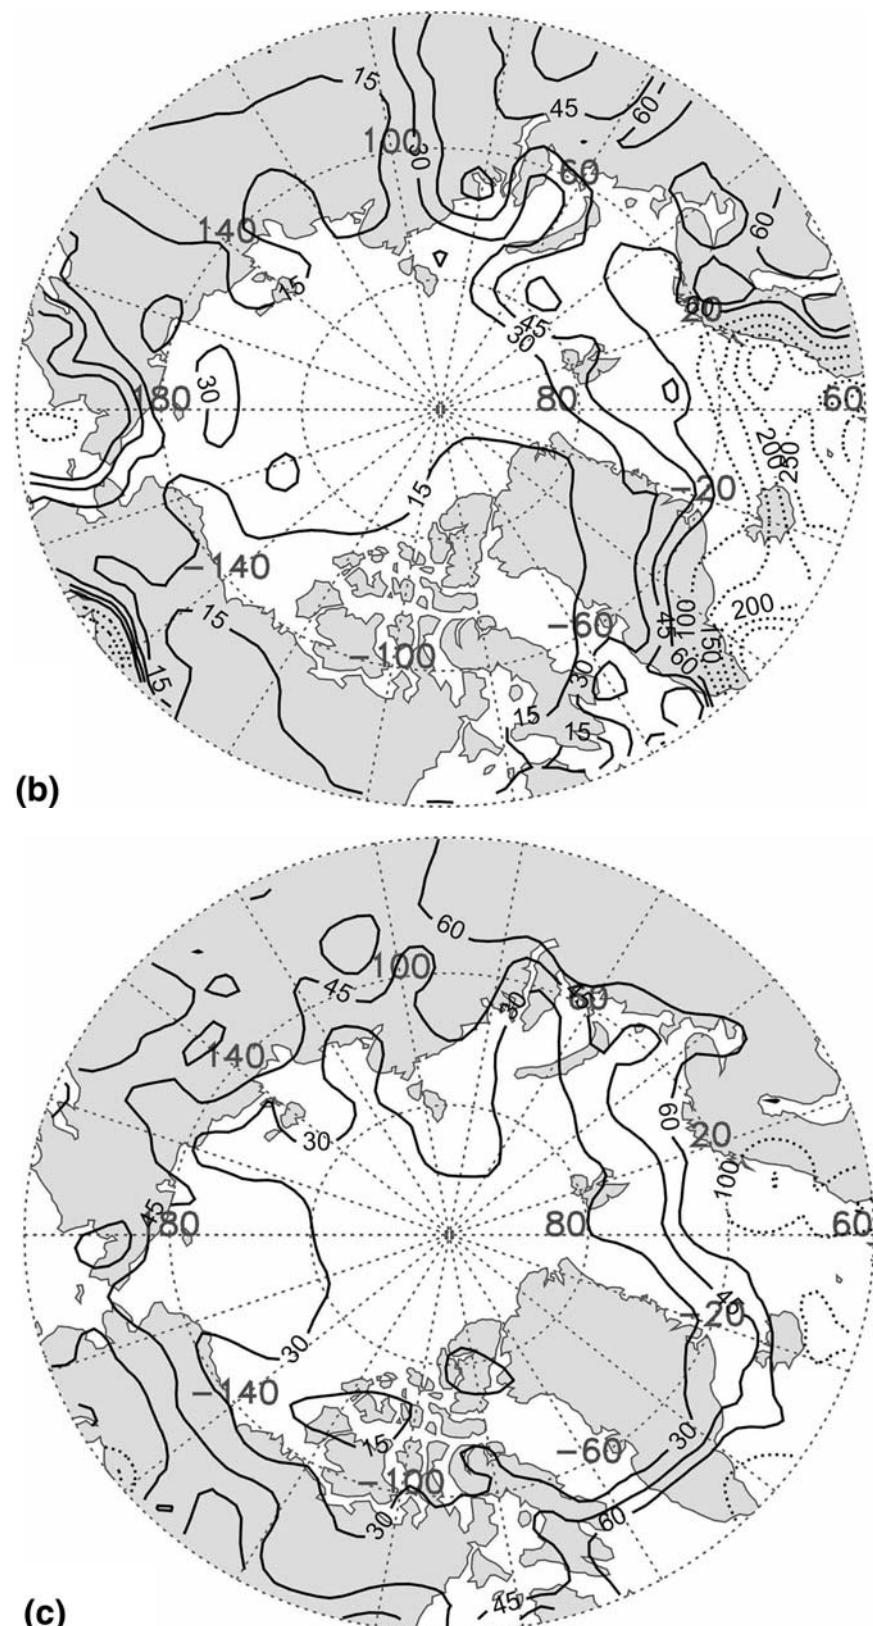

Figure A50 (a) Mean annual, (b) January and (c) July precipitation (millimeters) with estimated adjustments for wind-induced gauge undercatch, changes in instrument types and differences in observing methods. The annual map has isolines at every 100 mm up to 600 mm and at every 400 mm for higher amounts. The maps for January and July have isolines at every 15 mm up to 60 mm and at every 50 mm for higher amounts.

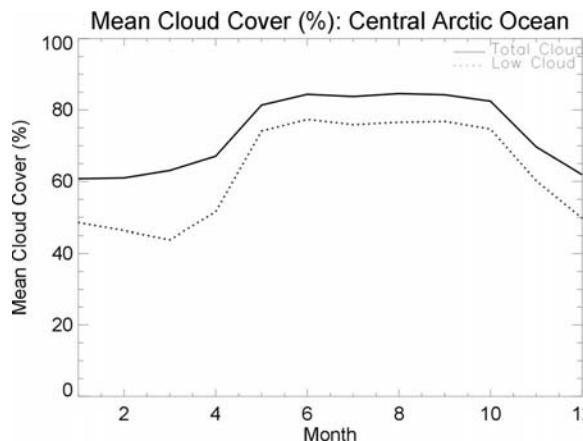

Figure A51 Mean monthly cloud cover (%) for the central Arctic Ocean based on available surface-based observations. Total (low-level) cloud cover is indicated by solid (dotted) line.

low-level stratus. While, traditionally, this summer increase is viewed as an airmass modification process whereby relatively moist air is chilled as it passes over the cold sea ice cover, the formative processes are not completely understood (Beesley and Moritz, 1999). The seasonal cycle of total and low-level cloud cover for the central Arctic Ocean is illustrated in Figure A51. While the dominance of low-level clouds is obvious, one can nevertheless observe many of the basic cloud types observed in middle latitudes. Perhaps surprisingly, convective cloud cover is frequent during winter over the Norwegian Sea – cold outbreaks from the north, when reaching the fairly warm, ice-free waters, result in destabilization of the air. Winter also finds low-level ice crystal clouds and “clear-sky” ice crystal precipitation (often termed “diamond dust”) in stable boundary layers, along with ice crystal “plumes” emanating from open leads.

Surface energy budget

The surface net allwave radiation flux (the sum of shortwave and longwave exchanges) in the Arctic is negative for most of the year. Surface-based and satellite-derived sources indicate that, for the central Arctic Ocean, a net radiation deficit prevails from October through March, with winter monthly means of -20 to -35 Watts per square meter. There is a surplus from April through September, largest in July with typical means of $+80$ to $+95$ Watts per square meter. Winter deficits over land areas are broadly similar, but summer surpluses are higher, in the range of $+100$ to $+130$ Watts per square meter in July. That net allwave fluxes are small should come as no surprise. From October through March, solar radiation is either small or absent (6 months of polar darkness at the pole), such that the radiation budget is dominated by the longwave budget, which is almost always negative. Except in summer over land and ice-free waters, the high surface albedo (reflectivity in solar wavelengths) of snow and ice results in most of the incident solar flux being lost to space. The albedo of fresh snow exceeds 0.80 and is above 0.50 even for bare sea ice. Compared to other regions the Greenland ice sheet sees stronger net radiation losses in winter and smaller gains in summer. This is due to the high elevation, promoting stronger longwave losses, and the persistently high surface albedo.

With respect to the non-radiative terms, the fundamental difference between the surface energy budgets of the Arctic Ocean and tundra is the portion of net radiation used to melt snow and ice. Once the snow is melted from the tundra in summer, energy can be used in sensible heating and to evaporate water. By comparison, during summer, most of the available net radiation over sea ice is used for melt. This is consistent with Figure A49, which shows that July surface air temperatures over the central Arctic remain at about the freezing point. A major exception to the generally small turbulent heat exchanges over sea ice can be found in winter over leads and polynyas. Here, the exposure of warm, open water can yield sensible heat fluxes reaching 600 Watts per square meter.

A final point to be made is the strong role on the surface radiation budget played by cloud cover. For most of the year the cloud radiative forcing is positive in the Arctic, meaning that clouds have a warming effect at the surface. During polar darkness this can be fairly simply understood in that cloud cover represents an effective “blanket” that reduces longwave losses to space. When solar radiation is present the problem is more complex. One must consider the reduction in longwave losses in comparison to the reduction in the shortwave gains due to the cloud albedo, along with other factors such as shortwave absorption by clouds, the surface albedo, and multiple reflections between the surface and cloud base. Curry et al. (1996) review the problem.

Climate variability and change

The Arctic exhibits pronounced climate variability on interannual to decadal scales. A major source is the North Atlantic Oscillation (NAO). The NAO describes co-variability in the strengths of the Icelandic Low and Azores High (a semipermanent area of high pressure in the middle latitudes of the North Atlantic). When the Icelandic Low and Azores High are both strong, the NAO is in a positive state. Surface air temperatures are above normal over Eurasian Arctic lands and below normal over northeastern Canada. The North Atlantic cyclone track extends deeper into the Arctic Ocean and precipitation increases in the Atlantic sector of the Arctic. When the Icelandic Low and Azores High are both weak, the NAO is in a negative state, with roughly opposing climate signals. Climate signals associated with the NAO are best expressed in winter and have been recognized for centuries. In recent years many investigators have preferred to view the NAO as a component of a more fundamental northern hemisphere annular mode (NAM), popularly known as the Arctic oscillation, or AO (Thompson and Wallace, 1998).

From about 1970 through the late 1990s, the NAO and AO changed from primarily negative to positive states. Among other changes this has been attended by surface air temperature increases over most of the northern continental landmasses and the central Arctic Ocean (strongest in winter and spring), a downward tendency in summer sea ice extent, and changes in the circulation of the sea ice and ocean.

Global climate models predict that the effects of anthropogenic greenhouse warming will be amplified in the Arctic due to feedbacks in which variations in snow and sea ice extent, the stability of the lower troposphere and thawing of permafrost play key roles. There is some evidence that positive phases of the NAO and AO may be favored by increased greenhouse gas concentrations or stratospheric ozone loss. Interestingly, paleoclimate evidence suggests that Arctic temperatures of the late twentieth century were the highest of the past 400 years (Overpeck et al., 1997).

ARID CLIMATES

The Earth's variable climate is a function of an unequal distribution of solar radiation. Average yearly net gains in insulation occur equatorward of 36° latitude, and net losses poleward this latitude. It follows that variations in air temperature and atmospheric pressure occur about the planet, which drive atmospheric circulation and ocean currents. Moisture content in the atmosphere is a function of air temperature and proximity to water sources. Warm tropical air rises, expands, cools adiabatically, condenses, forms clouds, and yields precipitation throughout much of the tropical zone. A rotating Earth causes air masses to migrate poleward where at about 20–40° north and south latitudes the air subsides, compresses, warms adiabatically, increases its moisture-holding tendency, and ultimately results in very warm, dry air at the surface. This middle tropospheric warming inhibits deep convection necessary for heavy rain to form. Arid climatic conditions ensure many of the world's deserts reside within these belts of high pressure that ring the planet. The Arctic and Antarctic contain polar deserts which will not be addressed here.

Aridity

Aridity refers to the dryness of the atmosphere. Aridity is a function of a continuum of environmental factors including temperature, precipitation, evaporation, and low vegetative cover. Aridity indexes are quantitative indicators of the degree of water deficiency at a given location (Stadler, 1987). Perhaps the best-known methods at identifying the arid zones of the world are classified by Köppen (1931), Thornthwaite (1931, 1948), and Meigs (1953), although the term aridity index specifically applies to Thornthwaite's work. A brief summary of these three works follows, but a more comprehensive treatment of aridity indexes may be found under Aridity Indexes (this volume).

Köppen devised a method for the identification of aridity that took into account the season of occurrence of precipitation. Rainfall occurring during a hot summer is less effective than the same amount of precipitation falling in winter. He classified arid environments as BW for arid deserts and BS for semiarid steppe regions. He also created a subcategory to distinguish between hot (h) and cold (k) dry climates. The B classification (dry climates in which potential evapotranspiration exceeds precipitation) is assigned to a region meeting one of the following criteria relating to mean annual precipitation (R in centimeters), and mean annual temperature in °C.

1. At least 70% of R occurs during the warmer 6 months, and $R < 2T + 28$.
2. If at least 70% of R occurs during the cooler 6 months, and $R < 2T$.
3. If neither half of the year includes more than 70% of R and $R < 2T + 14$.

Thornthwaite (1931, 1948) created indices based upon a percentage of water deficiency and water need during a growing season. The *Aridity Index* $AI = 100 \times d/n$, where d is water deficiency or the sum of the absolute values of monthly differences between rainfall and potential evapotranspiration when rainfall is less than potential evapotranspiration, and n is the water needed at a particular site calculated as the sum of the monthly values of potential evapotranspiration for months having a water deficiency. He also created a *Humidity Index* $HI = 100 \times s/m$, where s is excess water representing the sum of the monthly differences between rainfall and potential evapotranspiration for the months when precipitation exceeds evapotranspiration; and m is water needed at a site calculated as the sum of the monthly values for evapotranspiration during months having excess rainfall. The higher the Aridity or Humidity Index, the more arid or wet the region respectively.

Thornthwaite (1948) combined the Aridity Index with a Humidity Index to form a *Moisture Index* ($MI = HI - 0.60 \times AI$). This is a measure of precipitation effectiveness for plant growth that takes into account deficiency and excess water at a particular site. A climate classification was developed from this index where a MI less than 0 is assigned semiarid, and a MI less than –40 is assigned arid. Thornthwaite further considered regions arid when annual precipitation is less than 33% of potential evapotranspiration, and semiarid when annual precipitation is between 33% and 67% of potential evapotranspiration. Despite these indices there is little agreement on the complex number of factors leading to aridity, or how aridity can be compared using these indices.

Meigs (1953, 1960), under the auspices of UNESCO's Advisory Committee on Arid Zone Research, devised a system that delimited the arid zone and identified climatic differences within the zone. He identified arid climates (A) as those in

which there is not enough precipitation for crop production. In addition, he identified an extremely arid zone (E) on the basis of a dry period of 12 months or more in which no precipitation fell (Thornthwaite's moisture index values of less than -40 can be used to make specific determinations of the boundaries of these zones).

Meigs followed Köppen in recognizing the importance of season of precipitation, and Thornthwaite in stressing heat as a factor essential for the growth and ripening of plants. Where water is available for irrigation in arid lands, temperature becomes a more important factor than moisture in the regional climate. Meig's maps of arid climate types include a number of subdivisions where the first digit represents the coldest month and the second digit the warmest month. A value of 03 indicates a winter month with temperatures below 0°C and 3 indicates a summer month with average temperatures of 20–30°C. Meigs distribution of arid climates is shown in the article on Deserts in this volume.

The arid environment

Arid environments occur at the poles, along the equator, on mountains, plateaus, below sea level, along coasts, and within mid-continents. They may be hot or cold climate types. Deserts grade imperceptibly into semiarid deserts forming expansive dry lands about the planet. Deserts are both arid and semiarid lands, and account for over 35% (>61 million km²) of the Earth's land area (Mares, 1999). They are not capable of supporting a continuous cover of vegetation, and in the dryer portions of the arid zone, vast areas are without vegetation. Shortages of water characterize the arid climate. Water becomes a critical resource for the survival of plants and animals struggling to survive in this harsh environment. Arid zones are broad expanses (fuzzy boundaries) in which xerophytic vegetation composed of shrubs and succulents is widely scattered. It is along the desert margins that humans have tested nature by encroaching on areas that are often considered best left in their natural state.

The effect of the clear skies on temperature is readily apparent in deserts. Temperature ranges of 15°C to 22°C are common and objects in the shade are appreciably cooler than those in the sun. Some of the highest temperatures ever recorded have been measured in the arid lands. The highest temperature (58°C) was recorded at El Azizia about 40 km south of Tripoli (Kendrew, 1961). Temperatures in the tropical deserts are generally lower than this, but are usually above 40°C each day during the summer months. Nighttime temperatures are normally 16°C to 18°C lower. In winter, freezing temperatures at or near the surface are not unusual at night. Arid lands in higher latitudes experience temperature conditions comparable to those of adjacent humid environments. Advection of warm and cold air into these areas is more frequent and radiational cooling and heating of less significance.

Arid environments suffer a negative water balance in that the potential evaporating moisture exceeds the moisture supply provided by rainfall; therefore, potential evapotranspiration (the amount of moisture that would evaporate from soil and vegetation if a continuous supply of water were available) is directly proportional to temperature, wind speed, and relative humidity. Since transpiration is the most profuse of the two, if precipitation evaporates rapidly after falling, a much greater amount of moisture is required in the soil for the growth of plants than if precipitation evaporates slowly.

The results of climatic and human-induced arid conditions may initiate a threshold that spawns a physical transformation called desertification. The United Nations (1980) defines desertification as "a diminution or destruction of the biological potential of the land [which] can ultimately lead to desert-like conditions". In 1977 the United Nations announced that 35 million square kilometers were affected by desertification, and 35% of the Earth's surface at risk of similar changes. Disagreement exists on causes, processes, extent, and which changes are human-induced and what are natural. The question that begs to be answered is will the land that is desertified be reversible, and how much land is clearly at risk of change to deserts?

Identification and location of arid regions

In general terms arid regions (true deserts) typically receive less than 200–250 mm of irregular precipitation annually, with high evaporation rates. Hyperarid deserts receive less than 25 mm of precipitation annually, and have no rainy season and semiarid (steppe) regions receive greater than 250 mm and less than 600 mm of precipitation annually.

Deserts often form due to their proximity to cool, offshore ocean currents. Upwelling of colder water (Humboldt current off eastern South America, Benguela current off the southeast Africa coast) promotes cooler air at the lower contact with the ocean. Subtropical highs centered on the eastern half of oceans create equatorial movement of air along the western continental margins. This brings cooler, denser air to the warmer, subtropics enhancing the sinking motion associated with anticyclones. The relative humidity decreases, sharp temperature inversions develop that inhibit vertical convective activity, thus condensation and precipitation fail to develop. Little moisture is transferred from the colder waters flowing along the continental margins to air reaching land. The already dry, descending air mass becomes even drier, resulting in some of the most arid deserts in the world (Sechura/Atacama Desert system of Chile and Peru 20–28° south latitude, western Sahara Desert of west Africa 18–30° north latitude, Namib Desert of southwest Africa 18–30° south latitude, and the Sonoran Desert of southern California and northern Mexico 30–33° north latitude (Lydolph, 1973).

Continental deserts form as moist air traveling from the oceans, inland, loses its moisture (Gobi Desert of central Asia and central Australian deserts 40–50° north latitude). Rainshadow deserts form when moisture is removed as air rises, cools, and condenses on the windward side of mountain barriers, descends the leeward side, is compressed, and warmed (Great Basin in the USA). In those areas subject to surges of tropical air where thunderstorms occur, intensities near the centers of the storms are high, but duration is generally short. In those arid lands reached by tropical cyclones, rainfall intensities are great, and the storms can persist for several days, resulting in areas of heavy precipitation. Such storms are of particular significance in North America and Australia. In other arid lands, unusually heavy precipitation is generally associated with isolated thunderstorms that produce flash floods in desert washes and wadis.

In desert areas where virtually no rain occurs, dew and fog drip represent the only forms of atmospheric moisture available. In the coastal deserts of Peru and Chile, moisture obtained from the fog that moves inland across the Coast Ranges sustains a

moderately dense shrub forest. Because of the great amount of radiational cooling in the deserts, the formation of dew is a frequent occurrence. In the days of Roman occupation of North Africa, large rock piles above a cistern were used to collect dew for domestic water supply. Dew is an important contributor to the water budgets of many desert regions.

Perhaps the greatest amount of research into moisture sources in the arid regions has been directed at problems relating to reliability, frequency, duration, and intensity of precipitation. Generalizations about these matters are difficult because of the different kinds of atmospheric conditions that prevail in different parts of the world. For all of the arid lands it is safe to say that precipitation occurs infrequently.

Select references focusing on research organizations (Hunchinson and Varady, 1988; Hopkins and Jones, 1983), and discussions on world regional deserts (Mares, 1999; Ferrari, 1996; Bender, 1982; Petrov, 1976) are noteworthy.

World arid regions

One of the problems in delineating absolute boundaries to arid lands is that even the slightest climatic changes in these fragile environments may result in widespread changes in the natural and in human–environment relationships. Conversely, changes that humans make in the environment also result in changes in climate. General meteorological conditions are discussed for arid and hyperarid desert regions throughout the world. Table A26 lists many of the world's true deserts and hyperarid regions as classified by precipitation. Semiarid (steppe) regions are not included in this list.

African arid regions

The Sahara is a vast desert region that lies within the subtropical high-pressure belt. Across its northern margins, cyclonic storms that penetrate and cross the Mediterranean Sea from west to east drop precipitation, occasionally in the form of snow in the winter season. On the southern margins, precipitation is associated with the northward migration of the intertropical convergence zone. In the desert, dust storms associated with strong winds present problems for both sedentary agriculture and for migratory nomadic groups.

In southwest Africa, the Namib Desert along the coast and the Kalahari Desert inland are associated with the descending air masses and stable atmospheric conditions found at the eastern end of the South Atlantic subtropical high-pressure area. Portions of the Namib are extremely arid and devoid of vegetation. Stability of the air mass in the region is enhanced by cold upwelling water found on the coastal side of the Benguela Current. The outer desert of the Kalahari receives less than 250 mm of precipitation, while further into the interior precipitation amounts greater than 250 mm provide sufficient water to sustain a scrub forest.

Australian arid regions

Over half the continent is a desert with subtropical and tropical grasslands occupying much of the remainder. In the southern hemisphere summer the intertropical front dips southward into the continent, occasionally penetrating far into the desert interior. Runoff from heavy rains floods desert washes and creates vast playa lakes. Tropical cyclones affect the Queensland coast, and in the northwest the dreaded Willy Willies cause extensive

destruction to coastal settlements. Winter precipitation is associated with the troughs of low pressure that lie between the migratory anticyclones that encircle the globe north of Antarctica. Cold fronts force moist marine air to rise over the low hills and mountains of the coastal zones. The easterly flow of air on the backsides of the migratory anticyclones is forced to rise along the slopes of the Great Dividing Range to produce precipitation on the eastern coast of New South Wales and Queensland.

Within the Great Australian Desert differences in the appearance of the landscape resulting from variation in environmental factors are reflected in local names for that portion of the desert. The Great Sand, Simpson, Gibson, Great Victoria, and Sturt deserts reflect the variety of landscapes to be observed within the continent.

North American arid regions

The arid zone of North America comes under the influence of the belt of subtropical high pressure. Portions lie behind mountain barriers, and much of it is remote from sources of moisture. The driest portion, the Sonoran Desert, is dominated by the Pacific High for most of the year. In winter, occasional cyclonic storms penetrate the region, bringing small amounts of precipitation, occasionally in the form of snow. However, summer is the season of maximum precipitation. Afternoon thunderstorms associated with surges of tropical air may drop copious amounts of moisture on limited areas, causing temporary flooding. By far the heaviest precipitation and the most serious flooding comes with tropical storms that migrate into the area from the southeast Pacific Ocean in late summer and early fall.

In the Great Basin, maximum amounts of precipitation are associated with the cyclonic storms of winter that cross the area. However, these storms have lost most of their moisture in crossing the Sierra–Cascade barrier, and rainfall is generally light. Snow falling in the surrounding mountains represents a major source of water used in the region. In the summer season, thunderstorms forming in tongues of moist tropical air occasionally produce heavy rain and runoff.

The Chihuahua Desert of the Rio Grande Valley and north central Mexico lie in an area that is protected from air masses from the Pacific and Atlantic oceans by mountain ranges. Aloft, stable descending air limits the formation of convective storms. Heavy rains occur only in summer, when tropical hurricanes and easterly waves from the Caribbean and Gulf of Mexico penetrate the area.

South American arid regions

The Peruvian and Atacama Deserts of the west coast of South America are among the driest areas on earth. On the north, the intertropical convergence zone only occasionally penetrates more than several degrees south of the equator. When it does, a warm ocean current – El Niño – appears offshore and heavy rains cause innumerable problems for the irrigated oases of northwest Peru. On the south, the cyclonic storms of winter rarely bring precipitation much farther north than 32°S. Offshore, the cold Humboldt Current enhances the stability of the air in the South Pacific High, and fog frequently blankets the hills of the coastal zone.

On the eastern flanks of the Andes lie the deserts and grasslands of Argentina, Bolivia, and Paraguay. Storms sweeping out of the Pacific Ocean drop their moisture on the western slopes

Table A26 Desert regions about the world. Some deserts appear in both arid and hyperarid columns because of varied climate

Continent	Arid region	Hyperarid region
Africa	Namib Desert (southwest coast, Namibia/Angola). Libya Desert (Sahara). Sahara Desert (Nubian Desert in Sudan and Ethiopia). Sinai Desert (Egypt).	Libya Desert (Sahara). Namib Desert (southwest coast, Namibia/Angola).
Australia	Great Sandy Desert. Tanami Desert. Gibson Desert. Simpson Desert. Great Victoria Desert. Nullarbor Plain.	
North America (Mexico and USA)	Chihuahuan Desert (USA/Mexico). Great Basin Desert (USA). Sonoran Desert (USA/Mexico). Mojave Desert (USA).	Mojave Desert (USA).
South America	Peruvian/Chilean Desert. Monte Desert (Argentina). Patagonia.	Sechura Desert (Peru). Atacama Desert (Chili). Peruvian/Chilean Desert.
Asia	Sistan depression (Sistan Desert, Afghanistan). Ust-Urt (midwest Asia). Kyzyl-Kum (Uzbekistan). Kara-Kau (Turkmenistan). Bet-Pak-Dala (Kazakhstan). Kara Kum (Irano-Turanian Region). Turanian Plain (Irano-Turanian Region). Dusht-e-Kavir Desert (Iran). Dasht-e-Naumid Desert (Iran). Ala-Shan Desert (China). Gobi Desert (Mongolia/China). Takla Makan Desert (China). Thar (India/Pakistan). Syrian Desert (Syria/Iraq/Jordan). Negev Desert (Israel, western Arabian Desert, Sinai Peninsula). Ordos (China).	Registan (Afghanistan). Dusht-e-Margo (Afghanistan). Dusht-e-Lut Desert (Iran). Tsaidam Desert (China).

of the Andes Mountains. The desiccated air flowing downslope on the eastern side is warmed by compression, and contributes to the aridity of the region by absorbing the available moisture as it crosses the plains.

Two unusual zones of aridity are located along the northern coast of Venezuela and in northeast Brazil. Both of these areas have been the subject of intensive investigations and are considered to be somewhat anomalous. The Brazilian arid zone, in particular, has been of great concern to that nation because of recurrent drought and forced migrations from the region because of the lack of food and water.

Asian arid regions

The Arabian, Iranian, and Thar Deserts fall under the influence of the subtropical high-pressure area of the northern hemisphere, but are also located far from the principal source of moisture in the storms that cross the area. In the winter season, cyclonic storms that originate over the Atlantic Ocean or Mediterranean Sea pass through the area. However, only small amounts of moisture are left by the time the storms reach these interior locations. Additionally, mountains and high pressure tend to block their movements and divert the paths of the storms to the north.

The Turkestan, Takla-Makan, and Gobi Desert regions lie at the interior of the Eurasian continent, remote from sources of oceanic moisture and shielded from tropical air masses by gigantic mountain systems. In winter the Asiatic High blocks the movement of cyclonic storms across the region. In the summer the moist stream of air associated with the summer monsoon is diverted around the southeastern corner of Asia by the mountain masses of Pakistan, India, China, and Malaysia.

ARIDITY INDEXES

Aridity indexes are quantitative indicators of the degree of water deficiency present at a given location. A variety of aridity indexes have been formulated, although the term *Aridity Index* specifically refers to the 1948 work of Thornthwaite. Aridity indexes have been applied at continental and subcontinental levels and are most commonly related to distributions of natural vegetation and crops. Critical values of the indexes have been derived from observed vegetation boundaries. For instance, Köppen's 1918 classification defines the desert/steppe boundary as the 200-mm annual isohyet in regions where there is no seasonality of rainfall and the mean annual temperature is 5–10°C.

Formulation of aridity indexes is not straightforward due to the nature of aridity. First, aridity is a function of the interplay between rainfall, temperature, and evaporation. Use of mean annual rainfall as an index of aridity ignores the importance of temperature and evaporation. Aridity indexes that have gained widespread acceptance directly or indirectly take into account all three factors. Second, the arid regions generally have been recognized as having a paucity of climatological data. Given the temporal variability of precipitation inherent in arid regions, the lack of climatological data has been detrimental in attempts to quantitatively define the boundaries of aridity. Third, aridity indexes must be considered from the standpoint of their eventual use. For example, the 1968 US Army World Desert Classification defines aridity with respect to military operations;

application to world vegetation patterns would be inappropriate. A particular aridity index may serve several purposes, but no one index is appropriate for all uses. However, aridity indexes are often mathematically related and to some extent have been used interchangeably on a global scale.

Identification of the arid zones of the Earth has roots that can be traced two millennia. Classical Greek thought identified the latitudinally controlled torrid, temperate, and frigid zones of the world. Implicit in their thought was the concept that the torrid, low-latitude climates were arid. Not until long-term instrumental records and reliable world vegetation maps became available could true aridity indexes be developed. Thus, aridity indexes are a product of the twentieth century. Table A27 outlines the major developments regarding aridity indexes. For additional information, see Dzerdzeevskii (1958), Hare (1977), and International Crops Research Institute for the Semi-Arid Tropics (1980).

In 1900 Köppen originally qualitatively classified as arid those places that had desert vegetation. V.V. Dokutchaev in 1900 and A. Penck in 1910 qualitatively defined arid regions as places where annual evaporation exceeds precipitation. In 1905 both E.N. Transeau and G.N. Vyssotsky quantified this relationship. Yet this approach was not totally satisfactory because of the lack of reliable, worldwide evaporation measurements. Köppen's influential series of climatic classifications used mean annual temperature and precipitation combinations to define arid climates (1918, 1936). In a similar vein W. Lang's 1920 Rain Factor Index was a ratio between mean annual precipitation and mean annual temperature. Lang's index, and a modified version done by E. de Martonne in 1925, were widely used because their data requirements were minimal. However, their approach was limited in that the seasonality of temperature and precipitation were not addressed.

A. Meyer's 1926 Precipitation–Saturation Deficit Ratio was an attempt to obviate the need for dependable evaporation data. Meyer assumed the evaporation rate to be a function of the saturation deficit (saturation vapor pressure minus actual vapor pressure at a particular temperature). The Precipitation–Saturation Deficit Ratio was calculated from long-term temperature, precipitation, and relative humidity data and was found to be more reliable than temperature/precipitation-based indexes. Data availability limited the application of Meyer's ratio in that relative humidity data generally were not as available as were temperature and precipitation records.

Thornthwaite's work had an immense influence on the quantitative calculation of aridity. His Precipitation Effectiveness Index of 1931 is computed as ten times the sum of the monthly precipitation to evaporation ratio at a given location. Of practical importance was his accompanying empirical formula for deriving the Precipitation Effectiveness Index for stations recording only mean monthly temperature and precipitation. In 1948, and in subsequent revisions of his climatic classification, Thornthwaite employed the Aridity Index, which relates annual moisture deficit to annual potential evapotranspiration (see Water Budget Analysis). Weighted by 0.6 and subtracted from Thornthwaite's Humidity Index, the Aridity Index is a component of Thornthwaite's Index of Moisture. On the basis of the Index of Moisture, Thornthwaite categorized the world into nine moisture zones ranging from arid to perhumid. Evapotranspiration prominently figured in Thornthwaite's indexes, yet it was measured at only a handful of sites worldwide. So Thornthwaite devised a formula to estimate evapotranspiration through the use of a station's latitude and temperature.

Table A27 Selected summary of aridity indexes

Year	Author	Remarks	Formula
1900	W. Köppen	Xerophytic (arid and semiarid) climates qualitatively defined through presence of vegetative types. No formula used.	
1900	V.V. Dokutchaev	Defined aridity through comparison of annual precipitation with annual evaporation from a water surface. No formula used.	
1905	E.N. Transeau	Used ratio of annual precipitation to evaporation to describe aridity. Along with Vyssotsky, the first quantitative aridity index	$\frac{P}{E}$
1905	G.N. Vyssotsky	Used ratio of annual precipitation to evaporation to describe aridity. Along with Transeau, the first quantitative aridity index.	$\frac{P}{E}$
1910	A. Penck	Defined aridity through comparison of annual precipitation with annual evaporation from a water surface. An attempt to relate climate to landforms. No formula used.	
1911	E.M. Oldekop	Precipitation compared with potential evaporation. E computed by multiplying the saturation deficit of the air by a coefficient of proportionality.	$\frac{P}{E}$
1918	W. Köppen	Arbitrary climatic boundaries based on presumed vegetation boundaries. For example, desert and steppe were partitioned by 200 mm annual isohyet in areas where the mean annual temperature was 5–10°C; they were separated by the 320-mm isohyet where the mean annual temperature was 25°C. No formula used.	
1920	W. Lang	Rain factor. Mean annual precipitation (mm) and mean annual temperature (C) compared.	$\frac{P}{T}$
1922	W. Köppen	Precipitation compared formula at right. Several revisions of Köppen's scheme were formulated by the author himself and by others.	$2(T + 7)$
1926	E. de Martonne	Index of Aridity. A modification of Lang's Rain Factor Index.	$\frac{P}{T + 10}$
1926	A. Meyer	Absolute saturation deficit (mm of mercury) replaces evaporation.	$\frac{P}{D}$
1928	E. Reichel	Inserts the number of days with precipitation (N) in the formula of deMartonne.	$\frac{NP}{T + 10}$
1931	C.W. Thornthwaite	Precipitation effectiveness. Monthly precipitation to evaporation ratios determined, summed, and multiplied by 10 to eliminate fraction, (where n is an individual month, and T is the mean monthly temperature). For stations where evaporation data were not available, a formula using only precipitation and temperature data was provided. (Note: Formulae use English units.)	$\left\{ \sum_{n=1}^{12} \frac{P_n}{E_n} \right\} 10$
1932	V.B. Shostakovitch	t is the mean temperature during the growing period.	$\frac{P}{t10}$
1933	L. Emberger	An attempt to incorporate the effect of the seasonality of temperature on aridity. M is the mean maximum temperature of the warmest month and m is the minimum temperature of the coldest month.	$\frac{100P}{(M + m)(M - m)}$

Table A27 (Continued)

Year	Author	Remarks	Formula
1934	W. Gorozynski	Aridity coefficient. C is the cosecant of latitude, T_r is the difference between the means of the hottest and coldest months, and P_r is the difference between the greatest and least annual precipitation totals over 50 years. The coefficient increases with increasing aridity with its maximum value near 100. (<i>Note:</i> formula uses English units.)	$CT_r P_r$
1937	G.T. Selianinov	Effectiveness of precipitation in the growing season. Only mean monthly temperatures above 10°C are summed.	$\frac{P_{10}}{\sum_{n=1}^{12} T_n}$
1941	N.N. Ivanova	Calculation of a precipitation “potential” evaporation ratio using the formula at right where t is the mean monthly temperature and a is the mean monthly relative humidity.	$\frac{P}{E}$
1942	E. de Martonne	Modification of earlier work incorporating a representation of the temperature (T_d) and precipitation of the driest month (P_d)'	$E = 0.0018(25 + t)^2(100 - a)$
1947	N.V. Bova	Inclusion of soil moisture conditions in a precipitation/temperature ratio. H is the initial moisture content of the soil.	$\frac{H + P}{\sum_{n=1}^{12} T_n}$
1948	C.W. Thornthwaite	Represents a water balance approach to aridity where I_h is the Humidity Index, s is the surplus moisture in the humid season, n is the water deficiency in the dry season, I_a is the Aridity Index, and I_m is the Moisture Index. Later modifications were made to this work.	$I_h = 100 s/n$ $I_a = 100 d/n$ $I_m = I_h - 0.6I_a$ $I_m = \frac{100s - 60d}{n}$
1948	V.P. Popov	Index of Aridity. Σ_g is the annual effective precipitation, $t - t'$ is the mean annual wet bulb depression, and r is a factor based on daylength.	$\frac{\Sigma_g}{2.4(t - t')r}$
1949	J.A. Prescott	Refinement of earlier formulae using precipitation and saturation deficit. <i>Note:</i> This method uses English units.	$\frac{P}{0.7D}$
1950	A.A. Skvortsov	E_a , actual evaporation, compared to E_{st} , “standard” evaporation measured from a water surface.	$\frac{E_a}{E_{st}}$
1951	R. Capot-Rey	P and T refer to the mean annual precipitation and evaporation while p and t refer to the precipitation and evaporation of the wettest month.	$\frac{100 \frac{P}{e} + 12 \frac{P}{e}}{2}$
1951	M.I. Budyko	Radiational Index of Dryness. R is the mean annual net radiation and L is the latent heat of vaporization for water. This is the first index using a radiation balance approach.	$\frac{R}{LP}$
1952	S.J. Kostin	Precipitation versus potential evapotranspiration for the same period.	$\frac{P}{PE}$
1953	P. Meigs	Use of Thornthwaite’s Moisture Index to classify and map the dry lands of the Earth. No formula used.	

Table A27 (Continued)

Year	Author	Remarks	Formula
1955	H. GausSEN	Classification based on the duration and severity of dry months. A dry month is defined by the conditions at right. Other factors considered by GausSEN's definition of aridity include number of rainy days, humidity, mist, and dew.	$P \leq 2T$
1957	F.R. Bharucha and G.Y. Shanbhag	A reuse of the P/E index using the formula at right. E is the mean 24-hour evaporation in inches, B is the mean wind velocity in miles per hour, h is the mean relative humidity in percent, and e is the mean vapor pressure in inches of mercury.	$E = (1.465 - 0.0186B) \\ (0.44 + 0.11BW) \frac{100}{h} - 1e$
1960	P. Meigs	Revision of 1953 maps. This work has become the most widely used identification of the world's arid regions.	
1962	V.M. MeherHomji	Index of Aridity-Humidity. S is the "precipitation quantity factor" and X is the length of the day period.	$S + X$
1965	C. Troll	Defined arid climates on the basis of number of months that the expression at right holds true.	$P > PE$
1967	C.C. Wallen	Interannual variability (V_I), where n is a particular year in a series of N years. The second equation is an empirical one that describes the arid margin of dryland farming.	$V_I = \frac{100 \sum (P_n - 1 - P_{n-1})}{\bar{P}(N-1)}$
1967	J. Cocheme and P. Franquin	Matches water availability to a crop's growth cycle through a comparison of the values of precipitation and evapotranspiration (ET). Can be used for any growing period.	$P \text{ vs. } ET \\ V_I = 0.07P + 22$
1968	US Army	World Desert Classification. Based on rainy days per month with a rainy day defined as any day with greater than 0.1 inch of precipitation. Months are categorized in four categories by the categorization of the cumulative number of wet months in a year. Used with respect to men and military equipment.	
1969	H. Lettau	Approaches aridity from the standpoint of surface energy and moisture fluxes. B is the Bowen Ratio (cf. the ratio of sensible to latent heat fluxes) and C is the annual water surplus divided by the precipitation. The formula is equivalent to Budyko's Radiational Index of Dryness.	$(1 + B)(1 - C)$
1970	W.K. Sly	The ratio of growing-season precipitation to total amount of water required by the crop if lack of water is not to limit production. P is the growing season precipitation, SM is the start of the growing season, and IR is the calculated irrigation requirement during the growing season.	$\frac{P}{P + SM + IR}$

Table A27 (Continued)

Year	Author	Remarks	Formula
1971	G.H. Hargreaves	Moisture Available Index (MAI). For a specified period the ratio of the monthly rainfall total expected with a 75% probability to the estimated potential evapotranspiration. Values of 1.00 to 0.00 were considered increasingly moisture-deficient.	$\frac{P_p}{PE}$
1979	UNESCO	Map of the World Distribution of Arid Regions. Based on the ratio of precipitation to evapotranspiration with evapotranspiration being determined by Penman's method. This work was intended to replace Meigs's 1960 work.	$\frac{P}{ET}$
1980	R.P. Sarker and B.C. Biwas	Modification of MAI to consider weekly periods, various levels of rainfall total probabilities so that P_A is the assured rainfall of a period and PE is the potential evapotranspiration for the same period.	$\frac{P_A}{PE}$

Notes: Dates given are first appearance in the literature. All formulae are in metric units unless otherwise noted. Symbols have been modified from original sources for purposes of comparison.

His concepts have gained wide use because of the simplicity of their data requirements and their general agreement with world vegetation patterns. However, some engineers and agriculturalists have criticized his methods as too general for use in specific applications. The formulae have been found to produce unreliable results in certain tropical locales.

Budyko (1951) offered a new approach by considering the heat and water balance equations of the Earth's surface. His Radiational Index of Dryness was the ratio of the mean annual net radiation (i.e. the radiation balance) to the product of the mean annual precipitation times the latent heat of vaporization for water. The warm dry conditions synonymous with arid regions are well characterized by Budyko's index. In practical terms the Radiational Index of Dryness is the number of times the net radiative energy income at the surface can evaporate the mean annual precipitation. Although a number of writers have preferred Budyko's method of calculating aridity, a major limitation in application is the lack of long-term radiation records at many observation stations.

Other indexes have tended to be refinements and hybridizations of the above notions. Of recent interest has been the use of aridity indexes to define the agricultural boundary between arid and semiarid climates. UNESCO, FAO, and WMO are in accord that the boundary should be drawn where lack of water makes dryland farming impossible. Thus, aridity indexes are gaining increased importance in the planning of water supplies for crops.

Meigs's maps (1953, 1960) have been the most widely cited classification of aridity. Meigs used Thornthwaite's Moisture Index to define aridity. The 1:2 500 000 Map of the World Distribution of Arid Regions (UNESCO, 1979) has been produced to refine Meigs's maps. In this latter work approximately one-third of the world's continental surface is classified as having some degree of aridity.

Although UNESCO's 1979 map continued use of the ratio of precipitation to evapotranspiration, evapotranspiration was calculated by the more-favored Penman method. Calculation of aridity indices usually includes an input of evapotranspiration. The present international consensus is to estimate reference evapotranspiration using the Penman-Monteith formula (Allen et al., 1998). This formula is state-of-the-art but needs relatively esoteric atmospheric and soil input such as solar radiation and ground heat flux; if such data are not available locally, they can be estimated. An excellent explanation and commentary of operational drought-related aridity indices was compiled by Heim Jr. (2002).

Traditionally, climatologists and agriculturalists have used long-term weather data from standard weather shelters to create maps of aridity at Earth's surface. The difficulties of interpolating between observation points have created profound uncertainties in areas where data are sparse. For instance, there has never been a worldwide map of Thornthwaite's Moisture Index. The advent of satellites with continuous coverage of immense areas over a course of years has had a profound impact in the use of aridity indices. Recent advances in the archiving and collation of data have allowed worldwide monitoring of aridity as opposed to hindsight assessments.

The most commonly used satellite measure is the Normalized Difference Vegetation Index (NDVI). Derived from the Advanced Very High Resolution Radiometer (AVHRR) on the NOAA polar orbiter series, the NDVI at a location is closely related to the proportion of photosynthetically absorbed radiation that can be calculated from a ratio of reflectances in visible (0.58–0.68 μm) and near-infrared (0.725–1.1 μm). AVHRR channels:

$$(CH_2 - CH_1) / (CH_2 + CH_1)$$

Channel 1 (CH1) is the reflectance in the visible and Channel 2 (CH2) is the reflectance in the reflective infrared. CH1 is sensitive to chlorophyll's absorption of incoming radiation, and CH2 is in a portion of the spectrum in which the mesophyll structure in leaves causes great reflectance (Tucker et al., 1991). As the NDVI values increase, this infers increasing amounts of biomass. Active biomass is largely controlled by climate, so NDVI is essentially an aridity index when time series of values are calculated over area. Multiyear data sets are needed so as to sort the phonological effects of green-up and senescence from atmospheric variability.

Near-real-time monitoring of aridity to assess drought is now possible. Surface and satellite measures of short-term drought/aridity can be combined to provide operational assessments. An example of this sort of work is given by Svoboda et al. (2002). By using a blend of the Palmer Drought Severity Index, CPC Soil Moisture Model Percentiles, USGS Daily Streamflow Percentiles, Percent of Normal Precipitation, the Standardized Precipitation Index, and the Satellite Vegetation Health Index, a weekly Drought Monitor index value is calculated for each US climate division. The results are mapped and widely distributed.

As latter-day aridity monitoring and research continues, the climatological prospects are exciting – “intellectual descendants” of the aridity indices of the early 1900s are providing useful decision support to policymakers. As time progresses and time-series of these products achieve climatological proportions, academic analyses should offer unprecedented dynamism to our concepts of aridity.

ART AND CLIMATE

“Art and Climate” is the title of an article published by Richard Wagner, the famous German musician, in 1841. Wagner explains in the introduction that his opinions on the future of Art had been criticized for failing to take into account the *influence of Climate upon man's capacity for Art*. Broadly this criticism suggested that northern Europeans had a poorer capacity for art than those who were blessed with the Ionic skies of the warmer climates of the Mediterranean. Wagner was not impressed with this criticism and set out to prove in the article that “Everywhere, in every climate, will these works of Art be inspired by native skies: they will be beautiful alike and perfect”. However, many of Wagner's ideas have been controversial and considered almost racial and linked to what Livingstone (2002) has called moral climatology. Hence we have to be careful and state that the quality of art in a region is not in any way determined by climate. Climatic determinism will undoubtedly influence the content but not quality of art. Climate will therefore influence art but can art influence climate? Oscar Wilde, writing in 1889, certainly thought so:

At present, people see fogs, not because there are fogs, but because poets and painters have taught them the mysterious loveliness of such effects. There may have been fogs for centuries in London. But... They did not exist till Art had invented them (Wilde 1889: 925)

The climate of a region can be considered to be a restraining influence on the weather – keeping it within a season's allowable array. No such simple definition can be offered for “art”, a term derived from the Latin *ars* that, like the equivalent Greek word, also means science, skill, craft, ruse, etc. Here, art is defined as the manifest expression of the human experience in response to stimuli from the outer and inner world.

These expressions assume a multitude of forms, but only those that have significant relationships to climatic features as stimuli are considered here. Nevertheless, it should be mentioned that in architecture, e.g., the thickness of the walls of old houses in Europe is a function of the continentality of the region (Landsberg, 1958); or a bridge over the Oreto river at Palermo, Sicily, built in AD 1113, indicates that it originally spanned a much larger river, i.e. during a moister period in the Mediterranean area than prevails in our time (Lamb, 1968). Outdoor sculpture, an art related to architecture, can suffer from the ravages of wind, hydrometeors, and air pollution.

Another powerful medium for expressing human experience is the “international language” of music, vocal and instrumental, which is not limited to titles or texts that refer to climatic features, such as “Seasons” (Vivaldi, Haydn, Tchaikowsky, Glazunov), “Nuages” (clouds) by Debussy, or Brahms’ “Regenlied” (rain song). There is also musical imitation of weather sounds such as wind, thunder, even rain and lightning as, for example, in the fourth movement of Beethoven’s sixth symphony (Neuberger, 1961; Burhop, 1994).

A much wider range of atmospheric imagery is used in language, i.e. written or verbal prose or poetry, including drama and comedy (Aristophanes, 423 BC) and pictorial art using various media, but excluding sculpture.

Language

The spoken word

When communicating with one another, people express not only their opinion about the topic of conversation, but in their language also express other experiences in symbolic form for the purpose of emphasis or as circumscription of situations, happenings, or emotions. Considering our continuing exposure to atmospheric properties and phenomena, it is not surprising that much of our idiomatic speech involves meteorological imagery. Phrases such as thunderous applause, lightning speed, whirlwind courtship, know which way the wind blows, to be under a cloud, hazy recollection, foggy notion, snow-white, thunderstruck, etc., involve the appropriate properties of the pertinent meteorological phenomena. Similar idiomatic expressions are also used in French, German, Italian, Turkish, and many other languages (Neuberger, 1961).

The written word

As in spoken language, meteorological imagery abounds in the literature of Europe, the Middle East and the Far East. Starting with the Bible, through classical Greek and Roman literature, and from the Renaissance (Heninger, 1968; Janković, 2000) to the present time, with parallels in the Asian literature, we find weather imagery and weather and climatic descriptions. They are used in prose and poetry, in drama and comedy, thereby providing, literally and figuratively, an “atmosphere” for the actions and events described or as substitute expressions of human emotions. Bone (1976) examines clouds in the poetry of Wordsworth, Byron, Shelley and Keats. Three anthologies of poetry (one in German) revealed that 1152 out of 2563 poems (i.e. 45%) contained references to meteorological elements.

It appears that the extent to which weather images or descriptions are used in writing, is linked to the severity of weather and climate; thus, one finds many more references to weather in the British, Scandinavian, German, and especially Russian literature than in French and that of the Mediterranean countries in which milder climates prevail. Heninger (1968), in his extensive analysis of a large number of meteorological references in the literature of England, also cites descriptions of, and literary reactions to, air pollution in London and its environs, resulting from the domestic and industrial uses of coal. The employment of coal as fuel started in the thirteenth century, and due to the resultant smoke has led to a higher frequency, greater density, and longer duration of fogs. Early writers have also remarked on the deleterious effects of smoke on people, plants, and buildings

(Brimblecombe and Ogden, 1977; Brimblecombe, 1988, 2000). Monet painted 95 images of the London smog (Thornes and Metherell, 2003).

Literature written before the establishment of observational networks in the nineteenth century can also give valuable clues to the climate and its variations over time in different regions. Chronicles written by the ancient Egyptians and Babylonians always included special meteorological and climatological events such as advances or retreats of glaciers, lake or river freezes, floods, storms, hail, heavy rains, etc. (Lamb, 1967, 1968, 1995; Watson, 1984; Durschmied, 2000). In the literature of ancient Greece, the epics of Homer, the writings of Herodotus, of Hippocrates (460–377 BC), who could be called the first bioclimatologist, and of others indicate that colder and wetter periods than now occurred over most of Europe throughout the first millennium BC (Frisinger, 1977).

Hundreds of references to climatological and meteorological phenomena can be found in the works of Shakespeare. For example, in Hamlet, Act I, Scene I, line 63 reads: “He smote the sledded Polacks on the ice”; this undoubtedly refers to the deep freezes of the waters east and south of Denmark, as well as large portions of the Baltic Sea in 1589–1590. This was part of a longer cold epoch that also featured significantly during the Thirty Years’ War (1618–1648).

An interesting point was raised by Bonacina (1939) when he compared written descriptions with paintings. Words can depict as many details of an atmospheric event as can paintings, but a description can also report changes or sequences of such events. Pictorial representations reproduce only a moment in an event; however, some Medieval and Renaissance artists tried to overcome part of this limitation by putting non-simultaneous aspects of a story on the same canvas.

Pictorial arts

General remarks

Although this category of the arts includes etchings, drawings, cave paintings, and pictorial decorations of pottery (especially those of classical Greece), only murals and paintings in the most usual sense of the term will be considered here. This is not to say that the other media cannot, or do not, represent, or at least give clues to, climatic features; but such is relatively rare. In drawings there are no colors by which to judge the condition of the sky or, in prints and pottery, the color range is very limited. Nevertheless, there is among the Tassili Frescoes in the caves of southeastern Algeria the depiction of pelican heads (Lhote, 1961) and of a canoe, probably used for hippopotamus hunting, that indicates the existence of lakes in about 3500 BC on what is now part of the African Sahara (Lamb, 1977). Also some decorated ancient Greek pottery shows ships with billowing sails, implying wind.

Excluded from consideration here are the murals of the ancient Greeks and Romans; there are too few of them from which to draw significant conclusions with respect to climate. Yet, according to the late art historian, Dr H.W. Janson, (personal communication, 1968), there is an

almost complete lack of any clouds in ancient Roman painting. There are plenty of landscape backgrounds, but the skies are almost invariably cloudless. Suddenly, from the 4th c. AD on, clouds begin to appear in large quantity... the change from no-clouds to clouds occurs in a few decades.

This art-historic fact seems to correlate with the increase of nocturnal cloudiness in the zone between 30°N and 50°N latitudes from AD 300 to 500 as calculated from the frequency of discovery of comets in Europe and elsewhere. As in Roman paintings, the classical Greek and Etruscan frescoes and later the Byzantine school of painting contain only an occasional sky background. In general, Western art during the Middle Ages showed a preference for gold backgrounds in lieu of skies. It is only in the transition period to the Renaissance, starting perhaps with the turn of the fourteenth century, that artists seemed to become more aware of the pictorial opportunities of their natural environment; the awareness of nature being the hallmark of the Renaissance spirit.

Paintings

A visit to any art gallery, excepting those that exhibit abstract art exclusively, clearly shows that in every century many artists have chronicled almost everything in their own environment: fauna and flora, architecture, furniture, foods, fashions, weapons, utensils, tools, toys and games, sports equipment, and musical instruments.

Considering the powerful influence of the atmospheric environment on all life forms, we can expect that artists also became chroniclers of the climates they experienced. The expression of climatic features in art can be achieved in two

mutually nonexclusive ways: (1) directly in pictorial representation of clouds, frozen ponds, snowy landscapes, etc.; or (2) indirectly by images of people wearing heavy clothes, indicating low temperatures, or of a flowing scarf, billowing sails, waves on bodies of water, and the drift of smoke, all indicating wind. An example of the first category is "Storm over Taos" by John Marin (1872–1953). This painting shows a forcefully executed sky with a towering thundercloud on the left, a descending shower in the middle, and zig-zag lightning on the right (Figure A52). This watercolor also shows that modern painters have not abandoned the representation of nature. An example of the second category is "Lady at the Harpsichord" by Jan Miense Molenaer (1610–1668), painted between 1635 and 1640. The lady's attire is made of very heavy materials; it must have been quite cold, indeed. In order to avoid contact with the cold tile floor her feet are propped up on a footstool with a ceramic brazier, presumably containing hot coals (Figure A53). Another interesting feature is the landscape with clouds painted on the inside of the spinet cover by which the artist brings the outdoors into the room. Many other artists similarly have painted indoor scenes with windows or open doors through which a view of sky and clouds was admitted.

It appears that artists have used atmospheric imagery in several ways: as a decorative or incidental feature, as a primary subject, and/or as a symbolic support of or contrast to the emotional content of the human scene.

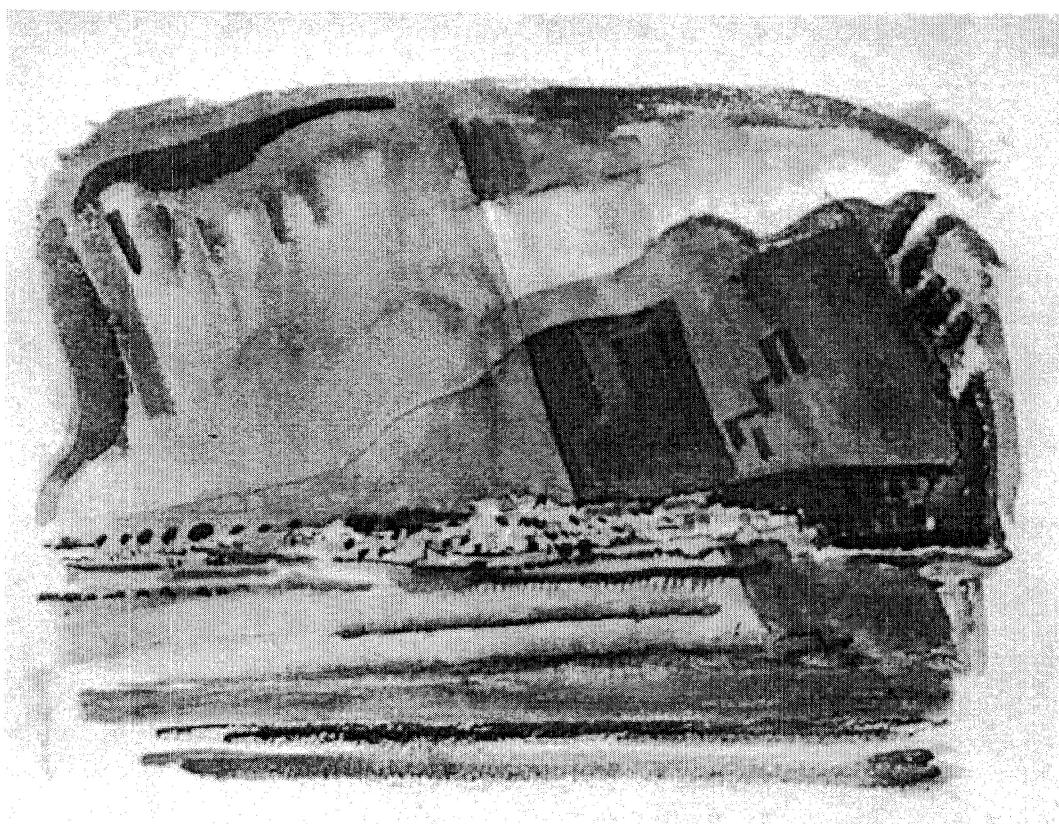

Figure A52 "Storm over Taos", by John Marin (courtesy of the National Gallery of Art).

Figure A53 "Lady at the Harpsichord", by Jan Miense Molenaer (courtesy of Fotocommissie Rijkmuseum Amsterdam).

An example of the first category is seen in Molenaer's painting mentioned above; the landscape inside the harpsichord cover is merely a decorative element. The painting by John Marin is representative of the second category, as the title indicates. The title of a painting, however, cannot be considered the main criterion for the subject category. For instance, "Breezing Up", by Winslow Homer (1836–1910), while showing a large amount of the canvas covered with an almost overcast sky and an agitated ocean, is basically a scene of human activity, namely, three boys and a man in a sailboat (Figure A54). For the purpose of this article, any painting in which the sky and/or other atmospheric phenomenon is the dominant feature can be considered a meteorological or climatological painting. The "Skating Scene", by the American painter John Tooe (1815–1860), belongs clearly to the second category, as the overcast sky, the snow-covered landscape, and the frozen

creek dwarf the skating scene proper (Figure A55). "Madonna and Child", by Giovanni Bellini (ca. 1430–1516), shows a sunlit strip of landscape in the middle and a few bright cumuliform clouds on the upper left; but then above the Madonna's head spreads an ominous dark thundercloud, a symbolic reminder of the future tragedy (Figure A56). This type of example can be found in innumerable religious paintings (Neuberger, 1961).

Many authors have written about the artist's perception of his or her climatic environment (Lamb, 1967; Botley, 1970; Gedzelman, 1989; Neuberger, 1970; Spink, 1970; Thornes, 1979, 1999; Burroughs, 1981; Walsh, 1991). A great deal of thought was given, not only to the esthetic aspects of clouds in landscapes, but also to the sudden and substantial increase of snowy landscapes in the sixteenth century, which coincided with the emergence of the "Little Ice Age". The first attempt at

Figure A54 "Breezing Up", by Winslow Homer (courtesy of the National Gallery of Art).

Figure A55 "Skating Scene", by John Toole (courtesy of the National Gallery of Art).

extracting quantitative information of climatic changes from paintings with respect to cloudiness was made by Lamb (1967); he demonstrated such changes by analyzing the amount of sky cover in 200 paintings of Dutch and British artists. He used only summer scenes painted between 1550–1568, 1590–1700, 1730–1788, 1790–1840, and 1930–1939; with such a small and biased sample the statistical results become uncertain, although

they are supported by other evidence. In order to test the hypotheses that the average climatic features derived from the paintings of many artists living in the same climatic epoch should be different for different climatic regions, and that such differences should exist for different climatic epochs, Neuberger, in 1967, evaluated 12 284 paintings in 41 art museums in 17 cities of nine countries.

Figure A56 "Madonna and Child", by Giovanni Bellini (courtesy of the National Gallery of Art).

The regional climatic differences

For determining the location of the artists, the art-historic classification according to countries and schools was the only method available. This does not account for the travels of many artists or their move to different countries and climates. Vincent Van Gogh (1853–1890), though considered a Dutch painter, moved to England, Belgium, northern France, and finally southern France, where he produced a great many paintings during the last three years of his life. This fact, together with the differences in style and idiosyncrasies of individual artists living in the same region at the same time and in the same climate, will tend to diminish the average differences. Another "handicap" is the fact that the indoor climates of different art galleries, as well as the age of the paintings, may alter, to a lesser or greater degree, the colors of the skies represented. These and other factors that operate against the verification of the above hypothesis will result in minimizing the statistical differences (Neuberger, 1970).

The regions

Only the following regions (art schools) were involved in Neuberger's study. *American*, which is essentially the eastern seaboard from Richmond, Virginia, to Boston, Massachusetts, where 90% of the artists surveyed lived and worked. For this region the climate of New York City is considered representative,

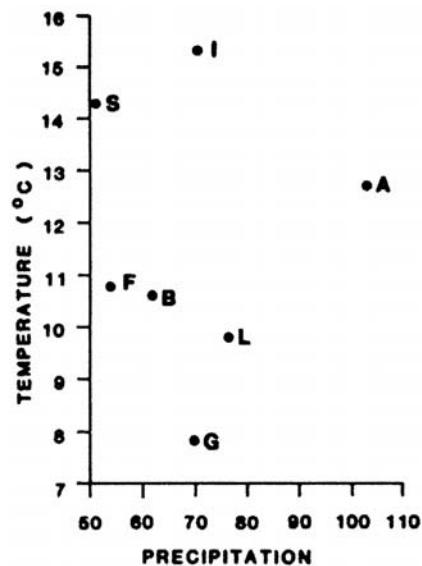

Figure A57 Mean regional annual temperatures and precipitation (in cm) for the period 1951–1960.

although the actual climate is different at both ends of the region. Finer detail of the climate did not seem to be warranted in view of the other factors mentioned above. *British*, with London representing the climate. *French*, with Paris representing the regional climate, although the same objection may be raised as in the case of New York City. *Low Countries*, combining Holland, represented by DeBilt, and Belgium, represented by Uccle: this combination is permitted in view of the great similarity of the climates as well as of the cultural aspects. *German*, including Austria, Switzerland and relatively few paintings from what is now the Czech Republic and Slovakia and adjacent countries – in other words, the central European region with Görlitz representing the regional climatic center. *Italian*, with Rome representing the climate. *Spanish*, represented by Madrid.

Figure A57 shows the regional differences of mean annual temperatures and precipitation for the seven regions, abbreviated with their initials, for the period 1951–1960. As will become evident in the evaluation of the paintings, the apparent similarity of the British and French climates is not always found in the paintings, largely because of the influence of the paintings by artists in southern France.

Climatic features in paintings

All paintings exhibited in each of the art galleries visited were evaluated with respect to the above-mentioned seven regions, the century and decade of the painting, the artist's name, the percent of canvas area covered by sky, the prevalent type and amount of clouds, the sky color (pale blue = 1; medium blue = 2; deep blue = 3), the visibility, i.e. the apparent transparency of the air painted in the picture (poor = 1; medium = 2; good = 3), and several other items. The qualitative values of sky color and visibility were subsequently converted into percentages by statistical means, so that the range from 0% to 100% would represent a very pale-blue to a

very deep-blue sky and a dense fog to a very clear atmosphere, respectively.

With respect to sky color and visibility, the possible effects of aging of the painting, its illumination in the museum, and of the technique used by the painter were anticipated at the start. Pointillists, like the French artists Seurat (1859–1891) and Signac (1863–1935), would produce more or less hazy-looking atmospheres in their paintings. However, since these and other influences would tend to negate the hypothesis, they were considered tolerable. It should be noted that, for the statistical evaluations, 325 works painted before the year 1400 were eliminated, chiefly because they had gold backgrounds or showed no sky or other climatic features; thus, the total number of paintings was reduced to 11 959. Although this seems to be a substantial statistical population, in reality it is only a minuscule sample of the total output by all the artists of Western culture, which must amount to hundreds of thousands of paintings. A hundred collections in the United States alone hold 43 143 works of American painters.

Regional differences in blueness of sky

In Table A28 the average blueness in percentages and the ratios of frequencies of deep-blue (d) to pale-blue skies (p) are presented for a total of 4411 paintings; the ratio d/p amplifies the regional differences by disregarding the medium-blue category. There is no significant difference between regions A, L, and F, but region B has by far the fewest deep-blue skies in its paintings. Central European paintings (region G) have 30 more deep-blue than pale-blue skies, and the Mediterranean regions S and I show a large predominance of deep-blue skies.

Regional differences in visibility

The average visibilities in percentages are given by regions for a total of 5601 paintings in Table A29. The results are similar to those in Table A28 in that there is little difference between the regions A, L, and F. The British region has the greatest opacity of the painted atmosphere, and central and southern European paintings show the highest transparency of the air. The statistical significance levels are 0.1% for all pairs of regions, except for A-L and F-S, and no significance for the difference between G and S.

Regional differences in painted clouds

Of each of the 5805 paintings with clouds, only the dominant cloud type was recorded according to the four commonly used categories: high, middle, low, and convective clouds. In Table A30 the relative frequencies of each of the four cloud families are shown. The highest frequency for each region is in boldface type. The average frequencies for all regions combined are 8% for high, 35% for middle, 25% for low, and 32% for convective clouds, showing the artists' preference for middle and convective clouds. A notable exception is seen in the artists of the British region who show a significant preference for low clouds.

The cloud amounts were estimated in the four categories: (1) clear (no clouds); (2) scattered (one-half or less of the sky area covered by clouds); (3) broken (more than one-half of the sky area covered by clouds); and (4) overcast (no blue sky visible). Table A31 gives the relative frequencies (percentages) of 6483 paintings in the four categories by region.

Table A28 Average blueness of painted skies by region

Blueness (%)	Region						
	A	B	L	F	G	S	I
40	35	44	45	54	79	70	70
0.5	0.3	0.6	0.7	1.3	8.1	3.9	

Table A29 Average visibility by region

Visibility (%)	Region						
	A	B	L	F	G	S	I
37	33	38	36	40	42	54	

Table A30 Average frequencies of cloud families by region

	Region						
	A	B	L	F	G	S	I
High clouds	5	5	5	9	11	6	9
Middle clouds	43	23	32	36	33	38	43
Low clouds	30	40	27	27	27	28	14
Convective clouds	22	32	36	28	29	28	34

Table A31 Relative frequencies of cloudiness categories by region

	Region						
	A	B	L	F	G	S	I
Clear	5	0	7	9	16	13	12
Scattered	16	4	11	10	16	13	24
Broken	47	48	44	49	42	38	42
Overcast	32	48	38	32	26	36	22

All regions show a maximum in the "broken" category, except that British painters avoided clear skies and showed as many overcast as broken skies. All regional differences are significant at the 1% or better level.

The average cloudiness for each region was statistically converted into percent cloudiness from the percent frequencies in Table A31. The results again show that the British painters have the greatest preference for very cloudy skies, whereas the Mediterranean painters prefer skies with considerably less cloudiness, as is evident from Table A32. The differences among the regions are significant at better than the 1% level.

Painted versus observed visibilities by region

Although Table A29 established regional differences in visibility painted, the question arises concerning the extent to which these visibilities correspond to the climatically prevailing visibilities. Actual observations at the stations shown in Figure A57 are available only since 1850, so that, for comparison, only the painted data for the period 1850–1967 are usable. Because the

painted visibilities were estimated in only three categories, the observed visibilities, which were recorded in different codes at the various stations, were also converted into three classes: 1 = visibilities less than 2.5 miles; 2 = those between 2.5 miles and 11 miles; 3 = those larger than 11 miles. Both sets of data were then expressed in percentages. Only 1677 paintings were available for the seven regions in the period 1850–1967. Table A33 shows that the observed data have a larger range and greater differences between regions. Both sets show minimum visibility for the Low Countries and maximum visibility for the Mediterranean regions. Nevertheless, considering the relatively small statistical sample and the coarseness of the estimates of painted transparency of the air, the fact that British painters paint a more transparent air than do the American and Low Countries artists seems to be supported by actual observations.

Painted versus observed cloudiness by region

For the comparison of painted with actually observed cloudiness, 1848 paintings were available for the period from 1850 to 1967. Figure A58 shows the observed versus the painted average cloudiness for each region. Although the artists exaggerate cloudiness, with the exception of the Italian painters, there is an excellent linear relationship between painted (P) and observed (O) averages with a correlation coefficient of 0.95 ± 0.03 and a regression equation $O_c = 0.5P + 26$ (O_c and P in percent). When we use the equation to compute O_c , we obtain the values in Table A34 in which the actually observed cloudiness averages (O) and the differences $O_c - O$ are given. These differences are well within the accuracy of the observations.

In summary, the quality of the relationships between the actually observed and the painted regional averages of visibil-

ity and cloudiness in the period from 1850 to 1967 permits the conclusion that the collective experience of climatic features by artists in a given region finds its expression in paintings that correspond well to the actually observed average values.

Climatic changes in paintings

The last major ice age ended about 12 000 years ago. However, the warming trend during the postglacial period was not a steady, continuous process but had intermittent relapses into colder periods. The so-called Little Ice Age was the latest and probably the best-documented excursion of climate that affected the entire northern hemisphere (Lamb, 1967). There is disagreement as to when it started. It seems to have emerged slowly with the beginning of the sixteenth century, although there were some precursors of it in the preceding century. The end can be dated more easily, as a warming trend set in by 1850. In general, the Little Ice Age was an epoch of frequent wet and cold years. Southward displacement of storm tracks brought snow and ice into the Mediterranean regions and rapid advances of Alpine glaciers and other climatic disasters occurred all over Europe (Neuberger, 1970).

Lamb (1967) has found from his brief survey of Dutch and British paintings that cloudiness increased from around the middle of the sixteenth century. With the large volume of data used here in Tables A28, A29, A30, and A32, averages combining the data of all regions were calculated for three epochs: the preculmination period of the Little Ice Age from 1400 to 1549; the culmination period of the Little Ice Age from 1550 to 1849; and the postculmination period from 1850 to 1967. In Figure A59 these averages show that there was a substantial paling of the blue color of painted skies toward the culmination period, but no recovery afterwards. The same trend is true for visibility. The failure of sky blueness and visibility to improve in the last epoch is in part due to the effects of the techniques of impressionism, which created a hazy atmosphere by the uncertain contours resulting from short brush strokes. This method reached its extreme in pointillism. On the other hand, this trend should have been counteracted by expressionism with its bold colors and sharp contours. It seems reasonable to assume that in the postculmination period the progressive industrialization, with its attendant air pollution, diminished both the blueness of the sky and the transparency of the air. The combined frequencies of low and convective clouds, both of which may lead to

Table A32 Average percent cloudiness by region

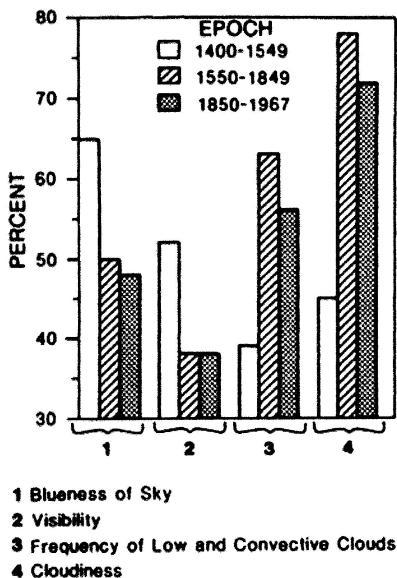

Figure A59 Averages for all regions of climatic features painted in the preculmination period, the culmination period, and the postculmination period of the Little Ice Age.

precipitation, show a strong increase from the first to the second epoch and a reduction in the third epoch. Similarly, the cloudiness has a large rise and a subsequent small decline, the latter probably being caused, at least to some extent, by human activities.

In conclusion, the collective climatic experience of artists in a given region at a given time is reflected in their paintings, notwithstanding the individual artist's techniques and intentions, or awareness of his or her surrounding climate. Subsequent physical and chemical effects of the climate on paintings are also reflected by the intensity and hue of the paint on the canvas. The importance of climate in the appreciation of landscape painting is now established and features in several recent art exhibitions such as "Impressionists in Winter" (Moffett, 1998); "Constable's Clouds" (Morris, 2000); "Holland Frozen in Time" (van Suchtelen, 2001).

Literature and Climate

ASIA, CLIMATES OF SIBERIA, CENTRAL AND EAST ASIA

Central Asian, Siberian, and East Asian mega climatic regions, located on the world's largest and most physically diverse continent, are experiencing a period of marked climatic change. The impact of climatic change is affecting the lives of nearly

two billion people. With more climatic types than any other continent, and with one-third of the world's land mass, any perturbation of Asian weather and climate is biophysically and socioeconomically important. Containing the highest point above sea level and the coldest inhabited place on earth, Asia's location and geomorphology contribute much to climatic diversity. Major variations of climatic types are defined by receipt of solar energy, moisture from the Atlantic Ocean in the west and the Pacific Ocean in the east, and the powerful Siberian Winter High Pressure Cell. A decrease in temperature occurs from south to north, with an increase in continentality from west to east. Latitudinal variations of climate are significant.

Asian climates

Using the Köppen climatic classification, north and east Asia may be divided into three major climatic realms: Siberia or Northeast Asia in the north (Dfb, Dfc, Dwa, Dwb, Dwc, Dwd, and ET); Central Asia or Desert Asia in the west and center (BS and BW); and East Asia or Monsoon Impacted Southeast Asia (Cfa and Cw). Siberia or Northeast Asia is the largest. A complex set of interactive climatic controls and many multifaceted physiographic features influence local climates and give distinctive regional climatic character to places (Figure A60). One of the most impacting and heat-determining factors is the length of day and night at different latitudes, particularly in Siberia and Central Asia (Table A35).

Siberia extends from the Ural Mountains in the west to the Pacific Ocean in the east. It is bounded on the north by the cold Arctic Ocean and on the south by Central Asia and South Asia. The climate of Siberia is one of the most continental on Earth, with great seasonal changes. The average frost-free period is only 75–82 days. Average annual precipitation ranges from 250

mm to over 2000 mm. During the winter Siberia is divided into two climatic parts: the northwest, dominated by frequent storms, high winds, and snow; and the southeast, dominated by clear skies and calm weather. A major part of Siberia is underlain by continuous permafrost, up to 1600 meters deep and extremely cold (-12°C). These factors impact temperature efficiency and moisture effectiveness in this region. The seasonal snow-melt layer is dynamical in space and time, impacts heat energetic conditions, and serves as diagnostic criteria for estimating global change or climate. Since the late 1960s a decrease in snow cover, a reduction in annual duration of lake and river ice cover, a temperature decrease, and significant changes in precipitation, cloud cover, temperature ranges, and drought frequency have occurred (Dando et al., 2003).

Along with a change in Siberia's climate, and an increase in urban conglomeration, urban climates have impacted all biophysical processes. Increased atmospheric humidity, increased absolute humidity, and extensive use of firewood and low-quality coal for heating and for power have induced a phenomenon that is detrimental to all cultural and physical activities – urban fog (Table A36).

East Asia, recording atypical weather perturbations, including persistent drought in normally moist areas and devastating floods in normally dry regions, is experiencing an unusually strong manifestation of global warming. Changes in high-pressure cell positions and characteristics, shifts in low-pressure cell locations and intensities, and a variation of jet stream seasonal paths have modified weather patterns. Warming of the atmosphere has increased evaporation, increased specific humidity, intensified drought, increased the amount of moisture in air masses, and increased the amount of moisture and energy in the air for rainstorms, snowstorms, typhoons, and tornadoes. Concomitantly, extreme cold temperatures in early winter, followed by anomalously warm temperatures in late winter, have disrupted natural processes in eastern Mongolia and northeastern China. Changes in precipitation regimes in spring, summer, and autumn in China and Japan have enhanced the potential for flooding. A combination of human activities that modify climatic elements and controls and natural causes of climatic change could lead to large-scale weather-related disasters and to a redefinition of the traditional boundaries of East Asia's climatic regions (Figure A61).

Climatic changes

In the 1999–2002 period a severe drought persisted across a large part of Central Asia, portions of south and southwest Asia, including Afghanistan, Iraq, Iran, Saudi Arabia, Syria, Israel, Turkmenistan, Uzbekistan, Kazakhstan, Tajikistan, Pakistan, and parts of India (Lawton, 2002). At the time it was the largest contiguous region of severe drought in the world. The International Research Institute for Climatic Prediction considered this widespread drought a “grave humanitarian crisis”. Scientists from the Ohio State University analyzing ice cores from glaciers in Central Asia noted a warming in this region over the past 50 years. At one site the recent warming and drying trend exceeded anything observed in the past 12 000 years. Current global warming has exceeded the normal range of climatic variations during the last 5000 years (Jones, 2001). Warming trends in Central and Desert Asia are not just natural fluctuations that will reverse quickly. Concomitant with the Pacific (SO) and North Atlantic Oscillations (NAS), humans have contributed to climatic changes in Central Asia. Drying of the Aral Sea is one of the best-known environmental disasters

caused by humans in the past three or four decades. There is widespread agreement in the scientific community that, with the reduction in Aral Sea level, the regional climate has changed for the worst and become more extreme.

Climatic elements

The unequal distribution of solar radiation over Asia is the primary factor in Asia's multifaceted weather and climate. In Asia's tropical belt the sun remains high with little seasonal variation, and this accounts for continuous warm to hot year-round temperatures. In Asia's mid-latitudes, solar radiation receipts

exhibit a strong seasonal maximum and a strong seasonal minimum which are reflected in greater seasonal variations in temperature than the tropical belt. And in Asia's high latitudes there is a period of limited to no solar radiation received at the surface of the Earth, resulting in a season with extremely low temperatures in the winter or low sun period (Figures A62 and A63). Total solar radiation received at the Earth's land – sea surface during the entire year in kcal/cm² per year ranges from 140 to 180 in Asia's tropical belt, 160 to 120 in Asia's mid-latitudes, and 100 to 60 in Asia's high latitudes. Maximum solar radiation received at the Earth's surface occurs in the steppe and desert regions of west-central Asia. Transformation of available solar

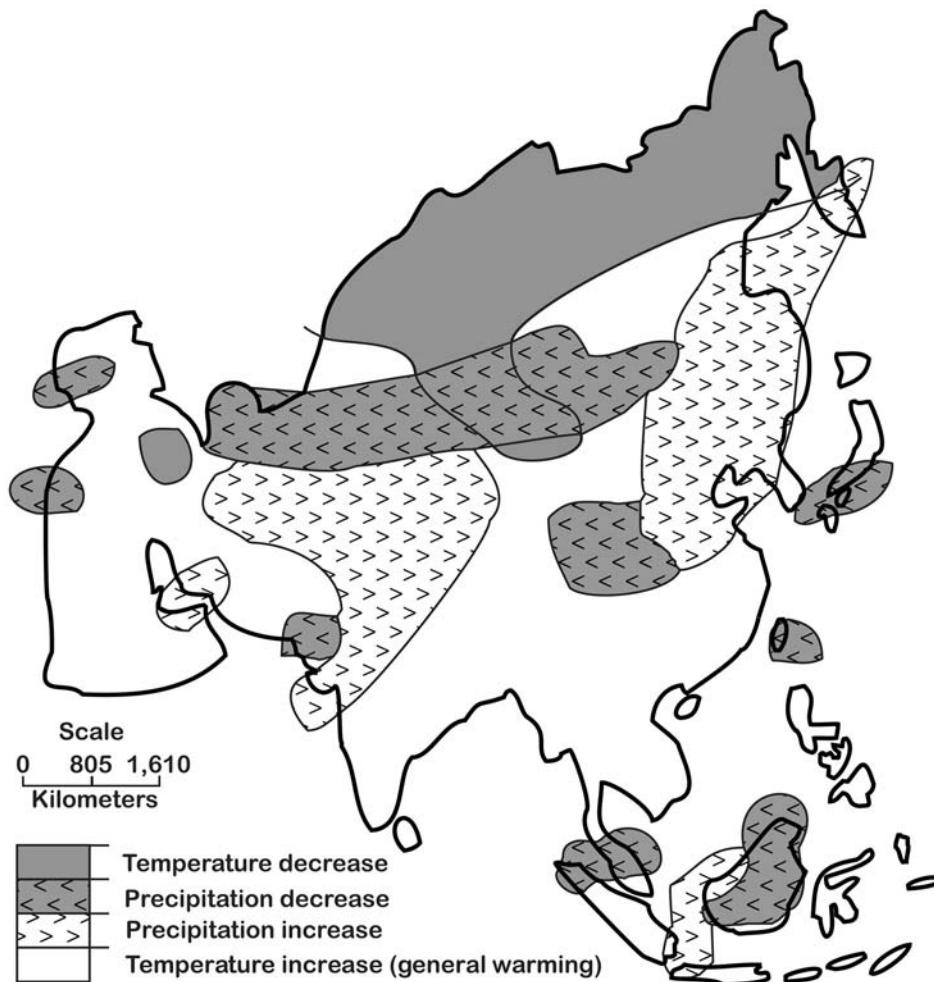

Figure A61 Trends in temperature and precipitation change: 1901–1998. Anna R. Carson 2003.

radiation is an essential ingredient of the process that produces Asia's climate – particularly temperature ranges (Borisov, 1965).

Temperature

Northern Asia, specifically Siberia, is climatically isolated from moist tropical air masses and records the greatest mean annual temperature range on earth (Table A37). At Verkhoyansk, in the valley of the Yana River, January temperatures average -49°C , July temperatures average $+15^{\circ}\text{C}$, and the absolute temperature range is 103°C . Oymyakon, located in the same physiogeographic region, records an absolute temperature range of 104°C . Siberian winter low temperatures are proverbial, and for most of Siberia the January mean annual temperature is less than -25°C . In contrast, much of southwestern Asia is subject to moderate heat (Arakawa, 1969).

The temperatures of eastern China resemble those of the eastern United States. Winter cP and cA air masses from Siberia are more powerful and colder than those that move south from Canada. Summer mT air masses from the South

Table A37 Average annual temperatures at selected Siberian stations (in $^{\circ}\text{C}$)

Station	Latitude (N)	Longitude (E)	Average annual Temperature

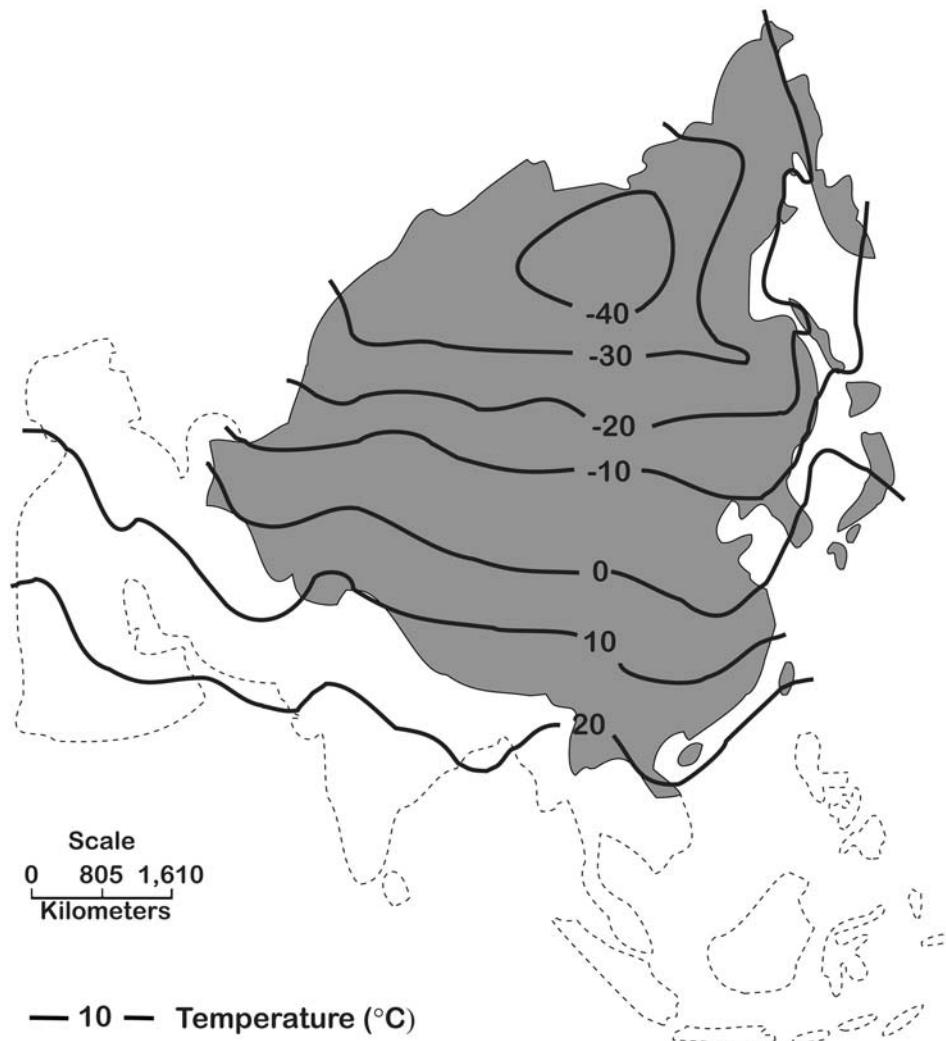

Figure A62 Average temperature: January. Source: *Geograficheski Atlas*, 1959, Moskva, p. 14; *Preroda i Resursi Zemli*, 1999, Moskva and Vienna, p. 52. Anna R. Carson 2003.

China Sea are stronger than mT air masses from the Gulf of Mexico. China extends farther north to south than the United States and has a wider range of climates and temperature regimes. China extends from 18° to 53° north latitude. This is the equivalent distance from Puerto Rico to Labrador. Concomitantly, no simple summary can give adequate insights into Japan's temperature regimes. The Japanese islands extend for 1400 kilometers or more and are surrounded by temperature-modifying ocean and seas. Irregularities in island topography induce sharp vertical temperature contrasts. The winter monsoon typically brings cold air masses and low temperatures from Siberia, while the summer monsoon brings warm, moist maritime air masses and warm, mild temperatures to Japan. The normal January temperature gradient is slightly more than 2°C per degree of latitude; the normal July temperature gradient is less than 1/2°C per degree of latitude.

Asia's spatial temperature differences and ranges are greatest in winter, least in summer, and more extreme in all seasons within the land-locked core, rather than the south and eastern maritime periphery (Figures A62 and A63). Winter isotherms reflect the influence of ameliorating ocean currents, mountain barriers, altitude above sea level, high-pressure cells, and solar radiation. Summer isotherms reflect solar radiation and latitude, along with altitude (Global Change, A and B, 1999).

Precipitation

Precipitation receipts, in general, increase from north to south and from the southwest to the southeast. Throughout most of Siberia the annual average precipitation is scarcely 250 mm and in parts of Central Asia, the Tarim Basin, and the Gobi Desert, less than 100 mm. In east China there are regions that receive

Figure A63 Average temperature: July. Source: *Geograficheski Atlas*, 1959, Moskva, p. 14; *Preroda i Resursi Zemli*, 1999, Moskva and Vienna, p. 52. Anna R. Carson 2003.

more than 2000 mm per year (Figure A64). A small part of China, north of Nepal, receives over 3000 mm annually. Seasonal distribution of precipitation becomes of greatest importance, for the summer heat and continental character of Asia affect precipitation effectiveness and thermal efficiency. In insular and island-studded southeast and east Asia, where there is limited or no frost, rainfall is relatively evenly distributed throughout the year (Cfa and Dfb). Interior and rainshadow locations in south and east Asia experience a distinct dry season in the low-sun period or winter (CW, Dwa, and Dwb). Mediterranean Sea-influenced west Asia and the dry eastern coastal region of the Caspian Sea receive most of their precipitation in winter, at least three times as much precipitation in the wettest winter month as the driest month of summer (Cs). Precipitation in the dry realms of southwest Asia, Central Asia, Tarim Basin, and the Gobi Desert is minimal and erratic, but most of the precipitation is secured in summer from violent convective showers (BW) or a combination of violent convec-

tive showers and frontal activity (BS). And in the subarctic and arctic areas of Siberia (Dwc, Dwd, and ET), summer is the season of maximum temperatures, highest specific humidity, deepest penetration of maritime air masses under the influence of the summer monsoon, and is the period of maximum precipitation (Figures A62 and A63). Asia's central dry realm separates Asia's eastern warm-to-hot wet belt from Asia's north and northeastern cool-to-cold limited precipitation belt (Griffiths and Driscoll, 1982).

Barnaul – an example of a precipitation regime impacted by continentality

Barnaul is located in Siberia, west of the Ural Mountains, in the extreme eastern portion of the zone of the Russian forest steppe. Barnaul's maximum monthly precipitation falls in July that is also the warmest month of the year. Precipitation is

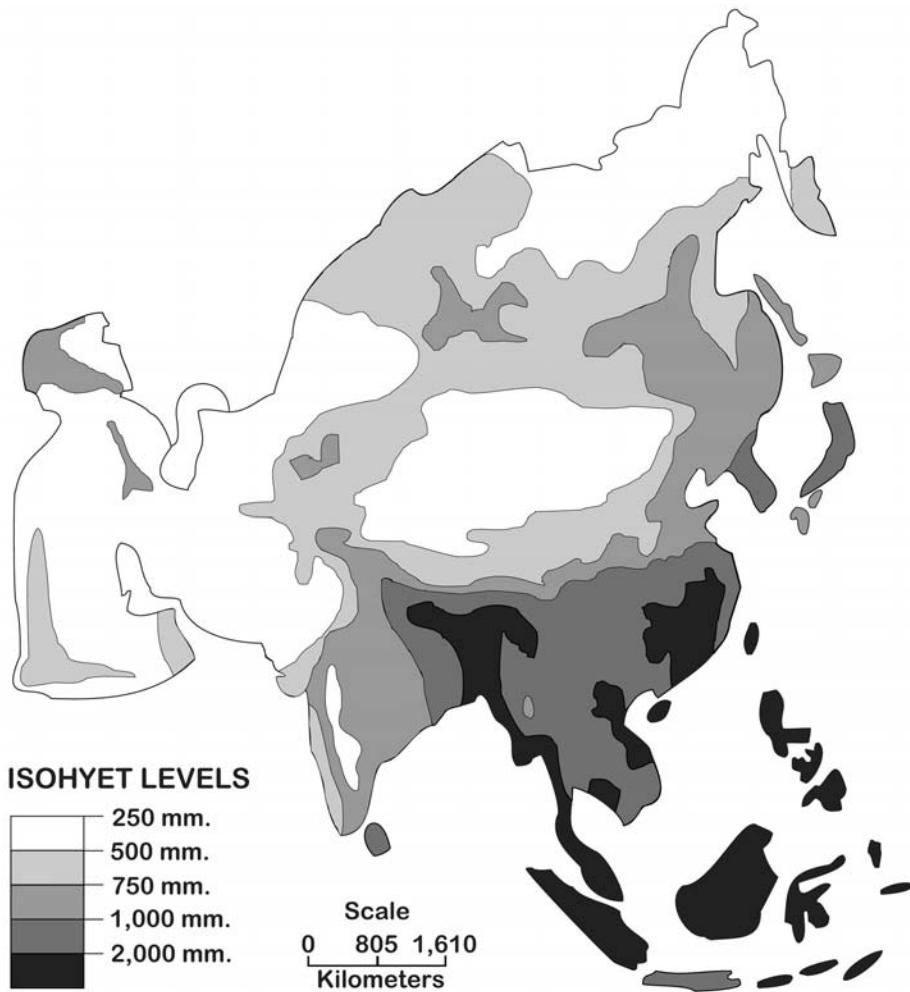

Figure A64 Asian precipitation. Source: *Geograficheski Atlas*, 1959, Moskva, p. 16; *Preroda i Resursi Zemli*, 1999, Moskva and Vienna, p. 56; *Oxford Economic Atlas of the World*, 4th edn, 1972, p. 2. Anna R. Carson 2003.

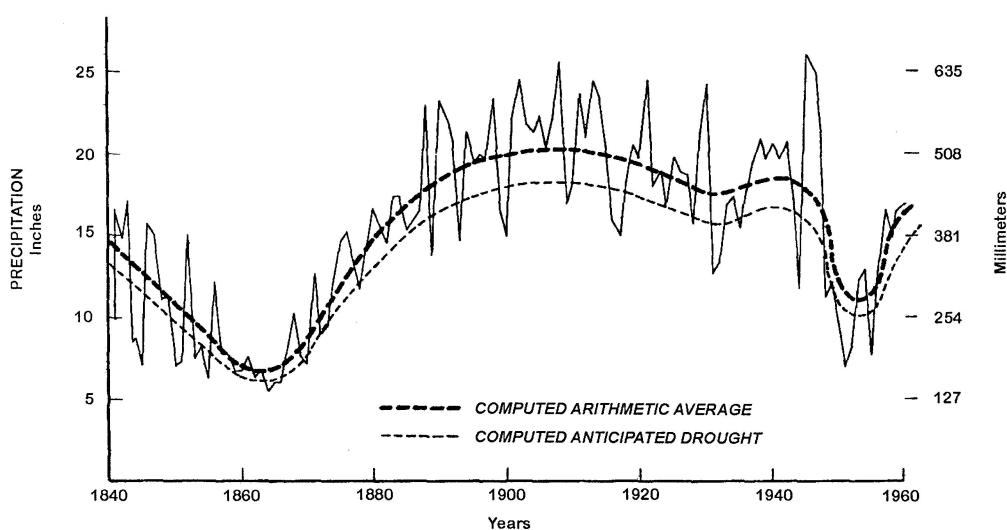

Figure A65 Barnaul – variation in precipitation, 1840–1960. Source: A.M. Shulyin, *Izv. AN USSR, serila geogr.*, 1963, no. 2, p. 168. Anna R. Carson 2003.

marginal for agriculture and for supplying moisture for economic development. Droughts are common, occurring once every 4 years on the average (Figure A65). A review of the climatic records for Barnaul from 1890 to 1966 shows that droughts were recorded in 1900–1902, 1904–1905, 1909–1910, 1917, 1920, 1923, 1927, 1929, 1931–1932, 1934, 1939, 1945, 1951–1952, 1955, and 1962–1963 (Figure A65). Analysis of precipitation data for Barnaul reveals a tendency toward the repetition of very moist years when all four seasons are wet or three seasons very wet and then a dry or very dry year or two followed by an average year or two.

Sukhovei – an Asian atmospheric enigma

Hot desiccating winds at times become associated with droughts, but these hot, dry winds or *sukhovei* can occur when there is no drought and can cause death to plants even when there are adequate reserves of moisture within the soil.

Sukhovei are hot, dry masses of air that envelop plants, increase evapotranspiration rates by factors of 2–3 to 20 times, and injure or destroy crops. Air in a *sukhovey* is so devoid of moisture that, in general, the relative humidity is less than 30% and, in many cases, less than 20% for an extended period of time. In a drought there are day and night variations in relative humidity, and at night dew may even form. In a *sukhovey* the relative humidity varies very little during the entire day/night period, and evaporation takes place continuously. The majority of cultivated plants cannot endure desiccation of their tissues; therefore the moisture lost to the atmosphere must be replaced by an inflow of moisture from the roots. Plants, unable to compensate for losses as a result of increased evaporation, lose turgescence, wilt, and die.

Sukhovei winds may reach speeds in excess of 70 miles per hour, but the usual velocity is from 7 to 11 miles per hour. Plant transpiration is increased by the most moderate wind speeds via the removal of water vapor from the apertures of the stomatal apparatus. Even wind with a velocity of 4–5 miles per hour increases plant transpiration threefold. When *sukhovei* winds achieve great speed they often turn into dust storms or so-called “black storms”, which remove vast amounts of unconsolidated material and even small plants over great distances. As much as 5 inches of soil have been removed from various steppe regions in one year by dust storms. *Sukhovei* winds may last for an hour or two, or they may last for several days, but the end result is the same: dry winds increase evaporation and disrupt the water balance (the ratio of the water inflow from roots to that transpired to the atmosphere) of the plant tissue.

The origin of *sukhovei* remains an enigma, but there is a general agreement that both droughts and *sukhovei* develop under the south-central edge of displaced anticyclones, anticyclones 10° to 20° north from their usual summer position. Displaced anticyclones with diverging, clockwise air masses are characterized by little cloud cover, low relative humidity (dropping, in some instances, to 10–17%), and the absence of rainfall. Intense solar radiation and very high temperatures create moisture deficits and desiccation of the soil.

Basic atmospheric circulation

Air masses

The basic atmospheric circulation features involved in giving regional character to Asia's climates are the movement of air

masses, transformation of air mass properties, and interactions between them along fronts. Asian air masses show great contrasts in temperature, moisture, and density. At any particular site the properties of air masses depend not only upon the nature of the source region but also the modification the air mass experienced en route from the source region. En route air mass modifications are of great importance in determining the nature of weather associated with an air mass (Lydolph, 1977; Takahashi and Arakawa, 1981). Some typical characteristics of air masses and their source regions are as follows:

1. Continental Arctic (winter) air masses are stable, intensely cold (-55° to -35°C), extremely dry, with inversions; cA air masses enter Siberia from the Arctic seas and at times penetrate to the Pacific Ocean; they are associated with clear skies, low temperatures, and dense air.
2. Continental polar (winter) air masses are very stable with strong temperature inversions and are cold (-35° to -20°C) and dry; they spread to the north and to the south of the “great ridge” of high pressure in Siberia and Outer Mongolia at approximately the 50th parallel and dominate the weather of the entire continent; generally cP air masses produce clear, cold, and cloudless weather.
3. Maritime tropical (winter) air masses are, for the most part, unable to penetrate eastern Asia in winter due to the intensity of the great Siberian High Pressure Cell; mT air masses that influence the weather in central Asia in winter circulate around the eastern edge of the Azores – Bermuda High Pressure Cell where upper level subsidence is strong; mT air masses are cool, dry, and stable in winter.
4. Maritime polar (winter) air masses have great difficulty penetrating deep into the Asian continent in winter, for the Siberian High Pressure Cell and strong outflowing winds in eastern Asia inhibit mP incursions. The mP air masses basically are conditionally stable, cool ($0\text{--}10^{\circ}\text{C}$) and moist; they have significant influence upon the weather of maritime eastern Siberia, Manchuria, and Korea.
5. Continental polar (summer) air masses are, in general, stable or conditionally stable, cool ($5\text{--}15^{\circ}\text{C}$) and somewhat moist; east and south Asia are so dominated by mT air in summer that cP air contributes little to the weather of that region.
6. Maritime polar (summer) air masses are a contributing factor to the summer weather of Manchuria, eastern Siberia, and Japan, and are, in most cases, stable to conditionally stable, mild ($2\text{--}14^{\circ}\text{C}$), and humid; conflicts between mP and mT air masses in summer lead to the formation of a semi-stationary front in northeast Asia with associated overcast and drizzly weather.
7. Maritime tropical (summer) air masses initially are conditionally stable and very moist; mT air masses provide moisture for the summer monsoon and in spring invading mT air meets cP air in central and south China producing very active cyclogenesis; mT air masses dominate the weather of eastern Asia during the high-sun period.
8. Continental tropical (summer) air masses develop over southwest Asia in summer and are conditionally stable, dusty, very hot ($30\text{--}42^{\circ}\text{C}$), and hold moisture; cT air flows north and northwest in summer into western Asia, advecting heat and absorbing moisture en route, plus contributing a characteristic opalescent haze to the local climates.

Asian air masses show great contrasts in temperature, moisture, and density. At any particular site, properties of air masses depend not only upon the nature of the source region but also the

modification the air mass experienced en route from the source region. En route air mass modifications are of great importance in determining the nature of weather associated with an air mass (Lydolph, 1977; Takahashi and Arakawa, 1981).

Siberian high-pressure cell

General atmospheric circulation over Asia is controlled by centers or cells of high or low pressure whose axes are, in general, east–west and whose pressure centers vary drastically from winter to summer. In winter an extensive and well-developed high-pressure cell, centered over Mongolia, dominates the weather over most of east Asia (Figure A66). Triangular in shape, with the apex extending in the west to the Caspian Sea and the base anchored in the northeast near the Verkhoyansk Mountains of Siberia and in the southeast near the Chin Ling Mountains of east-central China, the Siberian High effectively blocks penetration of moisture-bearing, moderating maritime

air masses in winter. Acting as a wedge forcing air masses to skirt northeasterly from the Black Sea across much of northern Siberia and to flow southerly along the Kamchatka Peninsula toward northern Japan, this intense high-pressure cell generates continental, land-trajectory, dry, cool, low-level air masses which surge from the north and northeast to the southwest across all of south and east Asia. The Siberian High, whose core and area of highest pressure is focused upon Lake Baikal, pulses in intensity and breaks at times into smaller high-pressure cells of less intensity. February marks the height of the Siberian High's dominance of the winter circulation over Asia. The Siberian High weakens and shifts its center westward into a position over northeastern Central Asia in April, then dissipates in May. The weather map of Asia begins to be dominated by an intensive, thermally induced low-pressure cell over southwestern Asia and focused upon the tip of the Arabian Peninsula, the Iranian Plateau, and the Thar Desert of Pakistan (Davydova et al., 1966).

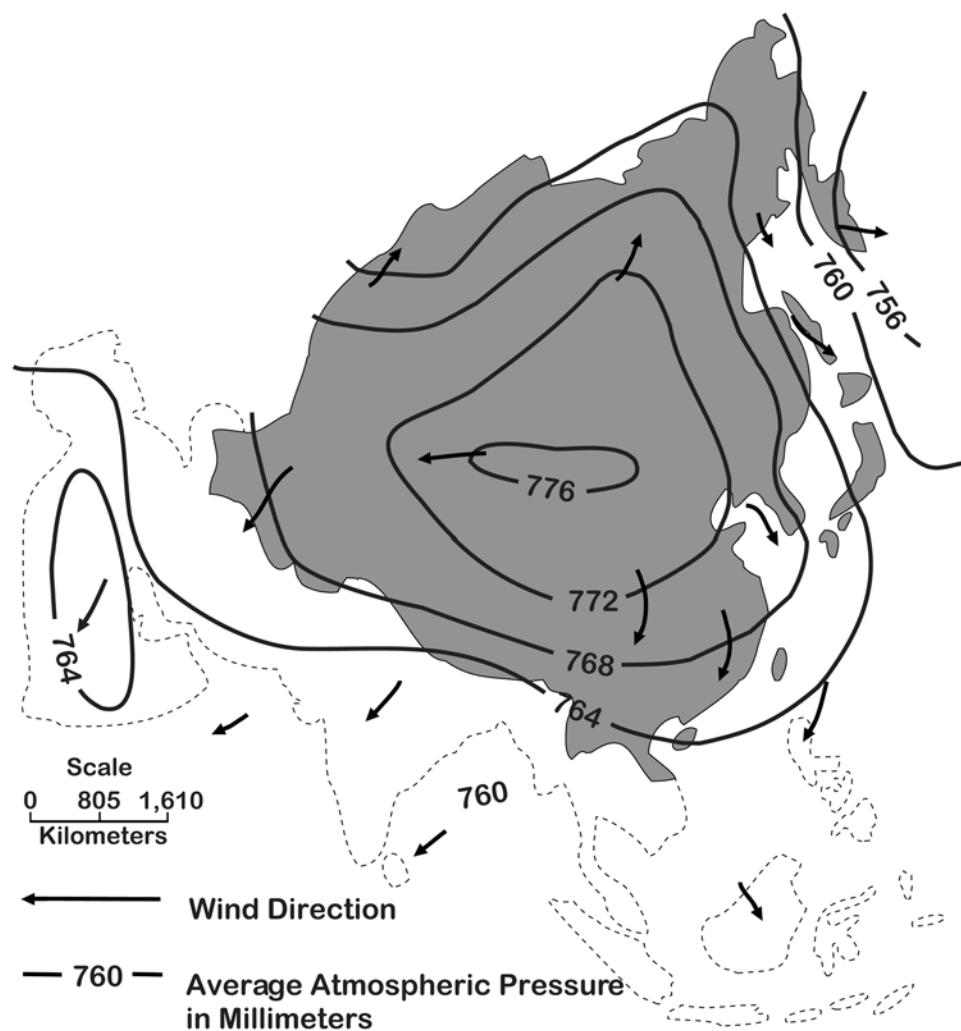

Figure A66 Atmospheric pressure and winds: January. Source: *Geograficheski Atlas*, 1959, Moskva, p. 15; *Preroda i Resursi Zemli*, 1999, Moskva and Vienna, p. 51. Anna R. Carson 2003.

Southwest Asian low

In summer, east Asia's weather is dominated by a large, deep, thermally induced low-pressure cell that extends from the Arabian Peninsula to central China and from central India to Central Asia – centered approximately 30°N latitude and 70°E longitude (Figure A67). A complex cell, the Southwest Asian Low experiences east–west locational oscillations and occasional intense pressure deepening. This low in summer has the effect of interrupting the subtropical high-pressure system in the northern hemisphere by dividing the globe-girdling zonal band into two distinct large oceanic cells. One intense depression, the Southwest Asian Low, induces a radical change in prevailing winds and storm tracts during the high-sun period. Air masses from the stable eastern end of the Azores–Bermuda High Pressure Cell skirt this low from a north to northwesterly direction across the eastern rim of the Arabian Peninsula; less intense air masses from the northern quadrant of the Azores–Bermuda High sweep eastward across

Turkey and into the northern extremities of Central Asia. Air masses and storms spawned under the western unstable quadrant of the Hawaiian High sweep from the south and southeast in a northerly trajectory across Japan, extreme eastern China, and the Russian Maritime Provinces. But the most constant and climatically significant air masses and storms are advected to this intense low-pressure cell as southwesterly trade winds spawned from a semipermanent high-pressure cell in the southern hemisphere over the Indian Ocean. In India and east Asia this modification of the general planetary wind system in summer constitutes the Asian monsoon (Tsuchiya, 1964; Chang, 1967).

Frontal dynamics

Frontal zones and wind systems conform to the location and circulation of major air masses. In winter three major zones of cyclonic activity are distinguished over Asia. One zone is located

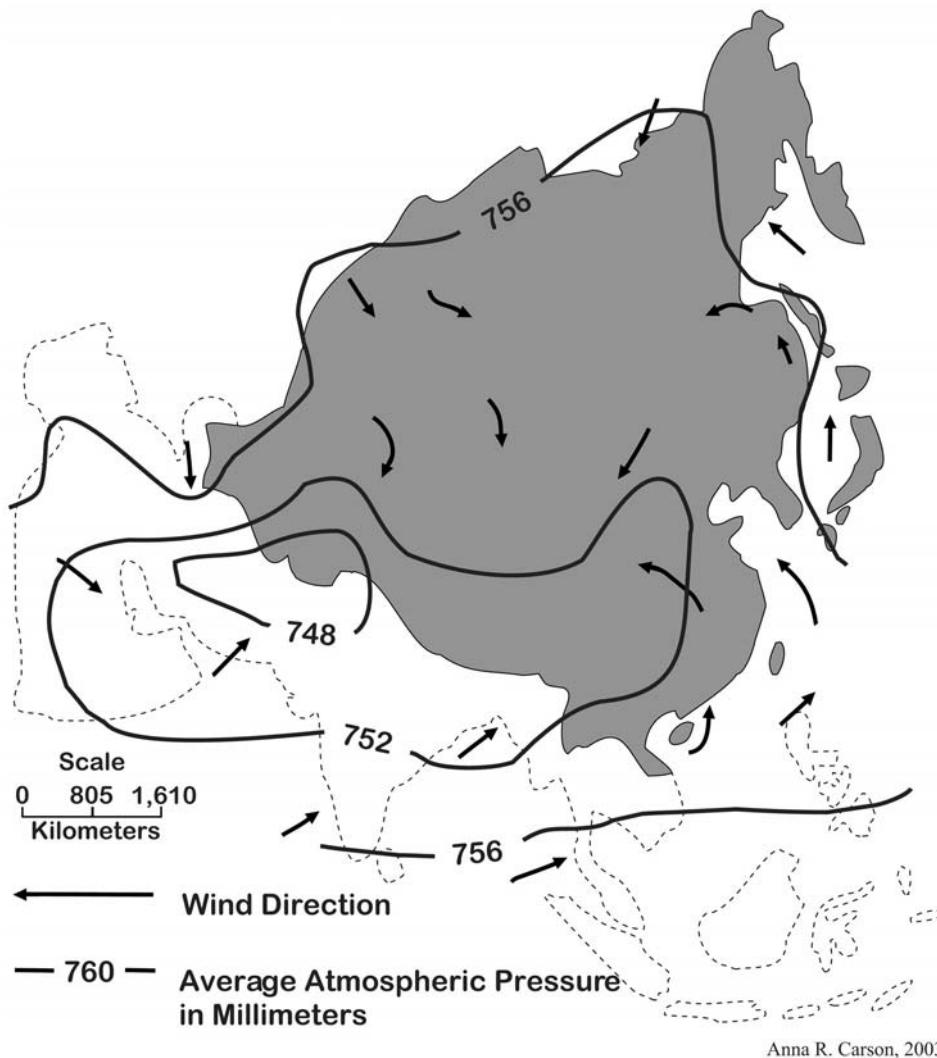

Figure A67 Atmospheric pressure and winds: July. Source: *Geograficheski Atlas*, 1959, Moskva, p. 15; *Preroda i Resursi Zemli*, 1999, Moskva and Vienna, p. 51. Anna R. Carson 2003.

along the Asiatic Arctic Front, well above the Arctic Circle in northern Siberia, extending along the shores of the continent. This front fluctuates greatly and Arctic air masses, at times, penetrate east-central Asia. The second zone is along the Southwest Asian Polar Front that develops in winter over the Mediterranean Sea and extends to the Caspian Sea. The third zone is along the East Asian Polar Front that aligns itself in a northeasterly path from extreme south Asia toward Japan. Along these winter frontal zones, and moving at various directions and speeds, depressions and anticyclones impart to the climates of Asia that special character by which one area differs from another.

During summer, three major zones of pronounced cyclonic activity can be identified. The first is the southward-displaced Asiatic Arctic Front that at times extends east–west across northwestern Siberia along the 70°N parallel. A second zone of pronounced cyclonic activity is the Asian Polar Front that normally extends from the eastern tip of Lake Balkash in Central Asia, over Mongolia, to the northernmost bend of the Amur River along the 50°N latitude. This oscillating and at times southward-dipping Asiatic Polar Front zone has been called the “barometric backbone of Asia” in summer or the “great ridge”, for a large number of anticyclones is observed each year between 50° and 55°N latitude. The third major zone is along the South Asian Intertropical Front. Extending over China at approximately 25°N latitude, the South Asian Intertropical Front is well defined in some locations, but in others it is weak or absent. In this belt, convergence of surface winds result in large-scale lifting of warm, humid, relatively unstable air, producing numerous weak, rain-generating disturbances (Trewartha, 1981). Along major frontal zones are found pronounced horizontal variations in temperature, humidity, and stability – usually jet streams. Strong, narrow jet stream currents, thousands of kilometers long, hundreds of kilometers wide, and several kilometers deep, are concentrated along a nearly horizontal axis in the upper troposphere or stratosphere, producing strong vertical and lateral shearing action.

Jet streams

Three distinct jet systems, the Polar Front Jet, the Subtropical Jet, and the Tropical Easterly Jet, have a major impact upon weather and climate in Asia. Latitudinal location of these jet systems, especially the Polar Jet, shifts considerably from day to day and from season to season, often following a meandering course. But in general, the Polar Front Jet gives rise to storms and cyclones in the middle latitudes of Asia, the Subtropical Jet noted for a predominant subsidence motion gives rise to fair weather, and the Tropical Easterly Jet is closely associated with the Indian monsoon. Over most of Asia the Polar Front Jet and the Subtropical Jet are most intense on the eastern margin of the continent and are best developed during winter and early spring. Jet stream wind speeds up to

500 km/h have been encountered over Japan. The Subtropical Jet, at times in winter, forms three planetary waves with ridges over eastern China and Japan. It frequently merges with the Polar Front Jet producing excessively strong jet wind speeds. During summer the Subtropical Jet loses its intensity and is mapped only occasionally.

East Asian monsoon

The East Asian monsoon is a gigantic multifactored, multifaceted, complex weather system, composed of diverse heat and moisture cycles intimately related to local topography, modified air masses, quasistationary troughs and ridges, and jet streams. Weather over most of eastern Asia during winter is dominated by the Siberian High-Pressure Cell and outflowing continental air masses. Low-level air flow is mainly from the north and is cold, dry, and stable. Successive waves of cold northeasterlies commence in late September and early October, progressing farther and farther southward, reaching the south China coast by late November or early December. In the higher mid-latitudes of Asia during the low-sun period, a steep north–south pressure gradient persists. During March and April the Siberian High gradually weakens, and incursions of moist maritime tropical air from the south and east replace the cold-to-cool northeasterlies, producing widespread stratus clouds, fog, and drizzle that may persist for days (Das, 1968).

In summer a combination of the deep and elongated Southwest Asian Low-Pressure Cell extending from the Arabian Peninsula to China, and the South Asian Intertropical Front, reaching its maximum poleward displacement, sets the stage for a marked seasonal reversal of air flow. Warm, moist, and conditionally unstable southwesterly maritime air masses from relatively cooler oceanic source regions eventually overcome blocking atmospheric conditions, and flow northwestward over China and Japan. Considerable convective activity develops over land, and heavy showers and thunderstorms contribute largely to the summer rainfall maximum of the region. Characteristics and attributes and onset and duration of the monsoon are site-specific. Duration of the summer monsoon in China varies between north and south. Dates of monsoon onset and percent of annual average rainfall received have been a focus of numerous studies in the past century. A synthesis of these studies is given in Table A38.

In all cases low-level wind patterns and resultant weather in summer are complicated by topography. Distance from air mass source regions, moisture content of air masses, and orographic barriers and atmospheric disturbances associated with cyclonic or inter-air mass convective activity determine distribution and quantity of precipitation. There is a pronounced difference between the East Asian and South Asian monsoonal weather. The East Asian winter monsoon is much stronger than the South Asian winter monsoon, and the East Asian summer

Table A38 Dates, duration and percent of rainfall by region

Location	Dates	Duration	Rainfall
1. South China	Mid-April; end October	6½ months	75–90%
2. South Central China	Mid-May; mid October	5½ months	60–80%
3. North Central China	June; end August	3 months	60–75%
4. North China/Mongolia	June; end August	3 months	Less than 60%

monsoon is much weaker than the South Asian summer monsoon (Trewartha and Horn, 1980).

Storms

Local winds

Owing to the great variety in relief and exposure, Asia is subject to numerous local winds and their associated weather. Ubiquitous in Asia are the warm, dry, gusty, downslope *foehn* winds generated, in most cases, by passing atmospheric disturbances in highland or mountainous areas. For example, in Central Asia and Siberia, *foehn*-like winds experienced along the Caspian Sea are locally called *germich*; in Uzbekistan, *Afghanets*; in Tadzhikistan, *harmsil*; in and near the great Fergana Valley, *ursatevskiy* and *kastek*; and along the Kazakh–Chinese border at the Dzhungarian Gate east of Lake Balkhash, *evgey*. Winds are given a medley of names, and the largest and most pronounced are a major contributing factor responsible for the broad aspects of Asia's climate (Critchfield, 1983).

For each season of the weather year, representative winds of local significance have been identified and named:

1. Summer – A hot, strong, and constant northerly summer wind carrying considerable dust and obscuring the atmosphere is called *karaburan* in the Tarim Basin of Sinkiang and northwestern China and *chang* in Turkmenia. At times, on the southern edge of a modified Arctic air mass that advects into southern Siberia and Central Asia, hot, dry moisture-absorbing *sukhovei* winds eliminate local cloud cover, permit intense solar radiation to strike the Earth and reduce relative humidity at the surface to a very low value both day and night.
2. Fall – Cold and often very dry northerly or northeasterly winds, preceded by a cold front, often blow with great strength and violent gusts down from the mountains and high plateaus of northern Siberia and the Caucasus. *Bora* is the term identifying this type of wind in the region between the Black and Caspian seas, and *sarma* and *kharanka* are bora-type winds in the Lake Baikal region of southern Siberia.
3. Winter – Very cold northerly or northeasterly gale-force winds, often blowing at temperatures below -20°C and accompanied by falling or drifting snow, are generated from the back side of winter depressions in Siberia and Central Asia. The sensation of cold temperatures is increased by the low wind-chill factor associated with a *buran* or a *purga*, and the break in the comparative calm associated with the Siberian High-Pressure Cell.
4. Spring – Continental depressions passing eastward over central China and the Yellow Sea in spring and early summer bring heavy overcasts, high humidity, and rain to China and Japan. *Bai-u*, *mai-yu*, or *plum rains*, as they are called, are an extended period of unstable weather caused by stagnation of the polar front.

Thunderstorms and tornadoes

Thunderstorms reach their maximum development in Asia over lowlands in summer. Most thunderstorms are ordinary convective cumulonimbus clouds within maritime tropical air masses that produce localized precipitation. Air mass thunderstorms,

randomly scattered, are initiated primarily by daytime solar heating of land surfaces. Frontal and orographic thunderstorms have distinct patterns and movements, for they are triggered in a place or zone where unstable air is forced upward. Severe thunderstorms may produce hail, strong surface winds, and tornadoes. Convective thunderstorms develop more frequently here because of strong insolation and low wind velocities. Clouds of convective thunderstorms reach elevations of 12 000 meters or more, and rainfall associated with these cells is short in duration, intense, and localized. Very few thunderstorms are observed over the tundra regions of Siberia – less than five per year. Thunderstorm activity is a summer phenomenon in China, much of Central Asia, Singkiang, Mongolia, the Maritime Provinces of the Far East, and Siberia. They commence during the fall transitional period, are more prevalent in winter, and decline in number during the spring transitional period.

The most destructive spin-off of a thunderstorm is the tornado, an extremely violent rotating column of air that descends from a thunderstorm's cloud base and can cause great destruction along a narrow track. An Asian tornado travels in a 150–500 meter wide, approximately several kilometers long, straight track, at speeds ranging between 50 and 100 kph. Although one of the least extensive, it is the most violent of all Asian storms. As the whirling mass of unstable air gains force, a rotating column of white condensation is formed at the base of the cloud. Dirt and debris sucked into this whirlwind darken the column as the column of air reaches the ground. A notable feature of the climate of Asia is the relative infrequency of tornadoes, particularly as compared to central and eastern North America at similar latitudes. Although records are inadequate, there are sufficient data to conclude that tornadoes occur on the order of once every 3–5 years in the northern Caspian Sea area and Central Asia during May, June, and July and two to five or more annually in China and Japan during August and September.

Tropical cyclones

One of the most powerful and destructive types of cyclonic storms is the tropical cyclone (Hsu, 1982). Referred loosely to any pressure depression (near 1000 mb) originating above warm oceans in tropical regions, tropical cyclones form an important feature of the weather and climate of south and east Asia – particularly from July to October. Different terms are used worldwide to describe this tropical storm: *typhoon* in the western Pacific; *baquios* or *baruio* in the Philippines; *tropical cyclone* in the Indian Ocean; *willey-willeys* in Australia; *hurricane* in the eastern Pacific and Atlantic; *cordanazo* in Mexico; and *taino* in Haiti.

Organization and development of tropical cyclones are not fully understood, and they are under intensive study. Formation of this type of storm is associated with warm ocean surfaces not less than 27°C , located between 5° and 10°N latitude, light to calm initial winds, and waves or troughs of low pressure deeply embedded in easterly wind streams converging into an unstable atmospheric zone. Large quantities of latent heat released through condensation are converged and transferred to higher levels, deepening the pressure center and intensifying the storm. An almost circular storm of extremely low pressure, into which winds spiral with great speed, is formed. Asian tropical cyclones travel slowly at speeds of 16–48 kph, cut a destructive storm path 80–160 km wide, and winds in the wall cloud area achieve speeds in excess of 200 kph. Passage of a tropical cyclone over

water and land is associated with strong winds and heavy rainfall. Storm tracks vary annually and no two recorded tracks have been exactly the same. Despite all irregularities, most tropical cyclones have a tendency to move westward, then poleward, finally turning eastward, toward higher latitudes under the influence of both internal circulation and external steering currents, penetrating into the belt of westerly winds. This awesome tropical storm contributes between 25% and 50% of the annual precipitation received in many tropical weather stations. Flooding, destructive wind force, and storm surge are responsible for much property damage and for human casualties.

Occurrence of tropical cyclones is restricted to specific seasons depending upon the geographical location of the storm-affected region. The Observatory of Hong Kong reports that 83% of the annual total recorded in Hong Kong occur between June and November. Approximately 50% of these severe tropical storms attain typhoon intensity. From mid-November to April, very few tropical storms pass over the coasts of China and Korea, but in the warm July through October period numerous tropical depressions, tropical storms, severe tropical storms, and tropical cyclones (typhoons) are experienced. In the 1884–1955 period at least 438 tropical cyclones crossed various sections of the Chinese and Korean coasts. Japan's tropical cyclone season begins in June and ends in November, reaching its peak occurrence in September. In the 1918–1947 period 85 typhoons were reported in Japan. The tropical cyclone season is slightly longer in the Philippines, extending from June to December. Almost 90% of all tropical cyclones in the 1948–1962 period were noted in the summer and fall seasons. Tropical cyclones usually weaken over land, and few penetrate and persist more than 500 km inland. The rise in sea level, when combined with high tides, accounts for more damage and loss of life in Asia than violent wind (Riehl, 1979).

Prospectus

Continentiality, as a climatic control or factor, is best manifested in the extremes found in the climates of Central Asia, Siberia, and East Asia. The land-dominated interior climates present striking contrasts to the maritime-impacted coastal and island areas. Winters are much colder than corresponding latitudes in western Europe and North America; also, those regions where continentality is a climatic factor are the regions where climatic change is most noticeable. Vegetal, agricultural, and biotic zones have advanced 10 km northward in some climatic regions. This is best revealed in satellite remote sensing images of Central Asia and Siberia. In the past 20 years Asian temperatures have remained above the long-term averages (Figures 3 and 4). An annual change in temperature of only a few degrees centigrade affects the climates of Asia sufficiently to render marginal agricultural regions unacceptable for food production and to wreak havoc on local food supplies (Bryson and Murry, 1977). Moreover, a combination of human activities that modify climatic elements with natural causes of climatic change could lead to more frequent or more severe changes in Asia's climatic regions (Christianson, 1999). For those struggling to secure a meager existence from a hectare or two of land in Asia, and for the urban dweller seeking water to maintain bodily functions, any climatic change disrupts lifestyles – because humans and human institutions are adjusted to precisely the climate and weather that prevail (Budyko, 1977; Dando, 1980; Martens, 1999).

ASIA, CLIMATE OF SOUTH

South Asia, which mainly includes India, Pakistan, Bangladesh, Sri Lanka, Nepal, and Bhutan in this article, is located between about 5° and 37°N, in tropical and equatorial latitudes, with the Indian Ocean to the south, the Great Himalayas and Karakoram to the north, the Baluchistan highlands to the west, and the meridional chains of mountains in Indochina to the east. The distinct geographical features in South Asia restrict the horizontal exchange of oceanic and continental airmasses and modify the climate to a characteristic pattern. Besides great mountains and upland systems there are also lowland depressions. Numerous bays and gulfs enhance the influence of the ocean. In winter a warm, westward-flowing current reaches eastern Sri Lanka, from where it diverges northward, affecting the southeast coast of India. During the summer a warm current in the Indian Ocean reaches the west coast of India and flows southward; from south of Sri Lanka the current moves east (Martyn, 1992).

South Asia mainly consists of four climate zones. The northern Indian edge, as well as the upland and mountainous part of Pakistan, has a dry continental, subtropical climate. The far south of India and southwest Sri Lanka are located in the zone of equatorial climates. The rest of the areas lie in the tropical zone, with hot semi-tropical climate in northwest India, cool-winter hot tropical climate in Bangladesh, and semiarid tropical climate in the center of the peninsula. The last two tropical climate zones are greatly affected by monsoon circulations (Martyn, 1992; Rao, 1981; Papadakis, 1966). In addition, mountain climate occurs in the Himalayas. Climates there vary with elevation, from permanent ice caps at high elevation to subtropical climate at lower lands.

The most important climate feature in the region is the southwest monsoon, which lasts for 4 months, from June to September. In this southwest monsoon period the precipitation is one order of magnitude more than during the rest of the year. Because temperatures in the South Asian monsoon region drop dramatically in June and July, due to the monsoon onset, March to May becomes the warmest period.

In this article the observational data for precipitation are from the rain gauges station data over land and the data are interpolated to 1° resolution (Xie and Arkin, 1997), covering 1948–2003. The surface temperature data are from the National Center for Environmental Prediction (NCEP), the Climate Analysis Center, and the Climate Anomaly Monitoring System station data achieve (CAMS, Ropelewski et al., 1985); they include data from 1948 through June 2003. The NCEP/National Center for Atmospheric Research (NCAR) Global Reanalysis data from 1948 to 2003 (Kistler et al., 1999) are used for circulation and radiation figures.

Radiation

Although the sun's altitude is high during the entire year, and the amount of daylight varies little during the year for the area south of 30°N (Martyn, 1992), the solar radiation still exhibits high seasonality and great spatial variability (Figure A68). Annual mean solar radiation amounts decrease eastward, from 290 W m⁻² in Baluchistan to less than 240 W m⁻² in Bangladesh. Annual mean downward long-wave radiation at the surface

decreases northward, which is consistent with the temperature gradient and water vapor quantity, with the two coasts having the highest long-wave radiation (about 390–400 W m⁻²) due to cloudiness.

January solar radiation is about 240–250 W m⁻² in the southern peninsula and western Sri Lanka, and drops to 220 W m⁻² in the northern peninsula and eastern Sri Lanka. Much lower solar radiation is received in the northwest subcontinent and northeast Bangladesh, with north Pakistan having the lowest (Figure A68a). The long-wave radiation shows a clear zonal pattern, with high gradients in the Himalayas associated with topography (Figure A68c). In July the solar radiation decreases southeastward from northwest South Asia. Pakistan and northwest India receive the most solar radiation, between 300 and 360 W m⁻². In northeast India and Bangladesh the solar radiation decreases southward from 300 to 200 W m⁻². The southern continent has less solar radiation, especially along the west coast of India, due to the cloudiness in these regions (Figure A68b). There are two very high downward long-wave radiation centers over the Indian Ocean, located at both sides of the Indian peninsula and associated with heavy rain in these two areas. Apart from the areas influenced by these two centers, in other parts of the peninsula and Sri Lanka it is quite uniform, between 410 and 420 W m⁻² (Figure A68d).

Circulation

A characteristic feature of the South Asian climate is the atmospheric circulation associated with the monsoon evolution. The extensive Eurasian continent and the Indian and Pacific Oceans play an important role in monsoon formation. In the winter the northeast monsoon prevails and sea-level pressure decreases to the south. The Intertropical Convergence Zone (ITCZ), associated with the equatorial low-pressure belt, runs across the entire Indian Ocean along 10°S latitude. The cold air from the Siberian High, which is centered at 45°N and 105°E, approaches eastern India and the Bay of Bengal starting in October. Since the barrier of Tibet and the Himalayas blocks the advance of cold polar air, low-level northeast winds only run across the Bay of Bengal and reach northeast India. The pressure gradient is strong to the north of the Himalayas but weak over the Indian Peninsula. From October to May the southern branch of the westerly jet stream, usually flowing between 28° and 30°N, crosses the Himalayas. This westerly wind in the upper troposphere is strongest in January and gradually slackens.

Meanwhile, in western South Asia, cold air from Iran and Afghanistan reaches Pakistan and northern India. Cyclonic disturbances are more frequent over the western Himalayas and Karakoram from early November to the end of May because of strong vertical wind shear in the basic current (Hamilton, 1979). They reach the Punjab, Rajasthan, and even Patna on the Ganges Plain. They bring clouds and precipitation in November and December, and cold weather, thunderstorms, and precipitation in the normally hot, dry period from March to May (Lockwood, 1974; Martyn, 1992).

Development of low pressure due to increased heating over land starts for South Asia in March. Heat lows are usually found in an area extending from Somalia across southern Arabia to Pakistan and northwest India between May and September, and are most intense in July. Middle tropospheric subsidence is considered to affect the heat low (Hamilton, 1979). The distribution of sea-level pressure, as well as

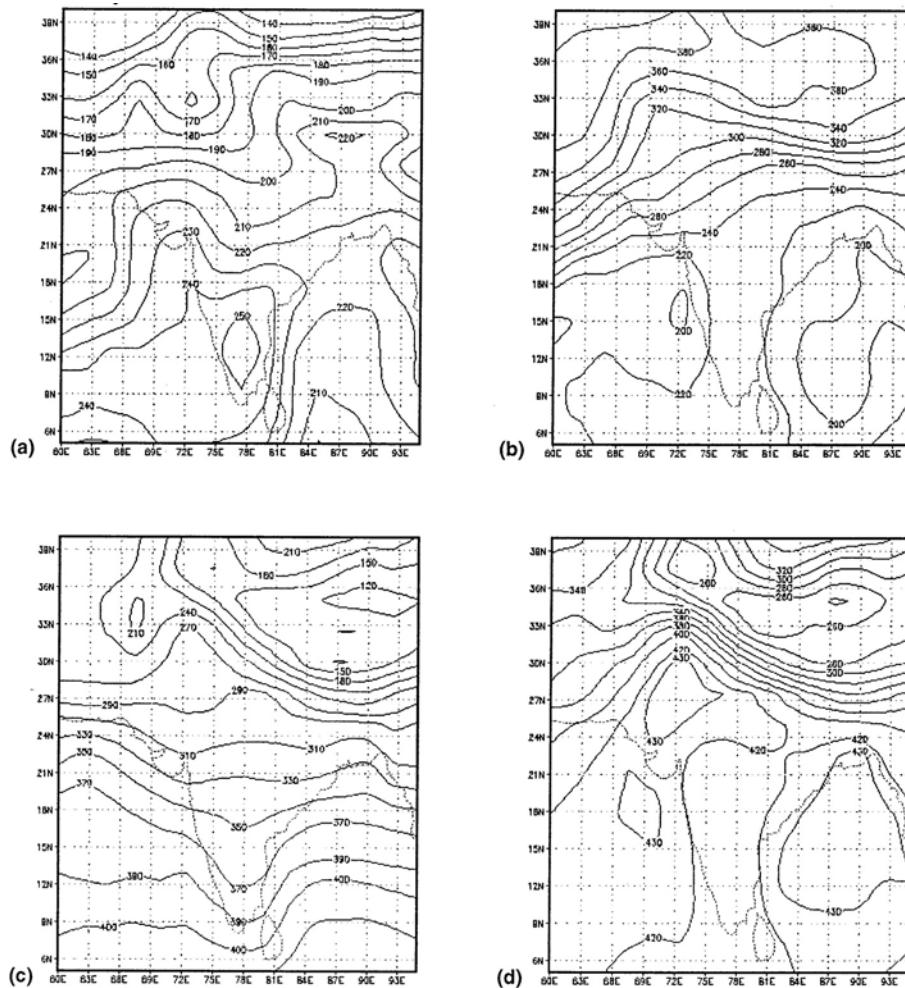

Figure A68 Monthly mean radiation flux at the surface (W m^{-2}): (a) January mean downward short-wave radiation; (b) July mean downward short-wave radiation; (c) January mean downward long-wave radiation; (d) July mean downward long-wave radiation.

low-level air flow over the Indian subcontinent, experiences a complete reversal from January to July (Figures A69a and A69b). Earlier northeasterlies are replaced by westerlies in April with the core of a subtropical jet stream at 200 mb near 27°N. This jet gradually weakens from an average speed of about 40 m s^{-1} in March to about 25 m s^{-1} in May (Hamilton, 1979; Keshavamurty and Rao, 1992).

In the summer the low pressures are centered over Pakistan, northwest India, and the Ganges Plains. The Indian Ocean high is strong and centered at 30°S and 60°E. At the beginning of June, as the jet stream disappears above the southern border of the Tibetan Plateau, the low over Pakistan deepens and the ITCZ moves in. The change in the direction of circulation to southwest occurs suddenly (called the burst of the monsoon) because of the very steep horizontal northward pressure gradient. The southwest monsoons, carrying enormous quantities of moisture from the Indian Ocean, reach the coast of India (Figure A69b). The monsoon circulation dominates South Asia. Because wind now blows off the sea, the summer monsoon contains far more water vapor than the winter monsoon. The

depth of the summer monsoon over the Indian Peninsula decreases northwards (Martyn, 1992). Humidity, cloudiness, and precipitation all increase in the summer, but the increase of temperature is checked. When the monsoons change direction during the summer, cyclonic activity increases rapidly over very warm seas and oceans and is extremely violent over the Bay of Bengal.

Monsoon depressions form in the Bay of Bengal from June to September, move west/northwest, and reach at least the central parts of the subcontinent before weakening or disappearing. They are usually moderately vigorous, with surface winds below 20 m s^{-1} and a central pressure range from 2 to -10 mb below normal. Many depressions are probably of a baroclinic type (Koteswaram and George, 1958) and usually exist in the presence of a large zonal wind shear between the upper and lower troposphere. Monsoon depressions are an important summer-time precipitation agency between 18°N and 25°N. They bring widespread rains in the southwest quadrant, with many heavy rainfall events. As a depression moves over land it usually weakens due to frictional dissipation of energy and a reduction of

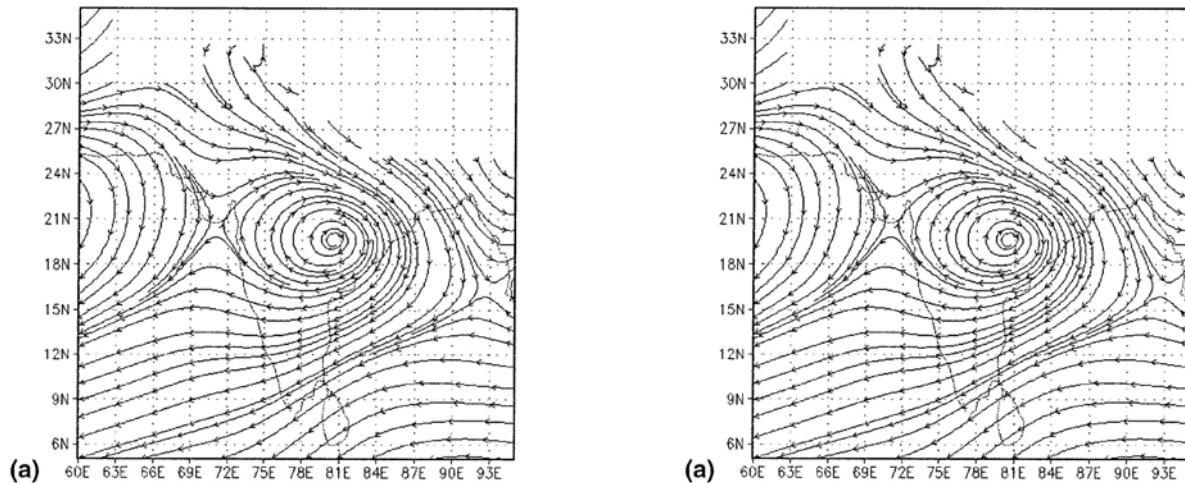

Figure A69 Monthly mean streamline at 850 mb: (a) January; (b) July.

moisture intake. Eventually, most depressions merge into the monsoon trough over northwestern India (Hamilton, 1979).

The transition of a summer circulation to a winter circulation is of shorter duration than the reversion from winter circulation to summer circulation. The transition comes suddenly over the Himalayas as the circumpolar westerlies begin to intensify and move south. A subtropical westerly jet stream develops at the northwestern end of the Himalayas, thereafter extending southeastward. By mid-October the jet is fully established south of the Himalayas. A winter circulation develops north of 25°N by early November (Yeh et al., 1959; Hamilton, 1979).

Surface temperature

The isotherms in January generally are parallel to the latitudes except near the coasts. January mean temperatures in northern South Asia are about 10°C, which is not as cold as most parts of Asia because the Himalayas and Sulaiman block the inflow of masses of cold air from the north. On the Indian Peninsula, south of 18–20°N in the east, the temperatures exceed 20°C and can reach 24–27°C on the equator (Figure A70a). In Kashmir the mean temperature can be 1°C at Srinagar (1666 m) and –15.7°C at Dras (Martyn, 1992), where below-zero temperatures are usual from November to April.

Land becomes progressively heated after January. The warmest period of the year precedes the monsoon from March to mid-June. In the far north the warmest month is July (Figure A70b), and the warm season begins earlier southward; for instance, in southern India it begins in April. During the warm period the mean temperatures in the northern Deccan exceed 35°C (and even reach 38–42°C), and in the interior of the peninsula they reach 33°C. Because of the greater moisture brought in with the sea breezes, coasts are not hotter in the afternoon hours than the peninsular interior. The west coast of India is about 5°C cooler than the east coast.

In July the southwest monsoon is established over India and the cloudiness is heavy. Monthly mean temperatures over much of Indian Peninsula are quite uniform, around 27°C (Figure A70b). However, temperatures of over 30°C are recorded in the

Great Indian Desert, and may reach 32–36°C. Temperatures in the Himalayan mountain valleys are from 24°C at elevations of 1700 m to 17°C at 3500 m (Martyn, 1992). Absolute maximums in some interior regions even exceed 40°C. The summer monsoon season is the second cooler period in the year because clouds and rain prevent the temperature from rising too much during the day. Once the monsoon ends the temperatures rise and a second annual maximum is attained. This is not as high as the pre-monsoon maximum because of the greater quantity of moisture in the air and the sun's lower altitude. Monthly mean temperatures over the entire subcontinent in October are generally within the range of 27–29°C. This is the month of the most equitable distribution of temperature on the Indian Peninsula. The range of annual temperature variation is about 1–5°C for most parts of the region.

Near-surface humidity and cloudiness

In January the relative humidity on the southern peninsula is higher than 50–60%, and even 70% on the coasts. A maximum relative humidity of over 80% in Sri Lanka and Hhasi-Janitia Hills in northeast India has been recorded. The driest areas are the Indus Plain and the adjacent areas of Pakistan and western India. In the western Himalayas the humidity is high when temperatures are very low, but becomes lowest in May–July. From March to mid-June (the warm months) the relative humidity is under 30–40% on the Indus Plain, in the Punjab, Rajasthan, and at the western end of the Ganges Plain, and under 50% on the Deccan Plateau and in central Burma (Martyn, 1992). In July the areas most affected by the monsoon have relative humidity of over 80%, while the southwest coasts of India, the Khasi-Janta Hills, and some sections of the Himalayas even reach above 90%. However, there are areas in Pakistan still with relatively low humidity. On the Coromandel Coast and in eastern Sri Lanka the relative humidity reaches the lowest value in a year (Martyn, 1992). In the driest regions of Rajasthan the relative humidity does not exceed 60%, and in central India it does not reach 80%. In the eastern Himalayas, where the effects of the monsoon are strong, there are two wet

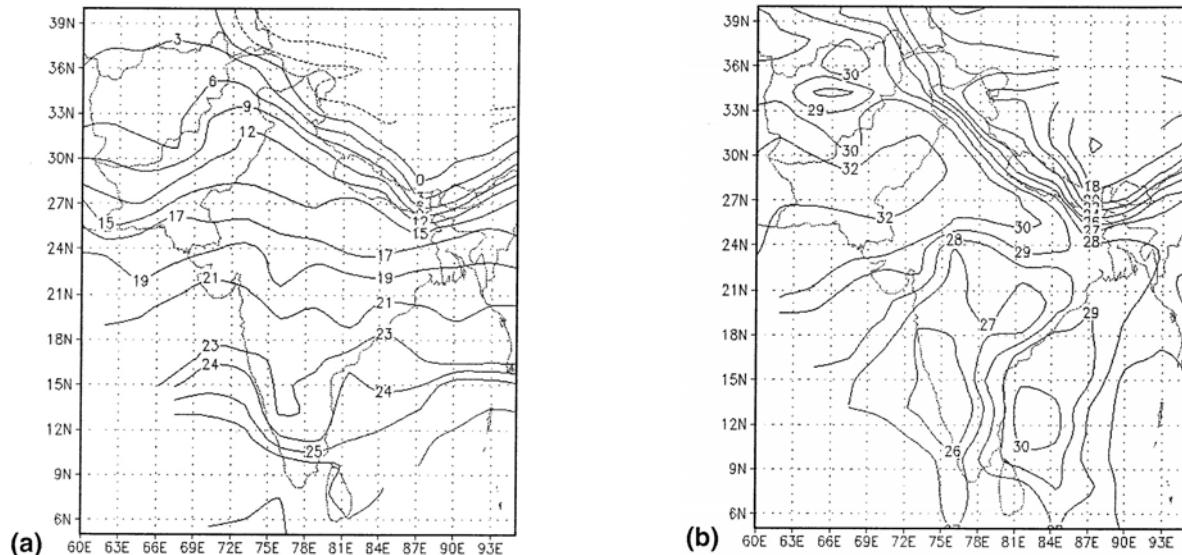

Figure A70 Monthly mean surface temperature: (a) January; (b) July.

periods, one in January and February and one from May through October, while two dry periods remain between these two wet periods.

The cloudiness and its annual variation are varied; they depend on atmospheric circulation and topography. With the arrival of the summer monsoon, which carries a huge amount of moisture from the Indian Ocean, South Asia becomes one of the most overcast parts of Asia, normally over 80%. Cloudiness even reaches 90% in western India in the upper reaches of the Godavari and the windward slopes of the Khasi-Jaintia Hills. The southern and northern parts of the region have greatest cloud cover from June to August, and from July to August, respectively. During the rest of the year the cloudiness is much less. In the west the cloudiness is 10–22% during the November–April period. In the east on the Bay of Bengal the lower cloudiness is about 22–45% during January–March. In January it is scanty (under 30% or even lower) in most parts of South Asia; but in the far north of India, where a westerly circulation is frequent, cloudiness is greatest (Martyn, 1992).

Precipitation

Precipitation attracts much more attention than any other aspect of Indian subcontinent meteorology. Precipitation in South Asia exhibits strong spatial variability. Pakistan and northwest India, where there is very little water vapor in the air and little precipitation due to limited evaporation and to dry air currents, have the most arid areas in South Asia. Annual precipitation is less than 250 mm in the driest parts of these areas (Figure A71a). Despite considerable low-level convergence into the low-pressure areas, there are very little clouds and precipitation because of extremely low humidity and/or because of stable inversion (Hamilton, 1979). From the east coast of India the precipitation decreases inland south of 17°N. The interior of the peninsulas, especially the lee side of the Western Ghats, has low precipitation, less than 1000 mm per year. Low precipitation is also found in the upper basin of the Bhima River (around 18°N) and its tributaries. In northern India there is a low precipitation strip from about 28°N

and 75°E to 25°N and 87°E; but topographic effects and monsoons produce significant precipitation along the Himalayas.

In monsoon areas the precipitation exceeds 1000 mm per year. Maximums of precipitation coincide with higher elevations in the Ghats and the eastern Himalayas. In the Khasi-Jaintia Hills the precipitation can reach as much as 11 000 mm per year. On the Malabar Coast and at the southern end of the Western Ghats in India the value reaches more than 3000 mm per year. In Sri Lanka the annual precipitation is also affected by monsoons and is higher than 1300 mm per year; in the southwest it exceeds 2200 mm per year. The pattern of rainy days is similar to that of annual precipitation. The highest number of rainy days (200 per year) is recorded in southwest Sri Lanka. The rainy days number about 170 per year in the eastern Himalayas and about 150 on the Malabar Coast. The interior regions of India have rain on 5–80 days per year, while in the Great India Desert it falls on less than 5 days (Martyn, 1992; Rao, 1981).

The precipitation in South Asia is linked to seasonal changes in the atmospheric circulation. Rains develop over southern India and the southern Bay of Bengal in May–June (Webster et al., 1998). The abrupt northward jump appears with the onset of the South Asian summer monsoon. Based on analysis of various data sets it was found that the South Asian monsoon onset was associated with the reversal of the meridional gradient of upper tropospheric temperature south of the Tibetan Plateau (Flohn, 1957; Li and Yanai, 1996).

The monsoons bring most of the region's precipitation (Figure A71c). On the Indian Peninsula north of 13°N the rainy season begins in mid-June and lasts until September; in Bangladesh it lasts until October. The monsoon usually advances from two locations – one from the Bay of Bengal to central India and southern India in June and reaching northwest India by early July, and the other one over the Arabian Sea 1 month later. This progression of monsoons is associated with large-scale ascent through the troposphere with strong lower tropospheric convergence and upper tropospheric divergence. The periods of maximum thunderstorm frequency precede and

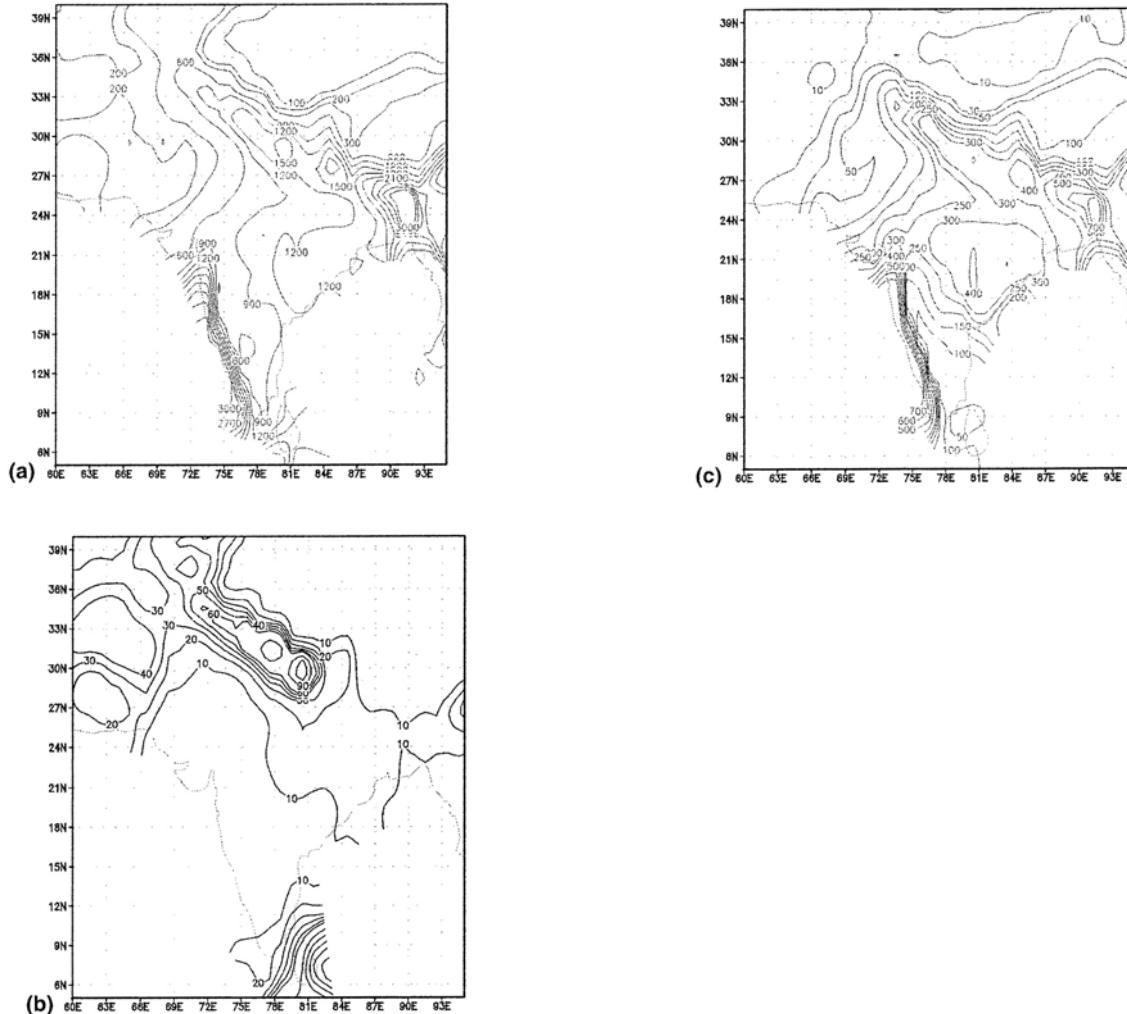

Figure A71 Precipitation: (a) Annual mean (mm year^{-1}); (b) January mean (mm month^{-1}); (c) July mean (mm month^{-1}).

follow the summer rains (Hamilton, 1979). In most parts of South Asia the spatial distribution of annual precipitation is similar to that in this period. The southwest monsoon rain provides water for agriculture in the world's very populous regions.

Orographic influence is dominant as onshore winds blow to the Western Ghats and the Khasi-Jaintia Hills. The main impact of the southwest monsoon is in a 250-km long stretch of the Himalayas between 87 and 90°E. Not only do the Himalayas receive heavy rains, but also the plains adjoining the foothills receive more rain than the plains further south. Even in north Pakistan the precipitation also ensues from monsoons from June to September. A trough (the monsoon trough) extends east-southeastward from Indo-Pakistan heat low to the northern part of the Bay of Bengal near 25°N in June and July and shifts a little further north in July–August, by which time it dominates weather over the Indian subcontinent. It retreats southward and disappears in September as a near-equatorial trough near 10°N. The position of this trough is an index of the activity of the monsoon over the subcontinent. If the trough is in a normal position it will be a normal monsoon year. When the trough

shifts to the foothills of the Himalayas this indicates a break situation (Rao, 1981; Hamilton, 1979).

Temporal variations in precipitation are associated with shifts of position in large-scale upper tropospheric circulation, the low-level monsoon trough, and the development of synoptic disturbances. The precipitation maximum occurs in May–August (some areas extend to September). Rain is very heavy, especially at the start of the monsoon season and during tropical cyclones. Along the Coromandel Coast the rains begin in July, sometimes even in August. There is rain on more than 20 days in a month. In some areas, rainy days reach 25–28. However, it is very dry on the southeast tip of the peninsula. In the northwestern parts of the subcontinent the precipitation also decreases progressively westward.

A seasonal reversal of winds at lower levels, the displacement of the monsoon airmass by the continental airmass, and development of anticyclonic flow indicate withdrawal of the monsoon. From mid-September, as the surface temperature falls, the atmospheric pressure over the Indus and Ganges Plain rises rapidly and becomes higher than that over the Bay of Bengal. In October the ITCZ lies at 10°N and only affects

southern India. Southern India and southwest Sri Lanka have two rainy seasons due to the movement of the ITCZ. The first one is from May to July, and the second one is from October to November. In addition, tropical cyclones have prolonged heavy rainfall on the Coromandel Coast in fall. The turn of the monsoons is the time when tropical cyclones develop over the Bay of Bengal. In the Bay of Bengal, based on 70-year records, 15% of cyclones arise in April and May, and 38% arise in October and November (Rao, 1981). Fall cyclones are much stronger than the pre-monsoon ones. Some are listed as severe cyclonic storms with winds of 48 knots or more. The most violent cyclones over the Bay of Bengal cross the central Deccan along the Krishnai river valley. Others turn to blow up the eastern coast toward Bangladesh. Considerable flood damage has occurred in the Ganges delta. Apart from this, the cyclones are accompanied by high winds, tidal waves, and heavy rain. There can be disastrous flooding.

The winter precipitation over South Asia is only a small fraction of the annual amount, except in Kashmir and its surroundings (Figure 71b). During winter in Kashmir, Karakoram, cyclonic precipitation is dominant. On the east coast of Sri Lanka the rainfall is still more than 30 mm per month, decreasing to 15 mm per month along the west coast.

Impact of the Himalayas/Tibetan Plateau on the South Asian climate

The northern edge of South Asia is bounded by the Himalayas, which run along the southern periphery of the Tibetan Plateau; it extends over the latitude-longitude domain of 70–105°E, 25–45°N, with a mean elevation of more than 4000 m above sea level. Strong contrast exists between the eastern and western parts of the Plateau in both land surface features and meteorological characteristics.

The sharp edge of the Himalayas and the vast and high Plateau force the large-scale airflow to go around rather than over it. This effect is clearly seen in the flow features well above the Plateau. The mid-tropospheric westerly jet stream is situated to the south of the Plateau before the onset of the summer monsoon, but it suddenly jumps to the north side with the monsoon onset. Earlier, the thermal influences of the Tibetan Plateau were inferred from the presence of a huge upper tropospheric anticyclone above the Plateau in summer (Flohn, 1957) and from the pronounced diurnal variations in the surface meteorological elements along the periphery of the Plateau (Yeh and Gao, 1979).

During winter the Tibetan Plateau is a cold source; it acts as a heat source from March until October. The elevated heat source above the Plateau acts to warm the mid-upper tropospheric air, and the temperature over the Plateau in summer exceeds that over the Indian Ocean (Yanai et al., 1992). This meridional gradient of temperature, appearing in May–June, is crucial for the onset of the South Asian monsoon. Concurrent with the reversal of the temperature gradient, the rain belt associated with the ITCZ over the Indian Ocean suddenly moves onto the Indian subcontinent and reaches the foot of the Himalayas.

With the cooling of the Plateau surface the westerly jet stream retreats to the south side of the Plateau in late October; this is just after the end of the southwest monsoon in India and almost concurrent with the commencement of the northeast winter monsoon over southeast India (Matsumoto, 1992).

ASIA, CLIMATE OF SOUTHWEST

The region commonly referred to as southwest Asia reaches from the mid-latitudes to the tropics and encompasses a swath of land stretching zonally from the eastern shores of the Mediterranean Sea to the Himalayan Mountains and meridionally from the Caspian Sea to the Arabian Sea (roughly 26°E to 70°E and 12°N to 42°N). In addition, this area includes the Gulf of Aden, the Arabian (Persian) Gulf, and the Red Sea. The

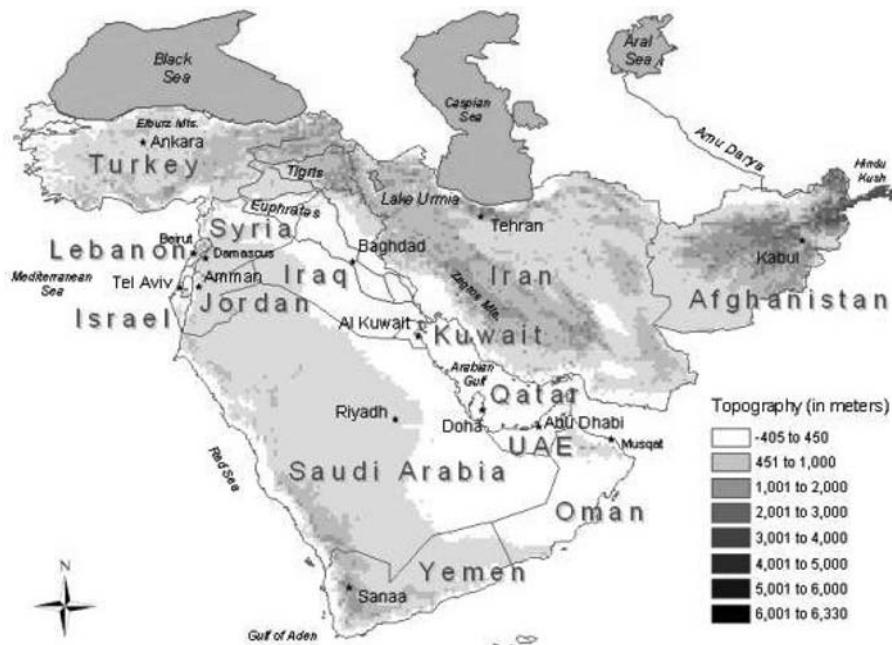

Figure A72 Topographic map of southwest Asia in meters above sea level. Topographic data were provided by the United States Geological Survey (USGS) Land Processes Distributed Active Archive Center (DAAC) established as part of NASA's Earth Observing System (EOS) Data and Information System (EOSDIS) and are available at <http://edcdaac.usgs.gov/main.html>. GTOPO30 is a global digital elevation model (DEM) with a horizontal grid spacing of 30 arc seconds (approximately 1 kilometer).

countries within this region include: Afghanistan, Bahrain, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, Turkey, the United Arab Emirates (UAE) and Yemen (Figure A72).

Location and topography

Southwest Asia is bordered by seven bodies of water: the Mediterranean, the Red, the Arabian, the Caspian and the Black Seas, the Gulf of Aden, and the Arabian (Persian) Gulf. There are three major plateaus:

1. The Iranian Plateau: with the Elburz mountain range bordering it to the north and the Zagros mountain range bordering it to the west.
2. The Anatolian Plateau: with the Septus and Pentus mountain ranges bordering in the north and the Toros mountain range bordering in the south.
3. The plateau of the Arabian Peninsula, which is characterized by a vast desert area including the Arabian, Syrian, and Iranian deserts.

Climatic classification

Southwest Asia is a region of diverse climates and is generally divided into three main climate types: arid, semiarid, and temperate. According to the Köppen classification system, a system of climate classification using latitude band and degree of continentality as its primary forcing factors, Central Asia is a predominantly B-type climate regime. This implies that 70% or more of the annual precipitation falls in the cooler half of the

year (October–March in the northern hemisphere). Based on the Köppen–Geiger classification, which factors in seasonal distribution of rainfall and the degree of dryness/coldness of the season, southwest Asia can further be divided into five climatic types (Figure A73). These climatic types are listed in Table A39.

General circulation

Southwest Asia lies at the boundary of three competing climate regimes. These three systems are: (1) the cold Siberian High in winter over Central Asia, (2) the monsoon Asian Low in summer over India, and (3) eastward propagating secondary low-pressure systems traveling through the Mediterranean and adjacent areas during non-summer seasons. Overall, the climate of northern southwest Asia is governed by extra-tropical synoptic scale disturbances while the climate of southern southwest Asia is governed by smaller-scale seasonal thermodynamics.

Airmasses

Polar continental air (cP)

Polar continental air (cP) is formed over Central Asia in winter and is characterized by extremely low temperatures in a shallow surface layer with a significant inversion reaching to 1500 m. The cP airmasses are stable in their source regions – the central parts of Asia and North Africa – but are modified upon entering southwest Asia. As an example, when cP air enters southwest Asia via the Caspian Sea the surface inversion is destroyed by heating from below, resulting in increased

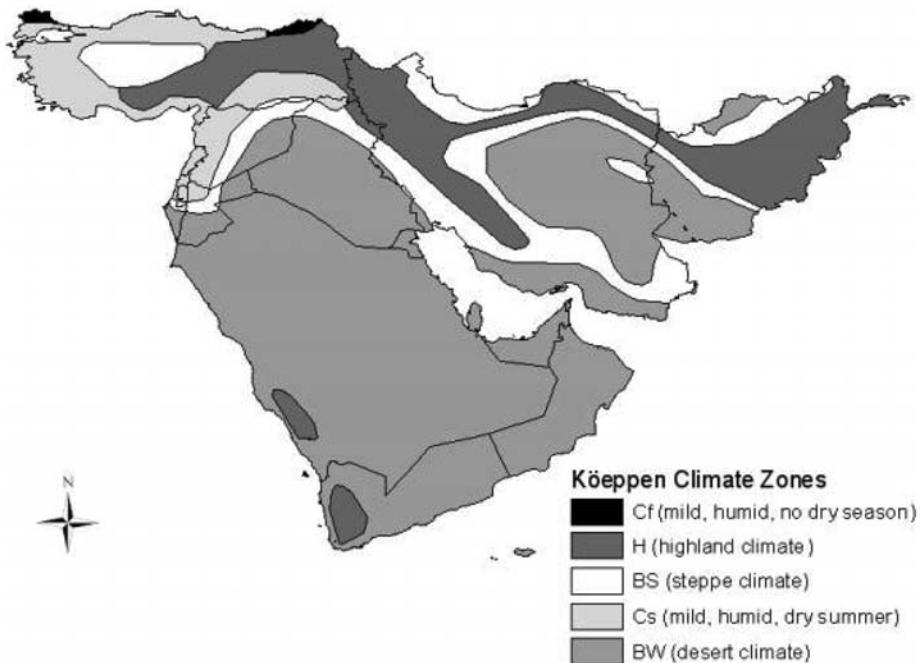

Figure A73 Köppen classification zones for southwest Asia. Köppen data were obtained through the Center for International Development at Harvard University and are available at <http://www2.cid.harvard.edu/ciddata/geographydata.htm>

Table A39 Köppen–Geiger climatic types for southwest Asia

Type	Winter	Summer	Location
Cs	Temperate, rainy	Hot, dry	Coast of Turkey, Syria, Lebanon and Israel
Cf	Temperate, rainy	Warm, rainy	Interior parts of the Anatolian Plateau
H	Temperate, rainy	Dry	Mountain ranges in southwest Arabian Peninsula
BW	Arid	Arid	Desert areas of Arabian Peninsula, Iran, Syria and Iraq
BS	Semi-arid	0.1/2.9	Arabian Peninsula, Oman, Jordan, Syria, Israel, Iraq and Iran

cloudiness due to the absorption of moisture. The cP airmasses are shifted north of 50°N in summer and hence do not influence the climate of the region.

Tropical maritime (mT)

The source region for tropical maritime (mT) airmasses is the southern portions of the oceans.

Polar maritime air (mP)

In winter polar maritime (mP) airmasses invade the Anatolian Plateau and the Black Sea and tend to be modified because of the long stretches across land. These airmasses tend to be more humid than cP airmasses and they follow the migrating low-pressure systems across Europe – losing most of their moisture upon orographic uplift. The mP airmasses are not present in the summer.

Tropical continental air (cT)

Formed over the dry land areas of central Asia and the African Sahara in summer, late spring, and early fall when surface heating is pronounced, tropical continental (cT) airmasses precede the “khamsin” dust storms occurring in late spring/early fall. These dust storms are very hot and dry and frequently proceed eastward through the Sinai or the northern Red Sea.

The characteristic airmasses of southwest Asia are cP, cT and mP in winter and cT and mT in summer – with each of these airmasses having a different source region.

Winter

The following section describes general climate conditions during the winter season in terms of sea-level pressure, temperature and precipitation. Average winter (December through February; DJF) total precipitation and average winter temperature are presented in Figure A74 and Table A40.

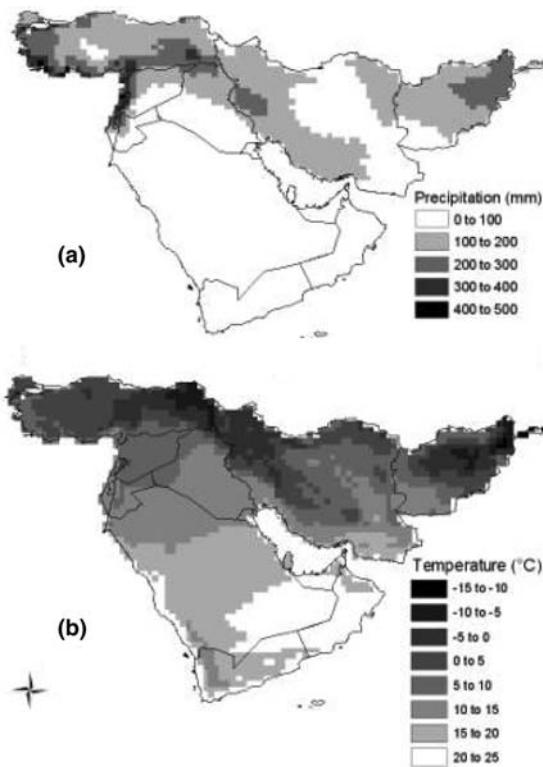

Figure A74 Average total winter precipitation is shown in (a) and average winter temperature is shown in (b). Monthly temperature and precipitation data (New et al., 2000) have a resolution of $0.5^\circ \times 0.5^\circ$ and are averaged over the period 1901–1998.

Table A40 Mean average temperature (T) in $^{\circ}\text{C}$ and total precipitation (P) in mm/day for summer and winter (S/W)

Country	T (S/W $^{\circ}\text{C}$)	P (S/W mm/day)
Afghanistan	24.1/3.3	0.8/5.9
Bahrain	NA/NA	NA/NA
Iran	27.4/7.4	0.3/3.6
Iraq	31.7/10.8	0.0/0.3
Israel	26.0/13.1	0.1/2.9
Jordan	26.0/10.4	0.1/2.8
Kuwait	35.7/14.7	0.0/1.4
Lebanon	23.9/9.8	0.0/10.1
Oman	29.0/21.4	1.2/1.5
Qatar	35.0/19.0	0.0/1.5
Saudi Arabia	31.7/17.5	0.40/1.0
Syria	27.6/8.0	0.02/4.3
Turkey	20.6/1.6	1.4/6.1
Yemen	26.7/19.3	2.6/1.3

Pressure

The general features of mean sea-level pressure in winter can be summarized as follows:

1. *Siberian and Azores High*: the northern portion of an anticyclonic ridge over the region is an extension of the Siberian High. This ridge results in northeast surface winds over the Black and Caspian Seas. The southern portion is related to

the Azores High which extends over the southern half of the Arabian Peninsula and is associated with an easterly current thought to be related to the easterly trade winds or to the northeast monsoons which prevail over India in winter. The intensity of this ridge is directly related to the passage of mid-latitude winter storms entering into the Mediterranean – these will be discussed next.

2. *Mid-latitude storms*: these depressions enter into the Mediterranean from the Atlantic via different tracks. These tracks include (a) northern Spain, (b) southern France, and (c) straits of Gibraltar. Some are secondary low-pressure systems, meaning they further develop upon entering into the Mediterranean – mainly the Gulf of Genoa, over Cyprus and in the Adriatic Sea. Orographic depressions are created on the lee side of the Alps in Switzerland and Atlas Mountains over North Africa. In general the Mediterranean low-pressure systems travel only 20–30 miles inland; however, when these low-pressure systems come in contact with the Caspian Sea and Arabian Gulf they are strengthened and have enough energy to penetrate into Iraq, Iran, and Afghanistan – providing the major source of rain to this region. Overall, it is the Mediterranean depressions which carry most of the precipitation to the northern half of southwest Asia – the area of greatest precipitation being the coastal regions of the Black, Caspian, and Mediterranean Seas.
3. *Subtropical jet*: the 200 mn upper-level winds show an axis of strong westerly winds centered at approximately $23\text{--}27^{\circ}\text{N}$ – this is the subtropical jet. Upper tropospheric divergence around the jet – together with low-level convergence – is considered a major factor in the development of the convective activity in non-summer seasons. The high cloud base and dryness over Saudi Arabia does not allow precipitation to fall to the surface; strong gusts, sandstorms and thunderstorms are observed. Upper tropospheric divergence, coupled with lower-level convergence, is also considered an important precursor for the development and maintenance of small-scale systems such as desert depressions.
4. *Polar jet*: along with the subtropical jet stream, a permanent feature of the upper tropospheric flow pattern in fall, winter, and spring, southwest Asia is also invaded by active branches of the polar jet which is associated with the passage of low-pressure systems generated in the Mediterranean.

Temperature and precipitation

In southwest Asia the precipitation primarily falls from winter storms moving eastward from the Mediterranean, with the high mountains of the region intercepting most of the water and the interior high plains left with large stretches of barren desert. This wintertime precipitation generally occurs between the months of November and April, with the peak between January and March. Much of the precipitation falls as snow in the higher elevations and the timing and amount of snowmelt is an important factor in the irrigated agriculture prevalent in the region.

Summer

The following section describes general climate conditions during the summer season in terms of sea-level pressure, temperature and precipitation. Average summer (June through August; JJA) total precipitation and average summer temperature are presented in Figure A75 and Table A40.

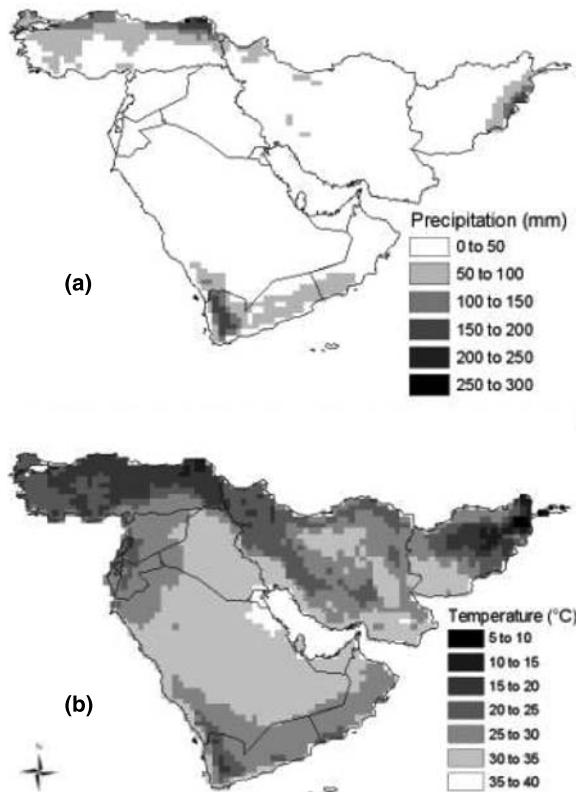

Figure A75 Average total summer (JJA) precipitation is shown in (a) and average summer temperature is shown in (b). Data used are same as in Figure A24.

Pressure

1. *Indian monsoon:* in summer the western branch of the Asian Low dominates southwest Asia which is approximately centered over 30°N. While appearing essentially fixed in time and space over the Arabian/Persian Gulf in the daily series of SLP, synoptic charts reveal zonal variability in the western branch – sometimes extending all the way into the eastern Mediterranean. During such an event, warm subtropical air will advect over the eastern Mediterranean region resulting in intense heat waves. The basic theory of these summer heat waves relies on the latitudinal elongation of the monsoon low over the Arabian/Persian Gulf or to an overall strengthening of the low.
2. *Quasi-stationary surfaces:* the summer season marks a time of generally stable conditions lacking significant daily variability. This allows for the emergence of quasi-stationary surfaces of separation between two unique air streams; namely the subtropical front and the intertropical front.

Temperature and precipitation

Very little rain falls in most of southwest Asia during the summer season. However, in eastern Pakistan the primary rainfall season is summer, associated with the northernmost advance of the Asian monsoon, which results in a summertime maximum in precipitation in the northern mountain regions of

Pakistan but generally suppresses rainfall over Iran and Afghanistan. Dust storms occur throughout the year in the desert high plains. Such storms are prevalent through much of the region in summer, often associated with the “wind of 120 days”, the highly persistent winds of the warm season which blow from north to south.

Observational records

Lack of meteorological observations continues to pose a problem for long-term climate monitoring aimed at “clarifying the climate picture”, making it difficult to cleanly differentiate between different climatic regimes.

Global warming

According to the Third Assessment Report (Working Group II) of the Intergovernmental Panel on Climate Change continuing emissions of greenhouse gases are likely to result in significant changes in mean climate and its intraseasonal variability in Asia (IPCC, 2001). General circulation models (GCM) suggest that the area-averaged annual mean warming over Asia would reach about 3°C by 2050 and 5°C by 2080. When the cooling effects of sulfate aerosols are added to the models, surface warming is reduced slightly, reaching 2.5°C by 2050 and 4°C by 2080. Seasonally speaking, warming over Asia is expected to be higher during northern hemisphere (NH) winter. Both the annual mean and winter season minimum temperature is expected to rise more than the maximum temperature in Asia, leading to a decrease in the diurnal temperature range (DTR) over these time periods. During summer, however, DTR is expected to increase, suggesting a rise in average summertime maximum temperature. When compared with other regions, the summertime DTR increase is expected to be significantly higher.

All GCM project an enhanced hydrological cycle resulting in rainfall increases over Asia due to continued growth in the emissions of greenhouse gases. A 7% increase is projected by 2050 and an 11% increase is projected by 2080. When the cooling effects of sulfate aerosols are added to the models the projected increase in precipitation is reduced to 3% in 2050 and 7% in 2080. As with temperature, precipitation increases are expected to be greatest during the NH winter. A decline in summer precipitation is expected in southwest Asia. Because this area already receives so little precipitation, severe water-stress conditions resulting in expansion of the deserts are a possibility – when factoring in both the rise in temperature and loss of soil moisture. Increased temperatures can also affect the amount and timing of snowmelt and river flow in southwest Asia. In addition, global warming could affect the role the tropical oceans play in the climate of the region as well as the character of winter storms that currently supply the majority of cold season precipitation.

Overall, southwest Asia appears to be highly vulnerable to anticipated climate change projections. Water stress is expected to be high with significant negative impacts on the agricultural sector. Agricultural productivity in southwest Asia is likely to suffer severe losses due to increases in temperature, soil moisture depletion, and the increased potential for severe drought – ultimately increasing the potential for food insecurity and famine. Adaptation strategies identified for southwest Asia include: (1) transition from conventional crops to intensive greenhouse agriculture, (2) improve conservation of freshwater

supply for times of enhanced water stress, and (3) protect lakes and reservoirs.

ATMOSPHERE

The atmosphere is the envelope of air surrounding the Earth. It consists of a physical mixture of gases and particle matter. Based on its temperature structure, the atmosphere can be divided into several sections. Below about 12 km is the *troposphere*, where the majority of the world's weather occurs and the temperature broadly decreases from about 15°C at the Earth's surface to –54°C at the top. Almost all of the processes of vertical transfer of atmospheric properties through turbulence and mixing occur in the troposphere.

Above the troposphere the temperatures increase to a level of about 50 km, in the region called the *stratosphere*. Here the atmosphere is very stable and contains layers of gaseous and particle matter, mainly of volcanic origin. The troposphere and the stratosphere are separated by the *tropopause*, which is located where temperatures suddenly begin to increase with altitude. Above the stratosphere is the *stratopause*, which separates the stratosphere from the *mesosphere* (48–78 km), where temperatures decrease with altitude again. Above the mesosphere is the *thermosphere* (above 80 km), another stratum in which temperature increases with altitude, where the thin outer layers of the atmosphere are directly interacting with emissions from the sun. Both the mesosphere and thermosphere contain gaseous atoms and ions in very rarefied concentrations.

Table A41 Physical characteristics of the atmosphere at sea level

Descriptor	Value	Units
Pressure	1013.25	hPa
Temperature	283	K
Density	1.29×10^{-3}	g/cm
Molecular weight (dry air)	28.966	—

Table A42 Average dry air composition below 25 km (after Barry and Chorley, 1987)

Gaseous component	Chemical symbol	Percentage volume
Nitrogen	N ₂	78.08
Oxygen	O ₂	20.94
Argon	A	0.93
Carbon dioxide	CO ₂	0.034*
Neon	Ne	0.0018
Helium	He	0.0005
Ozone	O ₃	0.00006

* Variable and presently increasing in concentration on a global scale.

Table A41 presents the average physical characteristics of the atmosphere at sea level. This part of the atmosphere is where the greatest interactions with the Earth's surface occur, and is defined as the *boundary* (or *mixing*) *layer*. Above the surface both atmospheric density and pressure decrease logarithmically. Thus, approximately half the mass of the atmosphere is situated below an altitude of 5.6 km, and the pressure at this altitude is about 500 hPa.

The atmosphere itself is not a chemical compound, but contains a wide variety of chemical compounds and individual gas molecules as part of its composition. The composition is not constant, but is highly variable between locations and over time. In terms of content it is dominated by four gases: nitrogen, oxygen, argon, and carbon dioxide, as shown in Table A42. All of these gases are stable in concentration except carbon dioxide and ozone. Carbon dioxide is a major greenhouse gas, and is controversially linked to the rise in global air temperatures over the past century. Ozone occurs naturally as a layer in the stratosphere, between 10 and 50 km and peaking in concentration around 25 km. Its major role is to protect the Earth's surface from harmful ultraviolet radiation from the sun. The ozone layer is threatened by partial destruction as a result of chemical reactions with chlorofluorocarbon emissions from human activities.

The most important gas not included in Table A42 is water vapor. Concentrations range from almost 0% by volume over the driest regions of the Earth (deserts and polar ice caps) to about 4% in the hot tropical regions. A greenhouse gas, water vapor, is an essential part of the hydrologic cycle and is crucial to the maintenance of life on Earth. It is the only compound that can exist naturally in all three states at one location.

The troposphere and lower stratosphere also contain spatially inhomogeneous quantities of particles, dust, and aerosols. Particle matter in the stratosphere originates mainly from volcanic explosions, and through scattering of shortwave radiation may create spectacular sunsets and affect global temperatures for periods of up to 2 years. In the troposphere, particle matter originates from sea spray, windblown surface material, air pollution emissions, and chemical reactions. Particles form

condensation nuclei for clouds, affect visibility through short wave radiation scattering, and are often responsible for pollution episodes in major cities around the globe.

radiate more heat than they receive. (The distribution of radiation over the Earth's surface is reviewed by Lockwood, 1979, 1985.) However, the equatorial belt does not become warmer during the year, nor do the poles become colder. This is because heat flows from the warm regions to the cold regions, maintaining the observed temperatures. An exchange of heat is brought about by the fluid motions in the atmosphere and oceans, thus forming the observed circulation of the atmosphere and oceans.

If the Earth's surface were homogeneous, and the planet was not rotating, the imposition of a theoretical latitudinal (north-south) heating gradient, with cold poles and a warm equator, would probably result in a single circulation cell in each hemisphere with an upward limb at the equator and downward limbs at the poles. Such cells would be energetically direct cells because they result from a direct transformation of potential to kinetic energy. They are often referred to as Hadley cells in tribute to the eighteenth-century scientist who first suggested their possible existence. In reality, on an Earth with one face always toward the sun, the equatorial segment of the sunward face would be extremely hot and the dark face extremely cold. The temperature gradient would be from the daylight to the dark face, not from equator to pole, with a corresponding circulation cell between the two faces. The Earth's rotation smears the region of strong solar tropical heating zonally around the whole globe and generates the observed equator – polar temperature gradients.

ATMOSPHERIC CIRCULATION, GLOBAL

Global atmospheric circulation consists of the observed wind systems with their annual and seasonal variations, and is the principal factor in determining the distribution of climatic zones, while variations in the atmospheric and oceanic circulations are responsible for many of the observed longer-term fluctuations in climate. The two major controls on the global wind circulation are inequalities in radiation distribution over the Earth's surface and the Earth's rotation. Global radiation distribution, together with gravity, drives the global atmospheric circulation, whereas the Earth's rotation determines its shape. Basically, the mean surface circulation consists of easterly winds with equatorial components in the tropics and westerly winds with poleward components in middle latitudes, the corresponding meridional flows aloft being reversed. Weak surface easterlies are observed in polar regions, and extensive areas of calms in the equatorial and also the subtropical regions. Strong, westerly winds are found in the upper troposphere poleward of about 25°N and 25°S.

Causes of the global atmospheric circulation

Radiation distribution

The planet Earth receives energy from the sun in the form of short-wave radiation, while radiating an equal amount of heat to space in the form of longwave radiation. This balance of heat gain equaling heat loss applies only to the planet as a whole over several annual periods; it does not apply to any specific area for short periods of time. The equatorial region absorbs more radiation than it loses, while the polar regions

The Earth's rotation

The real Earth rotates, and this makes the existence of simple Hadley cells extending from equator to pole impossible, since the rotation generates east–west motions in the atmosphere. To an observer on the rotating Earth it appears as if a force is acting on moving air particles that causes them to be deflected from their original path, and this apparent force-per-unit mass is termed the Coriolis force. The Coriolis force turns the wind to the right in the northern hemisphere and to the left in the southern hemisphere. Therefore, in the northern hemisphere, the upper poleward current of the Hadley cell assumes a strong eastward component (westerly wind) and the lower equatorial current assumes a westward component (easterly wind). For a given heating gradient the turning of the wind tends to reduce the efficiency with which a single cell can transport heat poleward. For a sufficiently large rotation rate a balance cannot be maintained, and the imposed latitudinally dependent heating would cause the meridional temperature gradient to increase with time, while remaining circularly symmetric about the pole. However, there comes a time when small meridional displacements of a suitable east–west size can become dynamically unstable and grow, the process being an example of baroclinic instability.

Baroclinic instability

The growth of these wave disturbances under baroclinic instability is characterized by the ascent of warmer airmasses and descent of colder airmasses, causing a decrease of potential energy and an associated release of kinetic energy. Potential temperature increases with height; thus this ascent and descent of airmasses takes place in a manner described by the term slantwise convection. In the normal atmosphere equal potential temperature (isentropic) surfaces slope upward from lower to higher latitudes, and in slantwise convection the trajectories of individual air particles are tilted at an angle to the horizontal that is comparable with, but less than, the slope of the isentropic

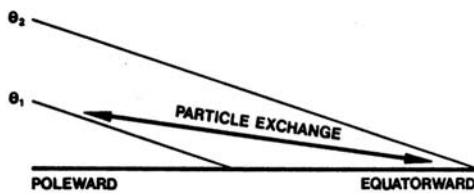

Figure A76 Height-latitude cross-section of the troposphere showing potential temperature θ increasing equatorward and upward. The system is stable for vertical convection, but energy can be released if particles are exchanged by slantwise convection along the thick solid arrow.

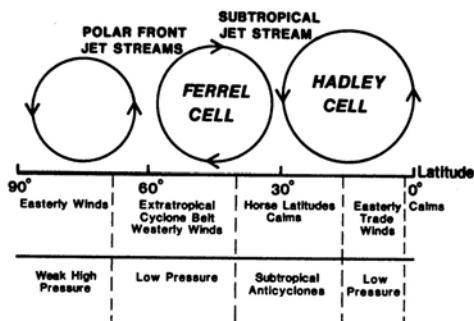

Figure A77 A schematic representation of the mean meridional circulation of the northern hemisphere.

surfaces (Figure A76). Therefore, while an air parcel may be prevented from rising vertically because the prevailing lapse rate is less than the appropriate adiabatic lapse rate, poleward travel brings it to an environment more dense than itself, enabling it to rise. Air at higher levels and higher latitudes may similarly descend by equatorward movement. Further details may be found in Lorenz (1967), Barry and Carleton (2001), and Houghton (2002).

Mean global atmospheric circulation

Mean meridional circulation

Disturbances with the dimensions of about five to eight waves about the pole will grow fastest under baroclinic instability. At the surface, anticyclones in this size range that develop will grow and ultimately move equatorward, finding final residence in the subtropics. Similarly, surface low-pressure systems develop and move poleward. The resultant mean meridional circulation is no longer simple. The single equator-to-pole direct cell postulated by Hadley to exist if the Earth did not rotate is contracted equatorward, so that the poleward descending limb coincides with the axis of the surface subtropical anticyclones (Figure A77). In the tropics baroclinic instability is virtually non-existent because of the weak Coriolis force, so that direct mean meridional circulation (the Hadley cell) is still the most efficient means for effecting a poleward heat transfer. In mid-latitudes unstable wave motion is the most efficient means for poleward heat transfer. An energetically weak indirect mean

meridional circulation, known as the Ferrel cell, exists in middle latitudes.

Subtropical jet streams

A schematic representation of the mean meridional circulation in the northern hemisphere during winter is shown in Figure A77. The simple Hadley cell circulation is clearly seen south of 30°N. Eastward angular momentum is transported from the equatorial latitudes to the middle latitudes by nearly horizontal eddies, 1000 km or more across, moving in the upper troposphere and lower stratosphere. Such a transport, together with the dynamics of the middle latitude atmosphere, leads to an accumulation of eastward momentum between 30° and 40° latitude, where a strong meandering current of air, generally known as the subtropical westerly jet stream, develops. The cores of the subtropical westerly jet streams in both hemispheres and throughout the year occur at an altitude of about 12 km. The air subsiding from the jet streams forms subtropical anticyclones. More momentum than is necessary to maintain subtropical jet streams against dissipation through internal friction is transported to these zones of strong winds. The excess is transported downward to maintain the eastward-flowing surface winds of the middle latitudes against ground friction. The supply of eastward momentum to the Earth's surface in middle latitudes tends to speed up the Earth's rotation. Counteracting such potential speeding-up of the Earth's rotation, air flows from the subtropical anticyclones toward the equatorial regions, forming the so-called trade winds. The trade winds, with a strong component directed toward the west, tend to retard the Earth's rotation, and in turn gain eastward momentum.

Mean surface winds

An idealized mean surface wind circulation with associated pressure distribution, as shown in Figure A78, may be described as follows:

1. The equatorial trough. A shallow belt of low pressure on or near the equator with light or variable winds.
2. The trade winds. Between the equatorial trough and latitudes 30°N and 30°S are northeast winds in the northern hemisphere and southeast winds in the southern hemisphere.
3. The subtropical anticyclones. Ridges of high pressure between about latitudes 30–40°N and S, associated with light, variable winds.
4. The westerlies. Belts of generally westerly winds, southwest in the northern hemisphere and northwest in the southern hemisphere, between about latitudes 40–60°N and S.
5. The temperate latitude low-pressure systems. Variable winds converging into low-pressure belts at about 60°N and 60°S, the subpolar low-pressure area.
6. The polar anticyclones. Regions of outflowing winds with an easterly component, diverging from weak high-pressure systems near the poles.

Further detailed descriptions of mean atmospheric circulation patterns may be found in the textbooks listed in the Bibliography.

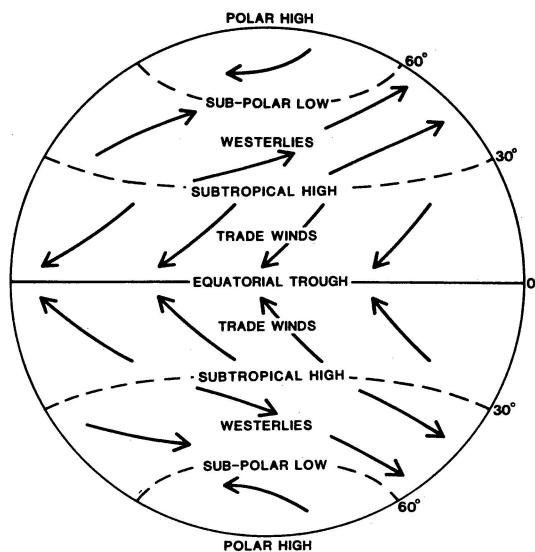

Figure A78 Idealized mean surface wind circulation.

Tropical circulation patterns

The mean surface winds in the tropics are directed predominantly toward the equator within latitudes 30°N and 30°S. Such motions can persist only if some force accelerates the air in that direction, and the only force in the atmosphere known to produce accelerations of large-scale windfields is the pressure force. Therefore, high pressure must exist in the subtropics and low pressure in the equatorial zone, with the resulting pressure gradients driving the mean winds. The average latitude of the equatorial low-pressure trough is about 5°S in the northern winter and 15°N in the southern winter. The annual mean latitude is about 5°N, so the meteorological southern hemisphere is larger than the northern hemisphere. This is largely a result of the differing ocean/continent configurations of the hemispheres (McGregor and Nieuwolt, 1998).

The trade winds

Between the equatorial low-pressure trough and the subtropical high-pressure belt lie two belts of tropical easterlies, each with an equatorial meridional flow. These wind systems are known as the northeast trade winds in the northern hemisphere and the southeast trade winds in the southern hemisphere. There tends to be a certain monotony about the weather of the trade winds since their extreme steadiness reflects the permanence of the subtropical anticyclones, which are inclined to be the most intense in winter, making the trade winds strongest in winter and weakest in summer. Figure A79 shows that all tropical oceans except the northern Indian Ocean have extensive areas of trade winds. Each trade wind region contains definite centers of resultant high wind speed that reach 6–8 m/s. In contrast, wind speeds are low in the subtropics and in the equatorial trough zone. According to Riehl (1979), when wind speed is averaged without regard to direction, an almost uniform value of 7 m/s appears everywhere except within the equatorial trough.

During the summer of 1856 an expedition under the direction of C. Piazzi-Smyth visited the island of Tenerife in the Canary Islands to make astronomical observations from the top of the Peak of Tenerife. On two of the journeys up and down the 3000 m mountain, Piazzi-Smyth carefully measured the temperature, moisture content, direction, and speed of the local trade winds. He found that an inversion was often present, and that it was not located at the top of the northeast trade regime, but was situated in the middle of the current; thus, it could not be explained as a boundary between two airstreams from different directions. He also noticed that the top of the cloud layer corresponded to the base of the inversion. These observations by Piazzi-Smyth have been confirmed many times and the trade-wind inversion is now known to be of great importance in the meteorology of the tropics. Broad-scale subsidence in the subtropical anticyclones is the main cause of the very dry air above the trade-wind inversion. The subsiding air normally meets a surface stream of relatively cool maritime air flowing toward the equator. The inversion forms at the meeting point of these two airstreams, both of which flow in the same direction, and the height of the inversion base is a measure of the depth to which the upper current has been able to penetrate downward.

Subsidence is most marked at the eastern ends of the subtropical anticyclonic cells; that is to say, along the desert cold-water coasts of the western edges of North and South America and Africa, and it is here that the trade-wind inversion is at its lowest. Normally, as the trade winds approach the equator, the trade inversion increases in altitude and conditions become less arid. Over the oceans the intense tropical radiation evaporates water that is carried aloft by thermals and eventually distributed throughout the layer below the trade inversion. The result is that the layer below the inversion becomes more moist as the trade wind nears the equator and the continual convection in the cool layer forces the trade inversion to rise in height.

The equatorial trough

Trade winds from the northern and southern hemispheres meet in the equatorial trough, a shallow trough of low pressure generally situated near the equator. Its position is clear-cut in January (except in the central South Pacific), and in July the trough can be located with ease over Africa, the Atlantic, and the Pacific to about 150°E. The equatorial trough shows a marked tendency to meander with longitude; in January it ranges from 17°S to 8°N, in July from 2°N to 27°N. This is largely the result of wide oscillations in the monsoon regions that cover the whole of southern Asia and North Africa in the northern summer, and southern Africa and Australia in the southern summer. The excursions into the southern hemisphere are smaller than those into the northern hemisphere, because the more constant westerly circulation of the southern hemisphere's middle latitudes constrains the equatorial trough to near the equator. Over southern Asia and the Indian Ocean the mean seasonal positions are around 15°N and 5°S, a difference of 20° latitude. In contrast, the trough is quasistationary over the oceanic half of the Pacific and Atlantic, where seasonal displacement is restricted to 5° latitude or less. Winds in the equatorial trough generally are calm or light easterly. Over some areas, such as the Indian

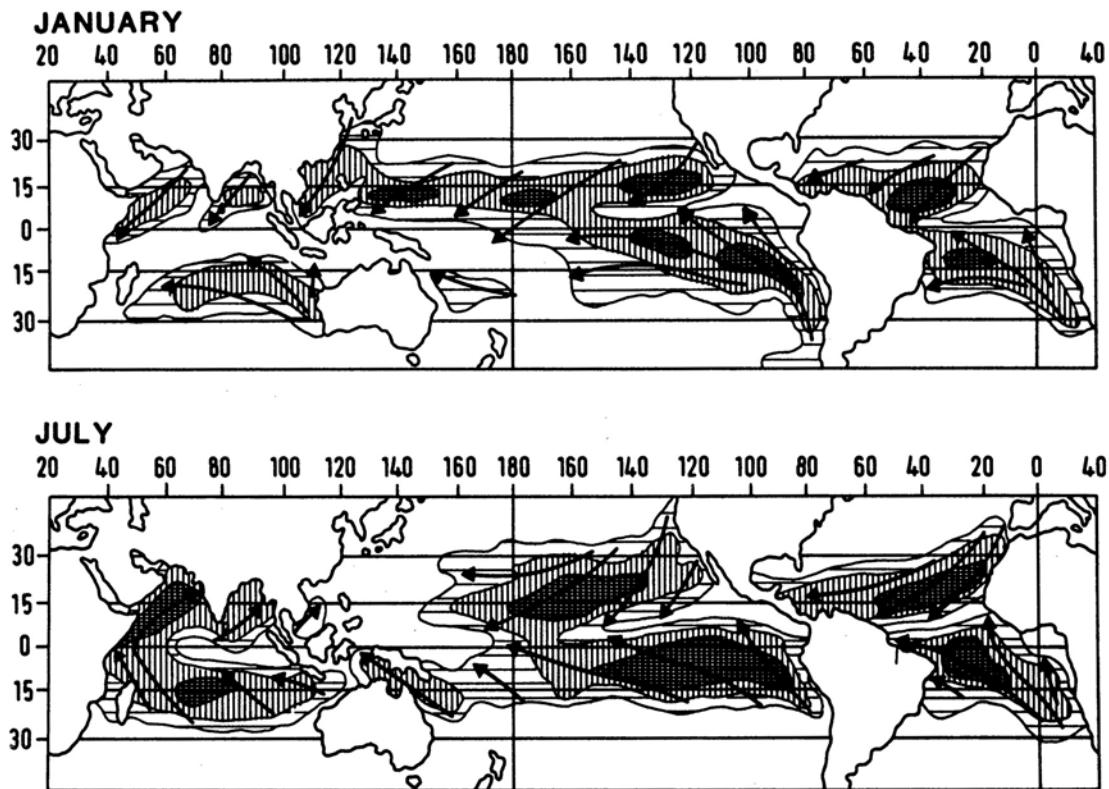

Figure A79 The trade-wind systems of the world in January and July. The isopleths are in terms of relative constancy of wind direction and enclose shaded areas where 50%, 70%, and 90% of all winds blow from the predominant quadrant with Beaufort force 3 or more (over 3.4 m/s) (after Crowe, 1971).

Ocean and Southeast Asia, the structure of the trough is complex and westerlies may be found.

The Walker circulation and the Southern Oscillation

Dietrich and Kalle (1957) have mapped the difference between the sea-surface temperature and its average value along the part of each latitude circle situated over the oceans. If cold-water regions are defined as ocean areas with sea surface temperatures below the latitudinal average, by far the most extensive cold-water area is the South Pacific cold water stretching about 85° westward from the coast of South America. In contrast the South Atlantic cold water continues westward from the coast of Africa by only about 40° longitude.

Bjerknes (1969) believes that when the Pacific cold ocean water along the equator is well developed, the air above will be too cold to take part in the ascending motion of the Hadley cell circulation. Instead, the equatorial air flows westward between the Hadley cell circulations of the two hemispheres to the warm western Pacific, where, having been heated and supplied with moisture from the warmer waters, the equatorial air can take part in large-scale, moist adiabatic ascent. In Indonesia huge cloud clusters with a diameter of more than 600 m develop each day, giving an area-averaged rainfall of around 2200 mm per year. This is equivalent to a release of latent heat of about 170 W m^{-2} , much more than the net radiation near the surface. The resulting thermally driven

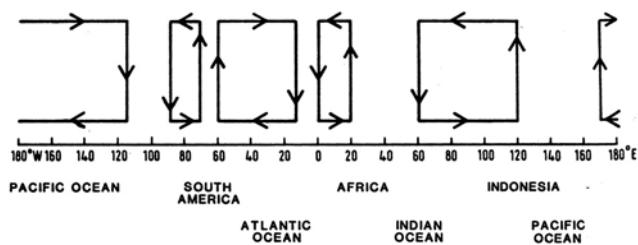

Figure A80 Schematic representation of the Walker circulation near the equator during the northern winter.

circulation (Figure A80) between an equatorial heat center – the maritime continent of Indonesia – and a cooling area in the eastern Pacific is often known as a Walker circulation. As shown in Figure A80, the equatorial Atlantic is analogous to the equatorial Pacific in that the warmest part is in the west, at the coast of Brazil. West–east contrasts of water temperature in the Atlantic are much smaller than in the Pacific, so the potential for a Walker-type circulation is less. Nevertheless, in January a thermally driven Walker circulation may operate from the Gulf of Guinea to the Andes, with the axes of the circulation near the mouth of the Amazon.

Sir Gilbert Walker described in his papers in the 1920s and 1930s what he named the Southern Oscillation. The Southern Oscillation is dominated by an exchange of air between the Southeast Pacific subtropical high and the Indonesian equatorial low, with a period that varies between roughly 1 and 5 years. The Southern Oscillation may be defined in terms of the difference in sea level pressure between Darwin, Australia and Tahiti. Records are available, with the exception of a few years and occasional months, from the late 1800s. During one phase of this oscillation the trade winds are intense and converge into the warm western tropical Pacific, where rainfall is plentiful and sea-level pressures low. At such times the atmosphere over the eastern tropical Pacific is cold and dry. During the complementary phase the trade winds relax, the zone of warm surface waters and heavy precipitation shifts eastward, and sea-level pressure rises in the west while it falls in the east. The latter phase is the more unusual and in the eastern Pacific has become known as El Niño, while vigorous episodes of the former are often termed La Niña. The combined atmospheric/oceanic conditions that give rise to these changes in rainfall across the Pacific and neighbouring areas are referred to as El Niño Southern Oscillation (ENSO) events. The El Niño phenomena are associated with extreme negative Southern Oscillation values, but for much of the time the series exhibits continuous transitions from high to low values with most values being positive. ENSO is important climatologically (Glantz, 1996; Diaz et al., 2001) for two main reasons. First, it is one of the most striking examples of interannual climatic variability on an almost global scale. Secondly, in the Pacific it is associated with considerable fluctuations in rainfall and sea surface temperature, and also with extreme weather events around the world.

Monsoon climates of southern Asia

Originally the term monsoon was applied to the surface winds of southern Asia that reverse between winter and summer, but the word is now used for many different types of phenomena, such as the stratospheric monsoon, the European monsoon, etc. The "classic" characteristics of a monsoon climate are mainly to be found in the Indian subcontinent, where over much of the region the annual changes may conveniently be divided as follows:

1. The season of the northeast monsoon:
 - (a) January and February, winter season
 - (b) March to May, hot weather season.
2. The season of the southwest monsoon:
 - (a) June to September, season of general rains
 - (b) October to December, postmonsoon season.

Halley proposed the first explanation of the Asiatic monsoon in a memoir presented to the Royal Society in 1686. His theory is general and can be applied to all continental regions, not only Asia. During winter intense cooling over the cold continents leads to the establishment of thermal high-pressure systems, while pressure remains relatively low in the warmer, lighter air over the oceans. The surface air flow therefore has a component from the highs over the land toward the lows over the ocean. During summer the land is warmer than the sea and a reverse current circulates from the relatively cool sea toward the heated land. The average sea-level pressure charts for the two extreme seasons show a

reversal of pressure over Asia and its maritime surroundings. In winter the Siberian anticyclone accumulates subzero masses of air (-40°C to -60°C) at an equivalent mean sea-level pressure of between 1040 and 1060 mb, while in summer the torrid heat (about 40°C) reduces the pressure to 950 mb over northwest India. Modern explanations of the Indian monsoon are much more complex (see Lockwood, 1974; Lighthill and Pearce, 1981; Pant and Rupa Kumar, 1997), but follow the basic idea of Halley.

According to Miller and Keshavamurthy (1968), the southwest monsoon current in the lower 5 km near India consists of two main branches; the Bay of Bengal branch, influencing the weather over the northeastern part of India and Burma, and the Arabian Sea branch, dominating the weather over the western, central, and northwestern parts of India. The low-level flow across the equator during the southwest monsoon is not evenly distributed between latitudes 40°E and 80°E as was previously thought, but has been found by Findlater (1969, 1972) to take the form of low-level, high-speed southerly currents that are concentrated between about 38°E and 55°E . A particularly important feature of this flow is the strong southerly current with a mean wind speed of about 14 m/s, observed at the equator over eastern Africa from April to October. The strongest flow occurs near the 1.5 km level, but it often increases to more than 25 m/s and occasionally to more than 45 m/s at heights between 1.2 km and 2.4 km. According to Findlater this high-speed current flows intermittently during the southwest monsoon from the vicinity of Mauritius through Madagascar, Kenya, eastern Ethiopia, Somalia, and then across the Indian Ocean toward India.

When upper winds are taken into account, the Asian monsoon is a fairly complex system (Pant and Rupa Kumar, 1997). During the northern winter season (Figure A81), the subtropical

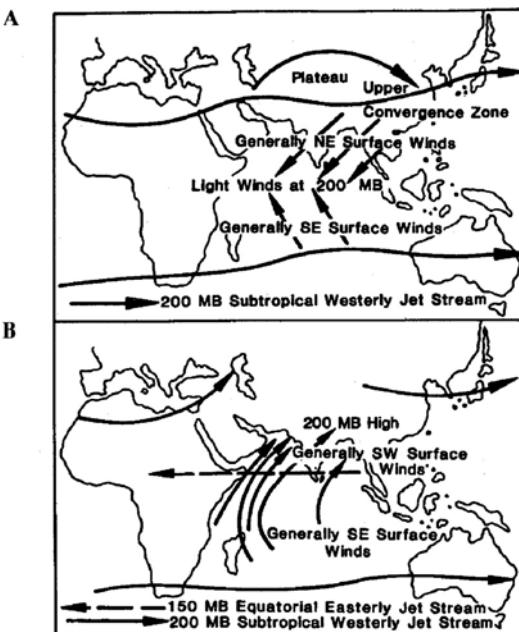

Figure A81 Schematic illustration of the major features of the Asian monsoon. **A:** northern winter; **B:** northern summer (after Lockwood, 1985).

westerly jet stream lies over southern Asia, with its core located at about 12 km altitude. It divides in the region of the Tibetan Plateau, with one branch flowing to the north of the plateau, and the other to the south. The two branches merge to the east of the plateau and form an immense upper convergence zone over China. In May and June the subtropical jet stream over northern India slowly weakens and disintegrates, causing the main westerly flow to move north into central Asia. While this is occurring, an easterly jet stream, mainly at about 14 km, builds up over the equatorial Indian Ocean and expands westward into Africa. The formation of the equatorial easterly jet stream is connected with the formation of an upper-level, high-pressure system over Tibet. In October the reverse process occurs; the equatorial easterly jet stream and the Tibetan high disintegrate, while the subtropical westerly jet stream reforms over northern India.

Middle and high latitude circulation patterns

The greatest atmospheric variability occurs in middle latitudes, from approximately 40–70°N and S, where large areas of the Earth's surface are affected by a succession of cyclones (depressions) and anticyclones or ridges. This is a region of strong thermal gradients with vigorous westerlies in the upper air, culminating in the polar-front jet stream near the base of the stratosphere. The zone of westerlies is permanently unstable and gives rise to a continuous stream of large-scale eddies near the surface, the cyclonic eddies moving poleward and the anticyclonic ones equatorward.

Compared to the Hadley cells, the middle-latitude atmosphere is highly disturbed and the suggested meridional circulation in Figure A77 is largely schematic. At the surface the predominant features are closed cyclonic and anticyclonic systems of irregular shape, while higher up, smooth wave-shaped patterns are the general rule. The dimensions of these upper waves are much larger than those of the surface cyclones and anticyclones which have dimensions of 1000–3000 km, and only rarely is there a one-to-one correspondence. In typical cases there are four or five major waves around the hemisphere, and superimposed on these are smaller waves that travel through the slowly moving train of larger waves. The major waves are called long waves or Rossby waves, after Rossby (1939, 1940, 1945), who first investigated their principal properties. These upper Rossby waves are important because they strongly influence the formation and subsequent evolution of the closed surface synoptic features.

Analyses of long time-series of climatological data reveal large-scale correlations between fluctuations at remote locations. These fluctuations occur at the low frequency range of timescales, and they are called “teleconnections” to stress the correlation-at-a-distance aspect of their nature. The term “teleconnection” was introduced by Ångstrom (1935) in the context of patterns of climatic fluctuations; Bjerknes (1969) and Namias (1963, 1969) later used it to describe patterns of atmospheric responses to a remote surface forcing. Some teleconnections arise simply from natural preferred modes of the atmosphere associated with the mean climate state and the land-sea distribution, while several such as ENSO and the North Atlantic Oscillation are directly linked to sea surface changes.

In a simple atmosphere Rossby waves could arise anywhere in the middle latitude atmosphere, as is observed in the predominantly ocean-covered southern temperate latitudes. In contrast

the northern temperate latitude Rossby waves tend to be locked in certain preferred locations. These preferred locations arise because the atmospheric circulation is influenced not only by the differing thermal properties of land and sea, but also by high mountain ranges and highlands in general. Influences on the propagation of Rossby waves through the atmosphere include zonal temperature asymmetries, transient synoptic weather systems and baroclinic effects.

Atmospheric thermal patterns

The basic thermal pattern of the lower half of the atmosphere in the temperate latitudes is partly controlled by prevailing mean surface temperatures. The mean thermal pattern may be usefully investigated by using the concept of thickness lines. The thickness of an atmospheric layer bounded by two fixed-pressure surfaces, 1000 mb and 500 mb, for example, is directly proportional to the mean temperature of the layer. Thus, low thickness values correspond to cold air and high thickness values to warm air. The geostrophic wind velocity at 500 mb is the vector sum of the 1000 mb geostrophic wind and the theoretical wind vector (the thermal wind) that blows parallel to the 1000–500-mb thickness lines with a velocity proportional to their gradient. This theoretical wind is known as the thermal wind and is shown in Figure A82.

The thermal wind is directed along the mean isotherms with lower temperature to the left in the northern hemisphere. Thus, in temperate latitudes the thermal wind will be westerly, and, since north-south horizontal temperature gradients are relatively steep, it will be strong. The upper winds are the vector sum of a rather weak surface wind field and a vigorous thermal wind field. This implies that, in the lower middle-latitude troposphere, winds will become increasingly westerly with altitude and that the upper wind field is strongly controlled by the thermal wind. Therefore, a parallel exists between the mean topography of the 500-mb level and the mean 1000–500-mb thickness patterns.

The mean January thickness patterns for the northern hemisphere show two dominant troughs near the eastern extremities of the two continental landmasses, while ridges lie over the eastern parts of the oceans. A third weak trough extends from northern Siberia to the eastern Mediterranean. Climatologically, the positions of the main troughs may be associated with cold air over the winter landmasses, and the positions of the ridges with relatively warm sea surfaces. As seen from Figure A83, the mean January 500-mb wind field, and therefore the mean Rossby wave locations, is similar to the thickness field.

In July the mean ridge in the thickness pattern found in January over the Pacific has moved about 25°W, and now lies over the warm North American continent, while there is a definite trough over the eastern Pacific. Patterns elsewhere are less marked, but a weak trough does appear over Europe, and may

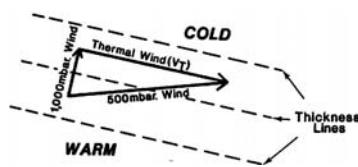

Figure A82 Definition of thermal wind. The thermal wind (V_T) is the vector difference between the 1000-mb wind and the 500-mb wind.

perhaps be connected with the coolness of the North, Baltic, Mediterranean, and Black seas.

North Atlantic Oscillation

A major source of interannual variability in the atmospheric circulation over the North Atlantic and western Europe is the so-called North Atlantic Oscillation (NAO), which is associated with changes in the strength of the oceanic surface westerlies (Marshall et al., 2001). Its influence extends across much of the North Atlantic and well into Europe, and it is usually defined through the regional sea-level pressure field, although it is readily apparent in mid-troposphere height fields. The NAO's amplitude and phase vary over a range of time scales from intraseasonal to inter-decadal. The NAO is profoundly linked to the leading mode of variability of the whole northern hemisphere circulation, the annular mode or Arctic Oscillation. This suggests that Atlantic effects are more far-reaching and significant than previously thought (Marshall et al., 2001).

The NAO is often indexed by the standardized difference of December to February sea-level atmospheric pressure between Ponta Delgado, Azores (37.8°N , 25.5°W) or Lisbon, Portugal (38.8°N , 9.1°W) and Stkkisholmur, Iceland (65.18°N , 22.7°W) (Hurrell, 1995). Statistical analysis reveals that the NAO is the dominant mode of variability of the surface atmospheric circulation in the Atlantic and accounts for more than 36% of the variance of the mean December to March sea-level pressure field over the region from 20° to 80°N and 90°W to 40°E , during 1899 through to 1994. Marked differences are observed between winters with high and low values of the NAO. Typically, when the index is high the Icelandic low is strong, which increases the influence of cold Arctic airmasses on the northeastern seaboard of North America and enhances westerlies carrying warmer, moister airmasses into western Europe (Hurrell, 1995). During high NAO winters the westerlies directed onto northern Britain and southern Scandinavia are over 8 m/s stronger than during low NAO winters, with higher than normal pressures south of 55°N and a broad region of anomalously low pressure across the Arctic. In winter, western

Europe has a negative radiation balance and mild temperature levels are maintained by the advection of warm air from the Atlantic. Thus strong westerlies are associated with anomalously warm winters, weak westerlies with anomalously cold winters, and NAO anomalies are related to downstream wintertime temperature and precipitation anomalies across Europe, Russia and Siberia (Hurrell, 1995; Hurrell and van Loon, 1996).

Overlying the interannual variability there have been four main phases of the NAO index during the historical record: prior to the 1900s the index was close to zero; between 1900 and 1930 strong positive anomalies were evident; between the 1930s and 1960s the index was low; and since the 1980s the index has been strongly positive. The recent persistent high positive phase of the NAO index, extending from about 1973 to 1995, is the most persistent and highest of the historical record. During each positive phase higher than normal winter temperatures prevail over much of Europe, culminating in the unprecedented strongly positive NAO index values and mild winters of 1989 and 1990. During high NAO index winters drier conditions also prevail over much of central and southern Europe and the Mediterranean, whilst enhanced rainfall occurs over the northwestern European seaboard (Hurrell, 1995).

Pacific atmospheric circulation oscillations

Interannual climate variability over the Pacific Ocean is dominated by ENSO (Salinger et al., 2001). This has the strongest SST signals of one sign along the equator over the central and eastern Pacific and a boomerang-shaped pattern of weaker SST signals of opposite sign extending over the middle latitudes of both hemispheres in the north and south Pacific. Salinger et al., (2001) comment that recently "ENSO-like" features in the climate system that operate on decadal to multidecadal time scales have been identified.

A recently identified pattern of longer-term variability is the Pacific Decadal oscillation (PDO) described by Mantua et al. (1997), which may be defined in terms of changes in Pacific sea-surface temperature north of 20°N latitude. Like the warm El Niño phase of ENSO, the warm or positive phase of PDO warms the Pacific near the equator and cools it at northern mid-latitudes; but unlike ENSO, PDO effects are stronger in the central and northern Pacific than near the equator, and it has an irregular period of several decades. It has been found that, during epochs in which the PDO is in its positive polarity, coastal central Alaska tends to experience an enhanced cyclonic flow of warm moist air which is consistent with heavier than normal precipitation. In these winters the mid-latitude depression track tends to split, with one branch carrying storms south to California and the other north to Alaska. The PDO was in its cool or negative phase from the first sea-surface temperature records in 1900 until 1925, then in warm or positive phase until 1945, cool again until 1977, and in warm phase until the 1990s.

An Inter-decadal Pacific Oscillation (IPO) has also been described by Power et al. (1998, 1999) and Folland et al. (1999), the time-series of which is broadly similar to the inter-decadal part of the North Pacific PDO index of Mantua et al. (1997). When the IPO is in a positive phase, SST over a large area of the southwest Pacific is cold, as is SST over the extratropical northwest Pacific. SST over the central tropical Pacific is warm, but unlike the ENSO situation it is less obviously warm over the equatorial far eastern Pacific. Also in contrast to

ENSO, warmth extends into the tropical west Pacific. Like the PDO the IPO shows three major phases this century: positive from 1922 to 1946 and from 1978 to at least 1998, with a negative phase between 1947 and 1976. A general reduction in sea-level pressure over the extra-tropical North Pacific Ocean during the winter (November to March) after about 1976 has been particularly evident. This appears as a deeper-than-normal Aleutian low-pressure system, accompanied by stronger-than-normal westerly winds across the central North Pacific and enhanced southerly to southwesterly flow along the west coast of North America.

Polar regions

Both polar regions are located in areas of general atmospheric subsidence, though the climate is not particularly anticyclonic; nor are the winds necessarily easterly. The moisture content of the air is low because of the intense cold, and horizontal thermal gradients are normally weak, with the result that energy sources for major atmospheric disturbances do not exist and are rarely observed. Vowinckel and Orvig (1970) suggest that the Arctic atmosphere can be defined as the hemispheric cap of fairly low kinetic energy circulation lying north of the main course of the planetary westerlies, which places it roughly north of 70°N. The situation over the south polar regions is more complex and the boundary of the Antarctic is not so clear.

ATMOSPHERIC NOMENCLATURE

Vertical temperature distribution is the most common criterion used in defining atmospheric regions. Three popular systems of nomenclature are based on the thermal stratification of the atmosphere. Figure A84 displays these three classification schemes and the vertical temperature structure of the atmosphere up to 110 km.

Chapman (1950) was the first to suggest the common four-layer division of the atmosphere. He classified the atmosphere into troposphere, stratosphere, mesosphere, and thermosphere. The upper boundary of each layer is given the suffix “pause”; for example, the upper boundary of the troposphere is referred to as the tropopause. Chapman’s subdivisions of the mesosphere into the mesoincline, mesodecline, and mesopeak were based on the temperature maximum occurring near 50 km.

In 1954 Goody devised a different classification of the upper atmosphere, replacing Chapman’s mesosphere. Goody suggested that Chapman’s mesosphere should be called upper stratosphere,

and the region above 80 km should be called ionosphere rather than thermosphere.

In 1960 the International Union of Geodesy and Geophysics recommended a nomenclature in an attempt to standardize terminology. In this classification the troposphere is the lowest 10–20 km of the atmosphere where temperature generally declines with height. The lower stratosphere is the relatively isothermal region immediately above the tropopause, and the upper stratosphere extends from the lower stratosphere to the maximum temperature level at 40–50 km (stratopause). The mesosphere is the region bounded by the stratopause and the temperature minimum occurring at 70–80 km (mesopause). The thermosphere is the region above the mesopause where temperature increases with height. Additionally, atmospheric physicists commonly often refer to the region from 15 km to 95 km as the middle atmosphere while the region above that is referred to as the upper atmosphere.

As opposed to thermal stratification, physical and/or chemical processes are also used to delineate discrete layers of the atmosphere. Today the term ionosphere is often restricted to the region around 70–80 km, where the existence of free electrons becomes significant. This region has importance in the transmission of radio signals over long distances. Conversely, the neutrosphere refers to the un-ionized region between the surface and the ionosphere. The ozonosphere, a subdivision of the neutrosphere based on appreciable ozone concentration, is located from 10 km to 50 km.

Other criteria have been suggested for classification of atmospheric layers. For example, the exosphere has been defined as the region near the top of the atmosphere where particles can move in free orbits, subject only to the Earth’s gravitation. Another criterion, based on composition, defines the homosphere as the region from the surface to 80–90 km, where

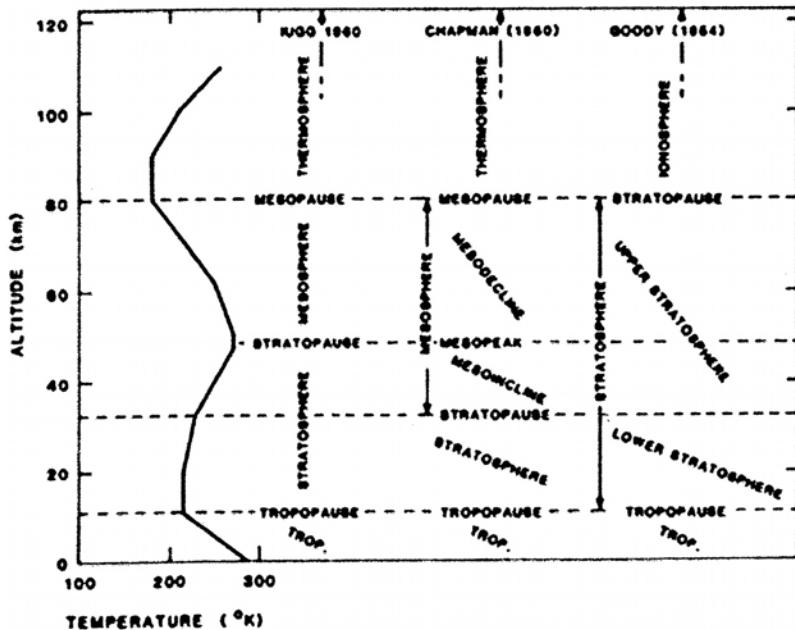

Figure A84 Vertical distribution of temperature up to 100 km, according to the US standard atmosphere, 1962, and three common systems of nomenclature (after Craig, 1965).

little photodissociation or gravitation separation occurs, and the heterosphere is the region above this, where atmospheric composition is not constant. The magnetosphere is defined as the region of the Earth's magnetic field which extends from the top of the ionosphere and is shaped by the solar wind. These and other variations in nomenclature have arisen in response to the needs of the various specialties in the atmospheric sciences.

ATMOSPHERIC NUCLEI AND DUST

Almost a century ago it was found that cloud and fog droplets form by condensation of water vapor from the atmosphere on small particles, so-called condensation nuclei. They were more systematically studied by Aitken toward the end of the nineteenth century. Condensation nuclei form part of the atmospheric aerosol content. These particles, aside from acting as condensation nuclei, also have an effect on the optical properties of the atmosphere and play an important role in atmospheric electricity. The light-scattering properties of these particles provided much information about their concentration and size distribution, especially in the early periods of investigation.

Nucleation process

In 1897 it was found that when a reasonably dust-free air sample, which was saturated with water vapor, was rapidly expanded so that adiabatic cooling occurred, droplet cloud formation would occur only if the expansion ratio was high enough to produce several hundred percent supersaturation. In the absence of nuclei a transition from the water-vapor phase to the liquid phase can occur only if the probability for aggregation of molecule clusters is high enough and supersaturation and temperature are adequate for such embryos to remain in equilibrium with their environment. However, if foreign particles are present in the air, condensation can occur at much lower

supersaturations. The water-vapor molecules will attach themselves much more easily to such nuclei, thereby initiating the droplet-forming process. The effectiveness of a particle as a condensation nucleus largely depends on whether it is hygroscopic or hydrophobic (water attractive or repellent, respectively). Therefore, in the presence of condensation nuclei, condensation can occur at supersaturations on the order of a few tenths of a percent. This is in agreement with atmospheric observations. Similar observations apply to the formation of ice crystals. Small water droplets can be supercooled to temperatures as low as 40°C without freezing. At still lower temperatures, sudden formation of ice crystals occurs, i.e. spontaneous nucleation takes place. In the presence of freezing and sublimation nuclei, formation of ice crystals occurs at much warmer temperatures (-10°C or -15°C). The relative importance of freezing and sublimation nuclei remains to be determined. The term sublimation nucleus assumes that the transition from the vapor to the solid phase occurs directly by sublimation of molecules on the nucleus; in the case of freezing nuclei it is thought that the transition goes through the liquid water phase.

Properties and composition of atmospheric nuclei

Not all airborne particles (aerosol particles) act equally well either as condensation nuclei or as ice-forming nuclei. In the case of condensation nuclei, water affinity is an important factor in their efficiency. Supersaturation required to sustain a growing droplet is a function of the particle size; the smaller the particle (i.e. the greater the curvature of its surface), the higher the required saturation. From this consideration it follows that larger particles are more apt to act as condensation nuclei than small ones. In the case of freezing nuclei, particles whose crystal structure is similar to that of ice (pseudomorphic particles) are most likely to act as a base for building on the ice crystal lattice, and therefore form good freezing or sublimation nuclei. This concept does not seem to be in complete agreement with experimental evidence, however. For instance, quartz dust is not a good freezing nucleus; silver iodide is a good artificial freezing nucleus (cloud seeding).

Several conclusions may be drawn from this diagram: (a) In an isolated population of droplets containing equal masses of solute, the very small droplets must grow at the expense of the larger droplets. (b) Beyond a critical size the larger droplets may grow at the expense of the smaller. (c) If supersaturation of the vapor with respect to a flat surface is limited, say to about 0.1%, droplets must contain more than 10–15 gram of NaCl (or other similar solute) in order to reach critical size. (d) Small droplets may exist in equilibrium with moist air of relative humidity far below 100%.

According to Junge (1963), the size distribution of natural aerosols can be described by an inverse power law, according to which the number of particles is inversely proportional to the third or fourth power of their radius, although considerable deviations may occur in individual cases. Junge also defines three size groups, the Aitken particles (10^{-7} to 10^{-5} cm or 10^{-3} to 10^{-1} m radius); large particles (10^{-4} to 10^{-3} cm; see Table A43). Particles smaller than a few hundredths of a micron become unstable because their tendency to coagulate increases. Particles much larger than a few microns become more and more affected by gravitational forces and fall out more rapidly than smaller ones.

It can be concluded that approximately 60% in mass of the natural aerosol consists of inorganic, water-soluble material;

^a Shading indicates size range at which labeled characteristics occur.

15% of organic material; and 25% of inorganic water-soluble material. The great majority of particles are mixed. In maritime airmasses, sea-salt particles are a major component in the natural aerosols. Such hygroscopic salt particles can act as excellent condensation nuclei. The continental aerosol originates partially from the ground itself (dust), but also from gaseous components. The inorganic nuclei seem to be formed to a large extent by the oxidation of sulfur gases (e.g. H₂S, SO₂) to sulfate compounds such as ammonium sulfate, etc. There are strong indications that a considerable portion of the nuclei in the size range below about 0.5 µm consists of organic materials and that these particles are extremely unstable. It is assumed that these are mostly particles formed from organic compounds with low vapor pressure. The vapors originate from certain types of vegetation and are changed to liquid or solid particles by photo-oxidation.

A group of cloud physicists believe that a correlation exists between the occurrence of meteor showers and precipitation. They assume the extraterrestrial meteors, by entering the

atmosphere, disintegrate into fine dust particles that act as ice nuclei in the formation of cloud and precipitation particles.

Since 1947, when Vonnegut discovered that silver iodide crystals act as freezing nuclei at temperatures below about -4°C, much research has been done on artificial nuclei. It appears that nature, with few exceptions, provides enough nuclei for condensation and/or freezing. Adding artificial nuclei may change the size spectrum of cloud particles, leading to an increase in precipitation, but it may also result in a decrease (overseeding).

AUSTRALIA AND NEW ZEALAND, CLIMATE OF

The climates of Australia and New Zealand are strongly influenced by general circulation patterns prevalent in the SW Pacific. Critical to the strength of this circulation is the temperature gradient between Antarctica and the SE Asian tropics, and between Antarctica and the Australian continent. The ocean plays a key role, since there are no major land masses between the South island of New Zealand and Antarctica. More regional circulations, such as El Niño Southern Oscillation, affect the climate patterns in this region. The classic reference, which provides the first detailed summary of the climates of Australia and New Zealand, is Gentilli (1971).

Climates of Australia

Australia's climate depends on four major factors. First, the size and shape of Australia determine how the general circulation affects the continent. Australia covers 7 682 300 km², stretching from 10°41'S to 43°39'S and 113°09'E to 153°39'E at the extremes. Its greater longitudinal distance (4000 km) allows considerable airmass modification and a strong degree of continentality. Its limited latitudinal span creates moderate changes on a seasonal basis compared to larger continents such as North America.

Second, Australia's topography does little to obstruct air moving over the continent. The average altitude of the land mass is only 300 m, with 87% of the continent less than 500 m and 99.5%

less than 1000 m. Only the eastern mountains, which extend north to south, have any major influence on synoptic flow.

Third, Australia is completely surrounded by water. Polar air originates from the Antarctic Ocean, and is basically cool and moist. The major influence of the ocean is coastal, and there is no significant upwelling of cold water. Australia's climate can be generally described as moderately continental with important ocean influences.

Fourth, Australia's geographical location places it under the global subtropical high-pressure zone. Much of Australia is under the influence of dry subsiding air and can be considered arid or semiarid, although not as dry as the west coasts of the other southern hemisphere continents. Particularly in summer, Australia experiences high sun angles and intense solar radiation under mostly clear skies. With the exception of Tasmania and much of the east coast, most of the continent receives over 3000 hours of sunshine per year, almost 70% of that possible (Bureau of Meteorology, 1988a).

Synoptic circulation patterns

In general, Australia is affected by midlatitude westerlies on the southern fringe, tropical convergence on the northern fringe in summer, and stable subsiding air under the subtropical anticyclone belt in between. The synoptic circulation patterns can best be described by comparing summer and winter seasons.

(a) Winter (May–October) (Figure A85)

The subtropical anticyclone belt covers the northern two-thirds of the continent. Dry stable SE trades dominate Australia north of 20°S, with greater than 50% frequency. This air originates over the Pacific, often loses some of its moisture due to orographic precipitation on the eastern highlands, and cools and stabilizes as it passes over the continental interior.

Frontal activity. South of 20°S the continent is under the influence of alternating anticyclones and cold fronts, associated with the northern edge of the midlatitude westerlies. Troughs and fronts from these systems extend into southern Australia (Figure A86), separating migratory anticyclones in 4–8-day intervals. These fronts move at an average speed of 35 km h⁻¹ and can be divided into two types (Sturman and Tapper, 1996). Ana-fronts are more active and are associated with convection in the frontal zone. Kata-fronts are less active and are linked to subsiding air from anticyclones.

The impact of these fronts on the main continent is not usually strong, and only in spring extends into the northern half of the country (Smith et al., 1995). Tasmania is most severely affected, being closest in location to the midlatitude depressions. There is a striking absence of warm fronts because the frontal systems form well to the west of Australia and the warm front has swung south before the system reaches the continent.

Precipitation associated with winter frontal systems often occurs from the Northwest Australian cloud band (Sturman and Tapper, 1996), a source of moisture and deep convection which can stretch for distances of up to 5000 km between the Indian Ocean and S to SE Australia. Eighty percent of these cloud bands occur between April and September, with an average of about two per month.

Occasionally, secondary depressions or cut-off lows moving toward low latitudes can initiate severe storm situations.

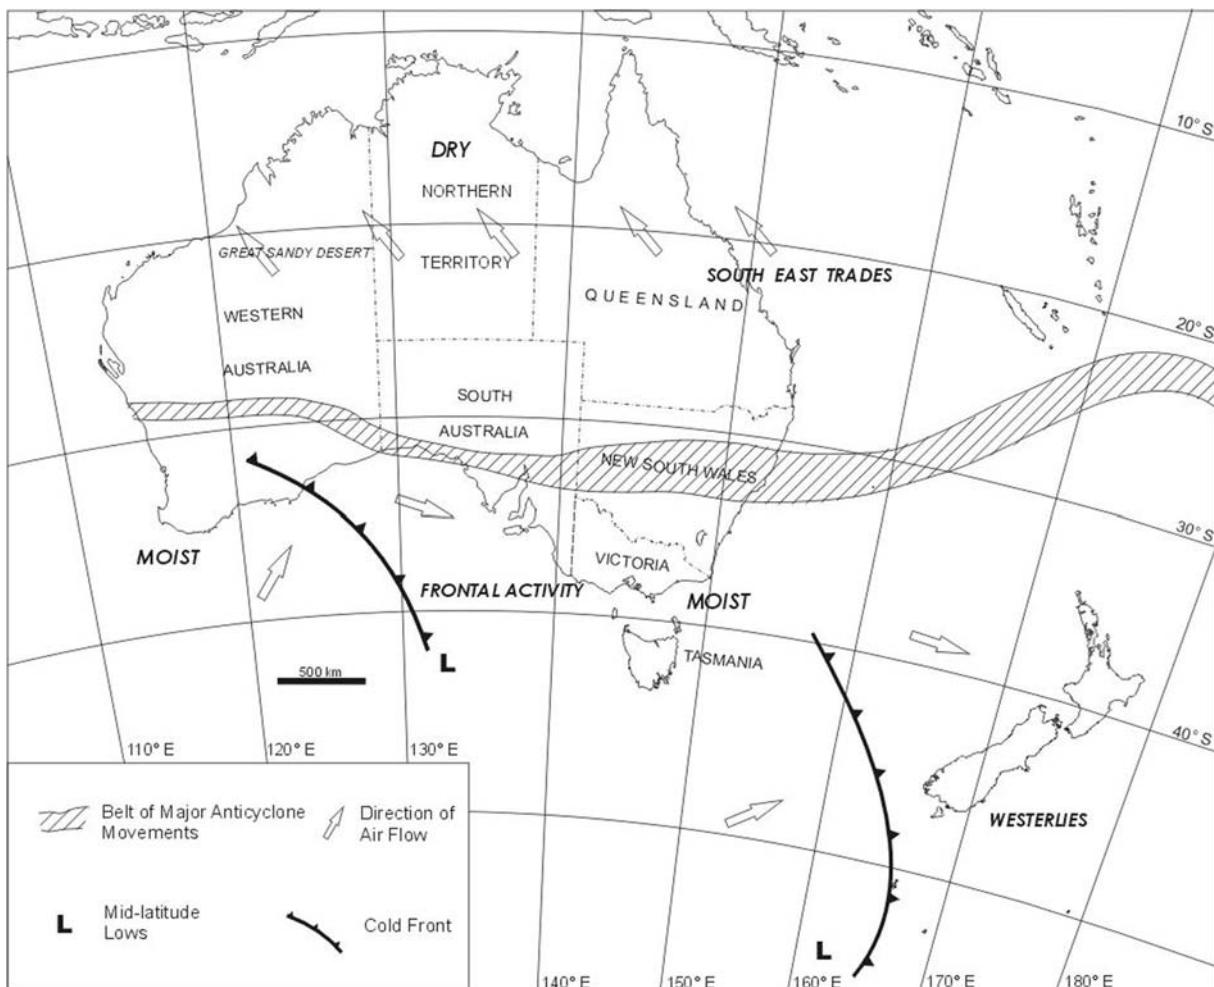

Figure A85 Simplified synoptic climatology of Australia, July surface circulation (Bridgman, 1987).

Development is better on the SE coast of Australia rather than on the SW. A slow-moving deep low-pressure system results, bringing strong winds and heavy precipitation for periods of 0.5–10 days (Tapper and Hurry, 1993). Such systems are more likely to develop in spring or fall (October–November or April–May) because the thermal gradient between airmasses is strongest. The cause is either the remnants of a tropical storm, or intense cyclonic development in an easterly dip in the isobaric pattern.

The interaction of the Indian Ocean air and the cooler maritime air south of the continent brings winter rains to S and SW Australia. In early winter these rains can be extensive and are related to mid-tropical convection and the strength of the westerlies. In late winter more showery precipitation occurs, associated with topographic and coastal convergence influences, and not with the general circulation (Allen and Haylock, 1993).

Winter anticyclones. Anticyclones dominate much of the continent in winter. On average, 40 anticyclones move over Australia in a year, with slightly less in fall–winter than spring–summer. Anticyclones enter the continent at about

115°E and 27°S on the west coast, dip to 35°S in S Australia, and exit about 30°S off the east coast (Figure A85). The mean anticyclonic track is furthest north in June–July except on the east coast of the continent, where the lag in ocean heating defers the maximum northward extent to August–September (Gentilli, 1971; Tapper and Hurry, 1993).

Over the continent the strength and persistence of the anticyclones can be intensified by wintertime cooling of the land. Anticyclones may remain stationary in the interior for several days, particularly if the high develops a meridional (longitudinal) orientation. This creates blocking, and is much more common east of 150°E, in the Tasman Sea. Eastward movement of weather systems is retarded and the convective motion associated with depressions is countered (Baines, 1990; Sturman and Tapper, 1996). Duration is up to 12 days, bringing dry, fine weather.

The presence of anticyclones in the winter enhances the effects of local topography on the continent, encouraging meso-scale inversions and cold air drainage to occur. It is not unusual to see nighttime floodplain temperatures 4–5°C cooler than those on the adjoining hilltop, caused by the downslope movement of cold air, and widespread frost and/or fog.

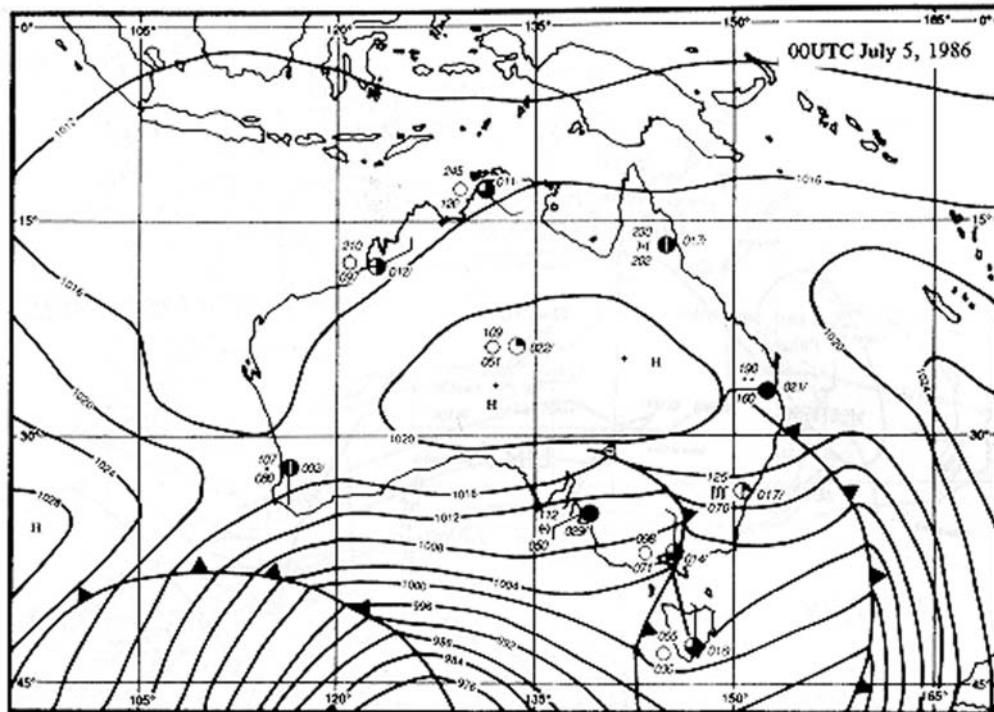

Figure A86 Representative synoptic meteorological situation in winter. Cold fronts parade across the southern third of the continent bringing cool cloudy weather and a light to moderate rainfall. Dry, cool conditions dominate the interior, with overnight frosts likely in many locations (Tapper and Hurry, 1983).

The subtropical jet stream. The trajectory and speed of movement of both anticyclones and fronts are strongly influenced by the subtropical jet stream, which is strongest over the southern part of the continent near 200–300 mb (10 000 m altitude) in the winter (Bridgman, 1998; Sturman and Tapper, 1996). The mean latitude of the jet is 26–32°S, but varies considerably from season to season and year to year. In winter its mean core speed is 70 m s^{-1} and northerly meandering from about 25°S is most apparent. In summer the jet is much weaker (30 m s^{-1}), with its mean axis position around 31°S. The jet is associated with the formation of upper air troughs and depressions which, when linked with a lower-level unstable airflow, can bring considerable rain to large areas of the southern half of the continent. Such troughs also provide the major medium for tropical moisture to reach the southern parts of the continent through the northwest cloud band. The strongest jets are also associated with strong cyclogenesis in the west Tasman Sea. It is not unusual in winter on the SE coast for a shallow surface anticyclone with surface pressures near 1020 mb to exist, with steady rain falling through the system from a mid-tropospheric trough.

When the jet is located between 20°S and 25°S it has a significant influence on rainfall systems occurring in late fall. Storms can bring strong rain and flooding to parts of the continental interior. They appear erratically in the general area from Geraldton–Port Hedland in Western Australia to Carpenteria–NE New South Wales in eastern Australia, providing secondary and sometimes primary rainfall maxima for some individual stations (Bridgman, 1998).

Anticyclonic shape and movements relate strongly to the area of upper tropospheric convergence on the equatorial side of the jet. If the jet meanders considerably across the continent, the anticyclones will be elongated longitudinally and will be slow-moving. If the jet has a strong zonal (east–west) component, the anticyclones will be zonally elongated and may move across the continent with considerable speed.

(b) Summer (November–April) (Figure A87)

Summer anticyclones. In summer the circulation systems are 5–8° further south, changing the climatic regimes affecting the northern and southern edge of the continent. Subsiding air from the subtropical high-pressure belt, now located poleward of Australia between 35°S and 45°S, covers most of the continent except for the northern tropical fringe and southern Tasmania. The descending air, originating at 10 000 m, warms adiabatically and subdivides into a series of traveling anticyclones (5–6 days periodicity) separated by troughs (Gentilli, 1971). The longitudinal extent of these anticyclones (Figure A88) is of the order of 2000–3000 km and the latitudinal extent 1000–2000 km. The counterclockwise circulation around the high during its passage ensures dry air from the hot interior moves coastward, limiting rainfall periods to troughs between anticyclonic systems or to onshore easterlies along the east coast of the continent. The pressure in the centre of the anticyclonic cells usually reaches 1030 mb, and falls to about 1005 mb in the trough between.

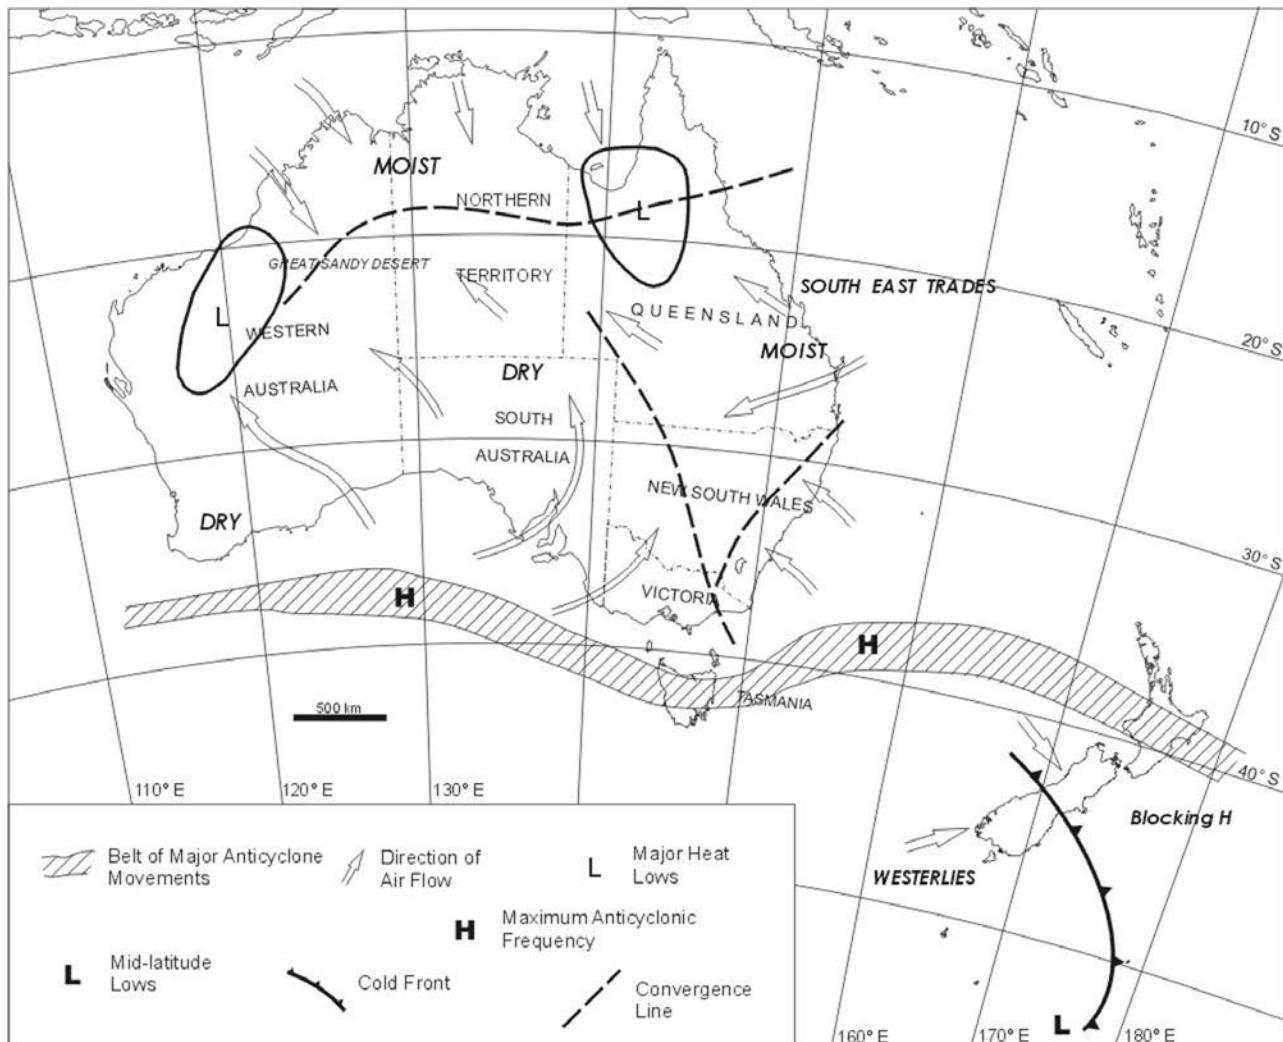

Figure A87 Simplified synoptic climatology of Australia, January surface circulation (Bridgman, 1987).

A typical weekly synoptic pattern for the southern half of Australia might be cooler S winds in the east side of a high, changing to E, NE and then NW winds as the high passes. Along the coasts, temperatures might warm from 22–24°C in the cooler Pacific maritime air to 36–38°C or higher in the continental air from the interior. The situation remains extremely hot and dry until the trough, or cool change between anticyclones, brings relief.

The summer cool change. In Western Australia the cool change is weak, often dry, and is mainly a change in temperature and wind direction (Reeder and Smith, 1992). It forms in the Cape Leeuwin–Kalgoorlie area as an incursion of Indian Ocean air, and is mainly controlled by the warm to hot air ahead, rather than the weak, cooler air behind. The change will often be sudden, bringing relief from exceedingly hot conditions, dropping temperatures by 10–15°C in the space of less than half an hour.

Cool changes, or Southerly Busters, reaching SE Australia, are often much stronger, with gusty winds and occasional rain, as they move east along the Victorian coast and then north along the NSW coast. They occur between November and March, and are channeled by the topography of the eastern highlands (Reeder and Smith, 1992; McInnis, 1993). Since the depth of the change is only about 3–5 km, this change in orientation is not reflected at 500 mb, but the buster may be associated with weak troughs at this level. The majority of the busters occur between 1300 and 2100, since their speed of movement strength is enhanced by a sea breeze. About half the cool changes are dry, but the change may be heralded by a roll cloud, gusty, squally winds (gusts up to 30 m s^{-1}) and thunderstorms. At passage a temperature drop of 10°C in a few minutes and up to 22°C in 24 hours may occur.

On occasion cool changes are associated with prefrontal troughs, which can bring severe weather, heavy precipitation, and flash floods. From 1957 to 1990, 69 meso-scale severe storms occurred in the Sydney region between November and

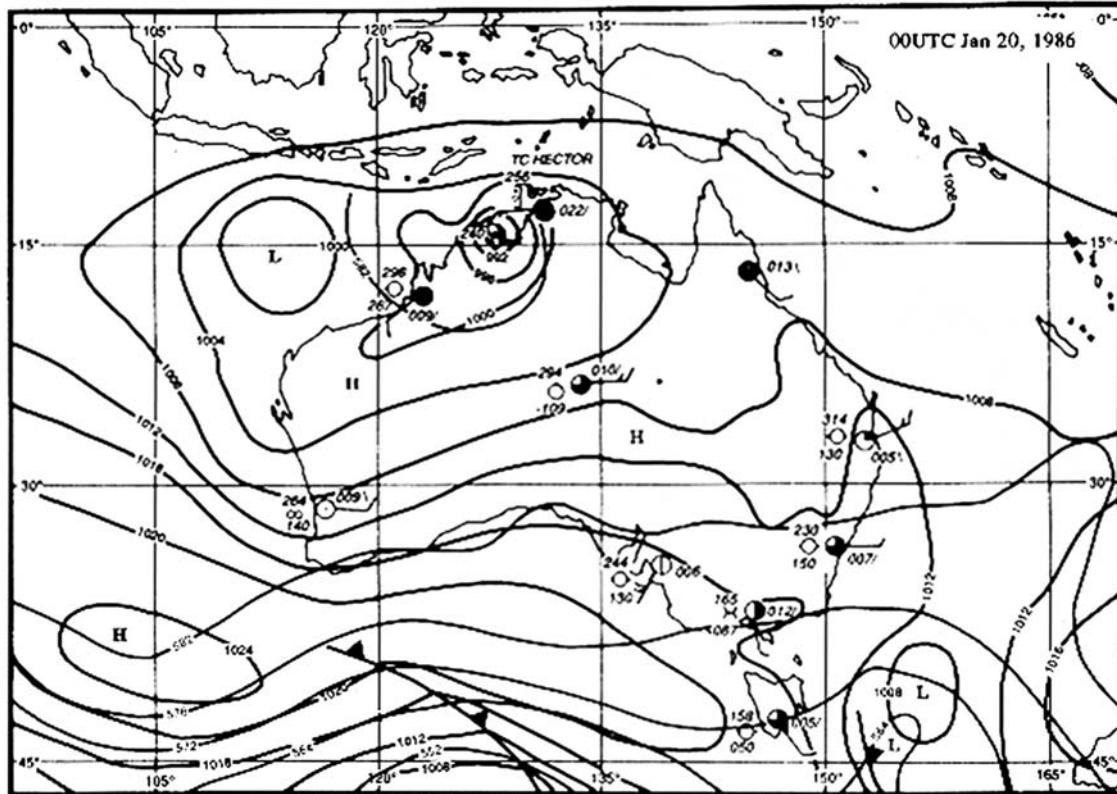

Figure A88 Representative synoptic meteorological situation in summer. A cool change separates an elongated high-pressure ridge. Hot NW winds from the continental interior invade SW Australia. Onshore SE winds affect the E coast, bringing cool, cloudy, and showery conditions. A tropical cycle (Hector) enters the continent near Darwin (Tapper and Hurry, 1993).

March (Speer and Geerts, 1994). The majority occurred between noon and 6 pm.

Regional and local circulations. The west coast trough develops between two strong highs centered south of the continent, as a dip in the isobaric pattern. The trough encourages hot strong NE winds from the interior to the coast, which continue until the trough moves inland and weakens (Tapper and Hurry, 1993).

The sea breeze brings cooling to the coast on summer days, as well as on occasional winter afternoons (Abbs and Physick, 1992). Established under clear skies and weak synoptic airflow, through land–water temperature contrasts of more than 7–8°C, the sea breeze can penetrate 80–90 km inland on average, depending on topography. A well-developed sea breeze may blow for 2–7 hours, depending on distance from the shore. Sea breezes are more strongly developed on the W and SW coasts than on the E coast. Bringing temperature relief of up to 15°C on a hot day, these breezes occur with daily frequencies of about 60% on the coast in summer. They often carry appropriate local names such as the Fremantle Doctor (Western Australia).

The morning glory is a spectacular wave structure that appears over the Gulf of Carpenteria just ahead of the wet season in Australia's north, created by a clash between two opposing sea breezes. It heralds strong wind squalls, long narrow roll

clouds, and a pressure jump, but precipitation is rare (Collis and Whitaker, 1996).

The northern Australia rainy season, or monsoon. In northern Australia the shift of the subtropical high-pressure belts and subtropical jet allows a dynamically active low to form over the northern part of the continent (Figure A87). These encourage the entry of the intertropical convergence zone (ITCZ). The result is a moist NW air flow which meets the SE trades along a line approximately from Port Hedland (Western Australia) to Cairns (Queensland), which is commonly described as a monsoon (Joseph et al., 1991; Suppiah, 1992; Cook and Heedegeen, 2001). Table A44 presents the range of dates of onset of the monsoon, illustrating the high variability in monsoon dynamics. There is a strong correlation with the previous season's monsoon rain in India, with

Table A44 Range of dates of onset and length of the North Australian summer monsoon (Suppiah, 1992)

	Minimum	Mean	Maximum	St Dev (days)
Onset	23 Nov.	24 Dec.	27 Jan.	15
Finish	1 Jan.	7 Mar.	6 Apr.	18
Length	11	74	119	25

below-normal rain creating a delay in monsoon onset in Australia.

The monsoonal flow generally extends to about 15°S, and is better developed east of 100°E. It brings the rainy season to northern Australia. Its onset can be abrupt, producing violent thunderstorms and tropical depressions during active phases. Rainfall is heaviest along the coast, decreasing quite rapidly inland. About 20% of the monsoon period consists of breaks, where moist humid air in the NW airstream is not triggered into precipitation (Sturman and Tapper, 1996).

To the south and east of the monsoonal trough SE winds dominate the eastern third of the continent. Low-level moisture from the Pacific Ocean is, to a large part, expended on the eastern highlands, but often reaches the interior. Convective and orographic activity results in rain through instability and thunderstorms, occasionally enhanced by an upper-level trough. The best rains occur when a mid-tropospheric trough extends southward from central Queensland, interacting with the unstable easterly flow (Tapper and Hurry, 1993).

Tropical cyclones. Australia is the only continent with the same incidence of tropical cyclones reaching either the W or E coast, due to the availability of warm seas to enhance formation and to the shape of the coastline. Ninety-five percent of tropical cyclones form in the latitudinal zone 9–19°S, in the shear line between the monsoon westerlies and the trade winds (Sturman and Tapper, 1996). The tropical cyclones season occurs between late November and early May. On average, eight to 10 cyclones form off the Australian coast every year, but there is considerable variation in frequency. About three on average reach NE Queensland each year, two or three reach Western Australia, and one reaches the Northern Territory (Figure A89). Landfall most often occurs around Port Hedland on the west coast, near Townsville on the east coast, and Wyndham, on the northeast coast of Western Australia. February and March are the months of highest frequency, particularly between 15°S and 20°S. The timing of the strongest tropical cyclones is linked to the active phases of the monsoon (Suppiah, 1992).

Tropical cyclones bring high winds and heavy rain to both coasts with considerable destruction potential. Flooding in much of Central Queensland and in Western Australia is inevitable if the cyclone moves inland. Much of the area is sparsely inhabited, however, and rains from tropical cyclones are often the main source of moisture for crops and grassland. Only on rare occasions does a tropical cyclone strike a heavily inhabited area. The most famous Australian cyclone is Tracy, which passed through Darwin on Christmas evening, 1974 and destroyed more than half the city.

Links to El Niño/Southern Oscillation. Tropical cyclones, the monsoonal flow, and precipitation in eastern Australia in general is very strongly influenced by the El Niño/Southern Oscillation (ENSO) circulation variations (Allen, 1988; Drosdowsky and Williams, 1991; Joseph et al., 1991), and the associated changes in sea-surface temperature, especially in spring and early summer. There is a significant correlation between the Southern Oscillation Index (SOI) and variations in precipitation, cloud cover, and the diurnal range of temperature. Lower SOI brings less rain (and often drought), lower cloud amounts, and greater diurnal temperature ranges. A positive SOI brings higher than average rainfall, deeper incursions of the monsoon into central Australia, and potential floods.

Correlations (r) between precipitation and SOI reach 0.6 in western NSW, and are generally 0.4 over much of the eastern half of Australia (Sturman and Tapper, 1996). Correlations diminish greatly toward the SW of the continent.

The climatic elements

Tables A45 and A46 present means of various climatic elements for January and July and some climatic extremes. Two elements are of major concern to Australia: temperature and moisture.

Temperature

The range of annual average air temperature is from 28°C on the Kimberly coast (NW Western Australia) to about 4°C in the alpine mountain areas (>1500 m) in SE Australia. In January (summer) the average daily minimum is virtually equivalent to the annual average air temperature. In July (winter) minimums decrease from 21°C in the Darwin area to –20°C in the SE Australian mountains. Particularly in winter, the minimums are tempered on the coast by the ocean. Local cold air drainage and topography eliminates any regularity of pattern in the eastern highlands.

Maximum temperatures are much more important. Australia is known for its heat extremes rather than its cold (Bureau of Meteorology, 1988a, 1989). In January, 35°C is exceeded over most of the interior and 40°C regularly in NW Western Australia. Towns in this area, such as Marble Bar, exceed maxima of 40°C for several weeks at a time. Maxima drop to less than 20°C in Tasmania and in the higher altitudes of the SE Australian mountains. The coastal sea breezes create maximum temperature gradients in all directions from the interior, with the south and east coasts having maxima in the mid and upper 20s and the north and west coasts in the lower 30s. The maximum for single days under one synoptic system has reached 47.6°C in Adelaide, 46°C Melbourne, and 45.3°C in Sydney (11–14 January 1939).

In July, except for the eastern highlands, maximum temperatures follow a latitudinal pattern, decreasing from 30°C near Darwin and on the Cape York peninsula to 12°C on the south and Tasmanian coasts. July maxima in the mountains do not usually reach 5°C.

The sun and seasonal extent of cloud cover determines the month of highest temperature. Most of northern Australia, equatorward of 20°S, has highest maximum temperatures in November just before the onset of the monsoon, with some areas near Darwin and in the NW having the highest maximum in October. Just south of this area, to a line from Geraldton (W.A.) to Tennant Creek (N.T.) to Cooktown (Qld.), the highest maxima occur in December. Most of the interior and the NE coast has highest maxima in January, and the west and east coasts in February, due to the lag in ocean temperatures.

A combination of hot dry climatic conditions and strong winds from the center to the coast can create serious bushfire problems, particularly in late spring and early summer. Bushfires are enhanced when a blocking summer anticyclone occurs in the Tasman Sea and there is slow approach of a trough or depression from the southwest. Bushfire behavior is controlled by fuel availability, topography, pressure tendency and wind direction. Cumulative antecedent rainfall, or the total rainfall over several previous months or seasons, correlates strongly with bushfire frequency (Love and Downey, 1986). The region of highest fire hazard is the coastal zone of E Victoria and S

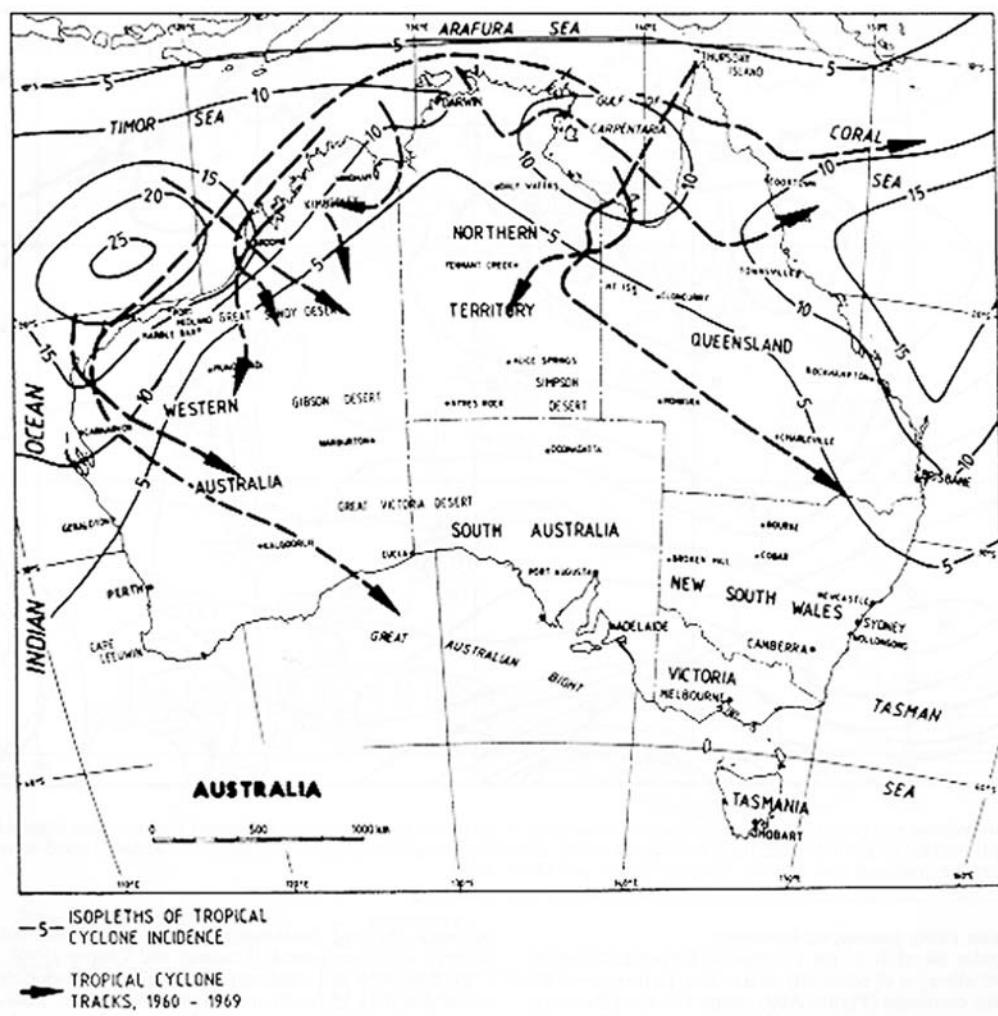

Figure A89 Average decadal incidence of tropical cyclone formation. Tropical cyclone tracks crossing the coast are shown to indicate representative storm paths (after Bridgman, 1998; Collis and Whitaker, 1996).

After Bridgeman (1987); Bureau of Meteorology (1988b).

New South Wales, where, due to the regular availability of good fuel grown during wet periods, large bushfires during dry periods occur every third year. In an area roughly from SE South Australia through Victoria and W New South Wales to the S Queensland coast, including S Tasmania near Hobart, one big fire occurs approximately every 10 years. Recent severe fires include the Ash Wednesday fires in Victoria and Southern Australia in February 1983, where 75 people were killed, more than 2000 houses destroyed, and property damage was \$430 million (Tapper and Hurry, 1993); the east coast fires in the Sydney/Newcastle New South Wales area in January 1994; and the 2002 bushfires which created major destruction of houses in E New South Wales, and the Mt Stromolo astronomical observatory in Canberra.

Moisture (Figure A90). Australia is a dry continent with certain localized exceptions, and has periods of extreme rainfall variability (Haylock and Nicholls, 2000). Vapor pressure and atmospheric water vapor do not change much diurnally (or in the interior seasonally) except along the coast or where there is a significant rainy season. Potential evaporation regularly overshadows precipitation. Fifty percent of the continent has a median rainfall less than 300 mm yr^{-1} , and 80% less than

600 mm yr^{-1} . Highest rainfall occurs on the NE and N coasts, reaching 3800 mm yr^{-1} in the eastern highlands, and lowest in the Simpson Desert ($<150 \text{ mm yr}^{-1}$) (Bureau of Meteorology, 1988a). Seventy-Five percent of the continent has an annual evaporation (class A pans) of greater than 2500 mm yr^{-1} . In the central and northwest sections of the continent, potential evaporation reaches 4500 mm yr^{-1} , more than 20 times the annual rainfall.

Rain days per year decrease from over 100 around Darwin and 120 or more on the NE Queensland coast, to less than 20 in the interior. In the area affected by the midlatitude westerlies, for example SW Tasmania, more than 150 rain days per year can occur.

Precipitation can be strongly seasonal, depending on location. Five main precipitation regimes dominate the continent (Bureau of Meteorology, 1988a, 1989; Stern et al., 2000) allowing an analysis by climatic zones (Figure A90):

1. In Northern Australia the monsoonal season (October to April) is markedly wet and the winter very dry. Most stations have more than 20 times the rainfall in summer compared to winter. The NE Queensland Coast has the highest annual rainfall in the country.

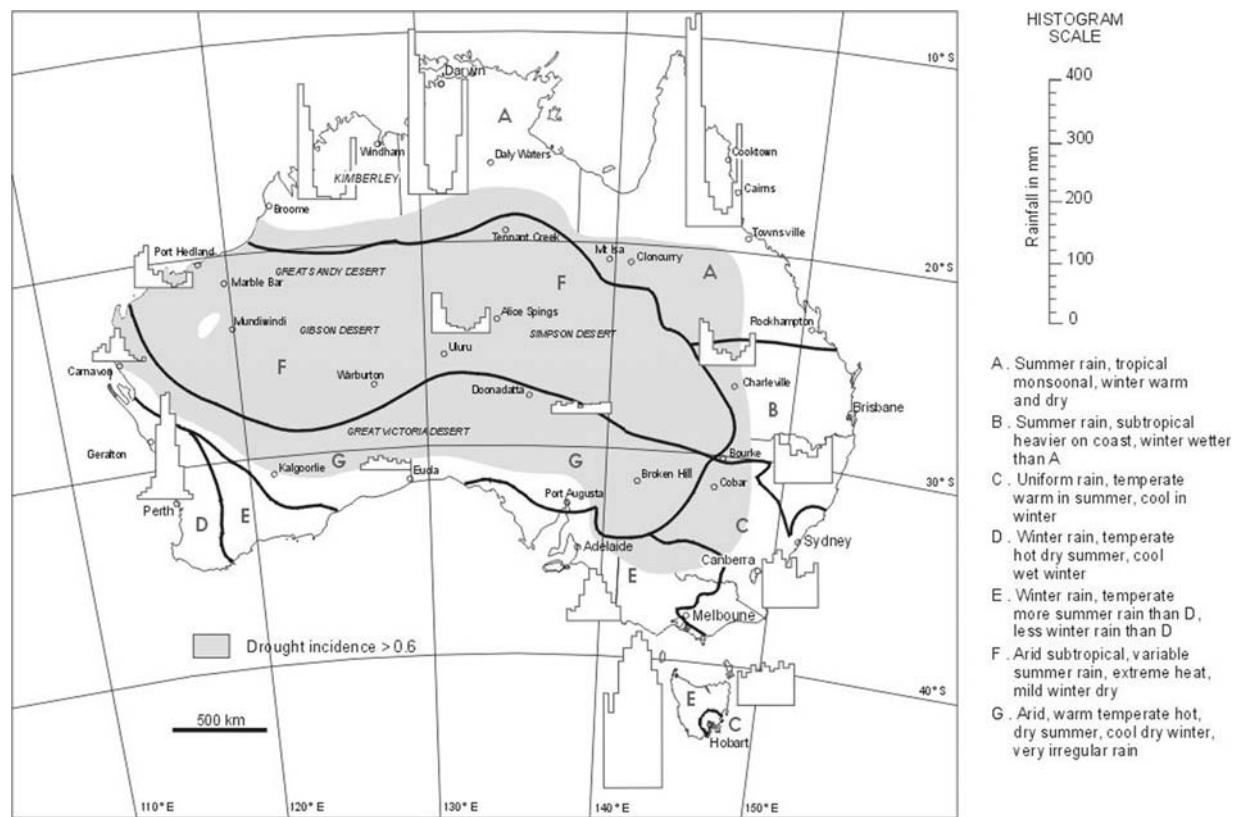

Figure A90 Representative monthly precipitation histograms (January begins at the left) for various parts of Australia. The data are averaged for meteorological districts and not representative of single stations. Included are climatic districts based on temperature and precipitation. The region of high to excessive drought incidence is shaded (Bridgman, 1998). A more detailed classification can be found in Stern et al. (2000).

2. In SE Queensland and NE New South Wales, summer is wet and winter is dry, but the difference between seasons is much less marked than under monsoon conditions. There is a tendency for a secondary peak in midwinter.
3. In SE Australia, including most of Victoria, E New South Wales and Tasmania, a relatively uniform precipitation regime exists. Victoria and Tasmania receive slightly more rain in winter than summer, and New South Wales the reverse, with the difference becoming greater closer to the equator.
4. SW Western Australia is winter wet (May to October), summer dry, the Mediterranean climate caused by the seasonal shifting of the subtropical high-pressure belt and the midlatitude westerlies. Climate here is strongly affected by changing conditions in the Indian Ocean (Smith et al., 2000).
5. More than half the continent, from NW Western Australia to the Great Australian Bight, is semiarid to arid, with a weak summer seasonal rainfall distribution in the west and north. This is the area of greatest rainfall variability, with heaviest rains associated with occasional tropical cyclones and severe local thunderstorms.

On a more local scale, severe thunderstorms associated with fronts and other convective triggers create flooding and damage (Kuleshov et al., 2002). Some of the strongest thunderstorms spawn tornadoes, particularly under extremely unstable conditions in the mid and upper troposphere. Tornadoes occur especially in the uplands of eastern Queensland and in the SW of Western Australia (Sturman and Tapper, 1996). The frequency of tornadoes may be 100–200 per year over the continent, occurring mainly outside the dry interior. In the northern half of the country, tornadoes are relatively rare and only develop in summer, as a result of strong local convection related to the wet season or sometimes associated with tropical cyclones. In the southern half, tornadoes in summer occur under convective activity associated with weak lows or troughs. In winter a secondary maximum occurs associated with cold fronts emanating from deep depressions in the mid-latitude westerlies.

Tornado formation is strongly influenced by upper atmospheric airflow, the subtropical jet, and upper air trough location. Most occur within 6° latitude of the jet stream or within 14° longitude of an upper air trough. Diurnally tornadoes occur most often between 1530 and 1830. Winds occasionally exceed 50 m s⁻¹.

Snow, associated with winter cold fronts passing over elevated areas, is mainly confined to the mountains in SE Australia, particularly just south of Canberra, and on Tasmania's Central Plateau and uplands.

The lack of consistent rainfall over most of the continent creates one of Australia's most serious climatic problems, drought. Drought can be defined as a severe water shortage depending on the amount of water needed, or by the failure of rains at specific places. Where seasonal rainfall is critical, drought is defined as the failure of the wet season. The Australian Bureau of Meteorology (www.bom.gov.au) defines an index of drought to establish the concept of drought potential: 50th percentile of rainfall minus 10th percentile divided by the 30th percentile. High indexes (greater than 0.6) mean a strong potential for drought. More than two-thirds of Australia has high to extreme drought indexes (see Figure A90). The only areas escaping are the N, S and E coast and Tasmania.

Table A47 Annual average cost of weather-related disasters in Australia (Sturman and Tapper, 1996)

Type of disaster	Annual cost (\$ million, 1989)	Percent of cost
Drought	303	24
Bushfire	68	5
Storm	202	16
Flood	386	31
Tropical cyclone	258	21
Other	33	3
Total	1250	100

Table A47 shows that drought, along with flood and tropical cyclones, create the highest cost from weather disasters in the country. The table emphasizes the importance of extreme weather to Australia.

New Zealand climates

New Zealand consists of two main islands and a number of smaller islands, located approximately 2500 km east of Australia. The country covers an area of 267 000 km², and is aligned north to south between latitudes 34°S and 47°S (Figure A91a). The distance north to south is approximately 1930 km, but the width of New Zealand reaches a maximum of only 400 km. New Zealand's size, location, orientation, and dominance by mountains (especially on the South Island), create a very different climatic regime than Australia.

Four major physical factors dominate New Zealand's climate. First, the ocean surrounding on all sides strongly defines the type of air that reaches the country. Important airmasses include tropical maritime air from the Pacific, with warm temperatures, 18–21°C, and considerable moisture; and polar maritime air from the southern ocean, with temperatures approximately 7–13°C. Thus New Zealand is consistently under the influence of moist air masses, allowing considerable rainfall. The ocean influences bring cool summers and mild winters, although cold air advection from the Antarctic Ocean can bring snow and frosts.

Second, the mountain ranges on the western sides of the two main islands create a considerable influence on atmospheric circulation (see Figure A91a). Dynamically, the mountains block upstream airflow, creating orographic uplift and vertical mixing, which leads to lee troughs on the downwind side. Very large spatial differences in precipitation can occur over the short distance between the windward mountain slopes and the rainshadows a few kilometers to the east. The mountains also act as channels for winds, and have significant influences on local airflows.

Third, New Zealand's geographic position places most of the country in the westerly circumpolar wind belt. Subtropical influences only occur irregularly, in the northern part of the North Island in summer.

Fourth, the much larger Australian continent exerts a seasonal influence. In winter considerable surface cooling under clear skies creates stabilization in the lower atmosphere. This effect extends eastward in the circulation pattern, helping weaken the westerly airflows over New Zealand. In summer the

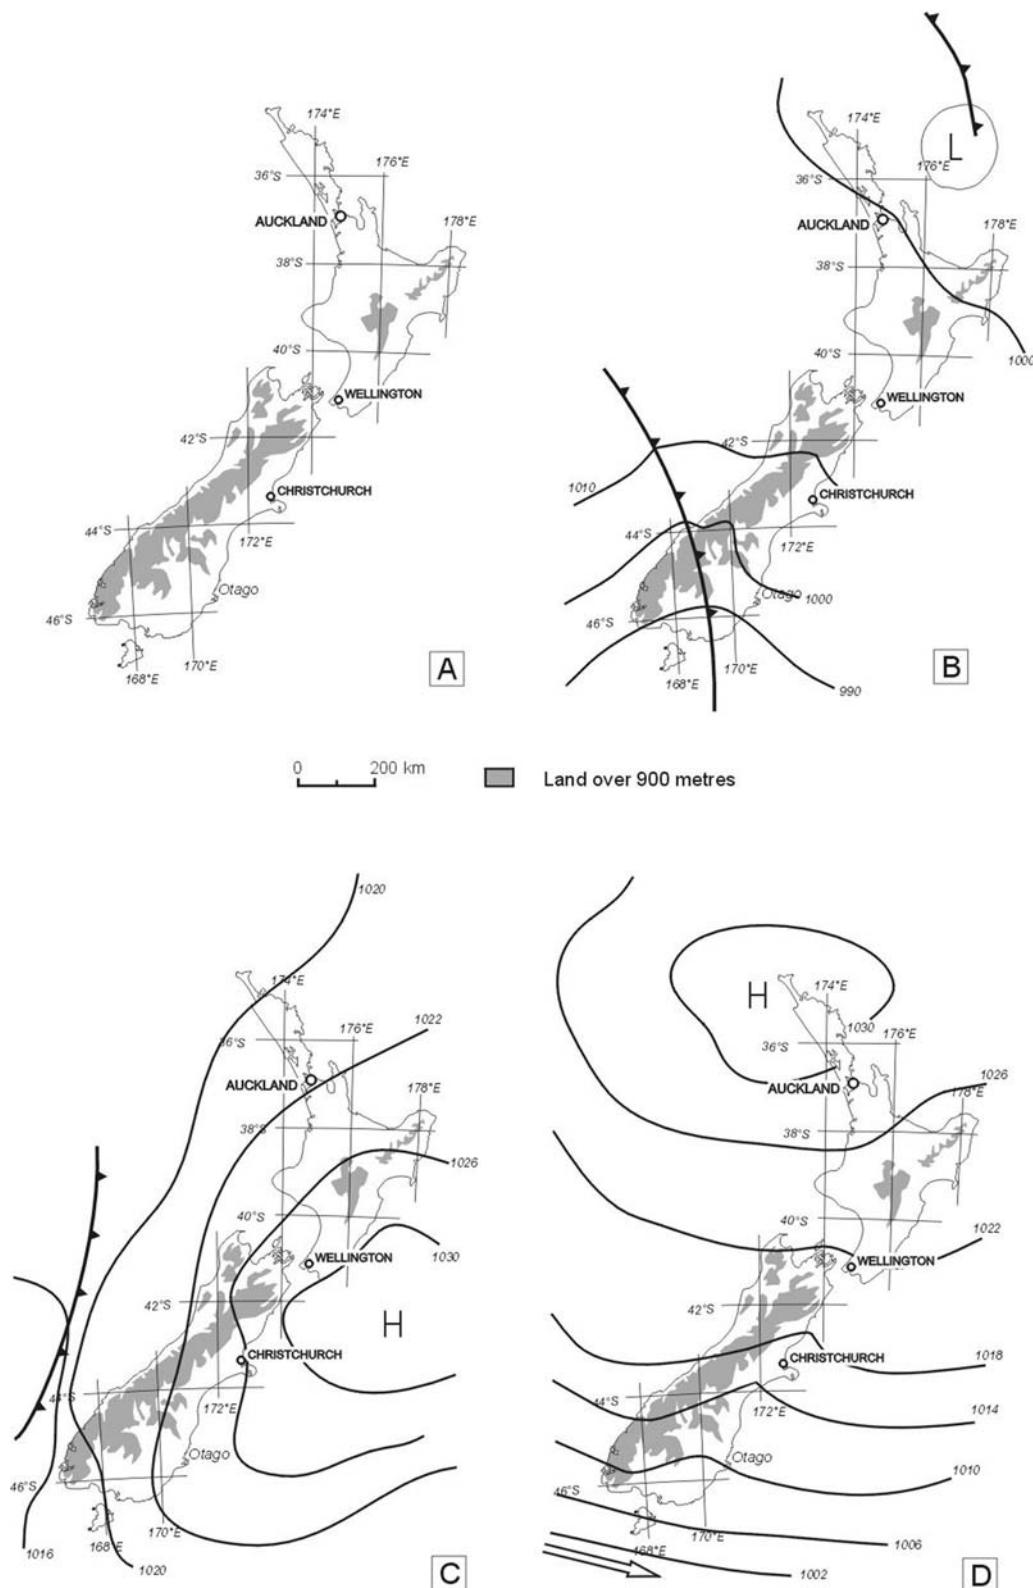

Figure A91 (a) New Zealand's physical features; (b) typical cold frontal passage over New Zealand; (c) typical blocking high situation to the east of New Zealand; (d) strong zonal circulation with high pressure to the north.

intense heating under clear skies over Australia creates a more convective atmosphere, which upon reaching New Zealand assists in creating stronger and more persistent westerly airflows.

The combination of these four factors has major influences on surface energy and water budgets. Unlike Australia, which has a water deficit over most of the continent and during most of the year, New Zealand's water budgets are generally positive. Latent heat has a greater influence than sensible heat, especially during daylight hours. The highly irregular terrain creates major spatial and temporal changes in the energy budget structure. For example, in the mountains, albedos can range from around 15% for alpine vegetation, to more than 60% for snow cover, over very small distances.

Synoptic circulation patterns

Figure A85 shows New Zealand's climatic circulation pattern in winter. The major band of anticyclonic movements extends to the north of the country. The westerlies, transporting fronts and depressions alternating with high-pressure systems, dominate. During this season the temperature gradient between Antarctica and locations further north is weakest, and therefore the strength of westerly circulation remains relatively weak.

In summer, as shown in Figure A87, the major belt of anticyclones now extends over most of the North Island. Here subsidence brings clear skies or extensive stratocumulus cloud sheets, over several days. The South Island remains under the influence of the westerlies. In spring and early summer the temperature gradient between Antarctica and the tropics, as well as the Australian continent, is strong. This is the season of strong winds and gales in the westerlies over southern New Zealand.

A more detailed evaluation of circulation in the New Zealand area reveals that three broad climate features provide the greatest influences:

- Troughs and depressions.* These are linked to cold frontal passages, occur regularly (approximately 40% of the time) during the year, although less frequently in fall. Depressions come from two main areas; those from the Southern Ocean are generally strong and move in a well-defined manner, guided by the

westerly circulation. More infrequently, depressions form in the Tasman Sea. These can move slowly and erratically. Figure A91b shows a typical cold frontal passage. The isobaric pattern can be strongly deformed by the mountains. Frontal structure can be retarded or lost, and then re-formed once the system passes through the mountain area. Approximately half the fronts dissipate before reaching Cook Straight, the body of water between the two islands. Winds preceding the trough are generally northwesterly, and after frontal passage change to southwesterly. Higher elevations have a significant influence, causing wind direction deviations. Winds coming from a direction west of 220° can be prevented from reaching the eastern half of the country. The result is often heavy cloud and rain on the western sides of both islands, but partially cloudy to clear conditions to the east. Overall, precipitation is above average, but there is considerable spatial variation depending on geographical location.

Troughs, depressions and fronts are usually steered by jet streams. In winter the jet stream is located between 25°S and 35°S, and can reach speeds of over 40 m s⁻¹. In summer the jet shifts to 45–50°S and is considerably weaker. There is considerable day-to-day variation.

- Anticyclonic or Blocking High.* Such conditions occur most frequently in summer and fall. Figure A91c presents an example. The frequency of blocking highs in this location is the highest in the southern hemisphere, and is linked to a split in the jet stream. Most frequently, blocking highs occur just to the east of New Zealand, and extend their influence over most of the country. They bring warmer temperatures than average over most of the country, higher precipitation to the northeast and lower precipitation to the southwest.

Blocking highs bring settled weather, with light winds and mainly clear or partially cloudy skies. This encourages more local airflows to develop, such as sea breezes and katabatic winds (see discussion below). Fog can be prevalent inland.

- Strong zonal circulation to the south with an anticyclone to the north* is the third circulation regime. Figure A91d provides an example. This pattern creates drier and warmer than average conditions to the north, but higher rainfall to the

Table A48 Circulation periods affecting New Zealand climate during the twentieth century and impacts (after Salinger and Mullan, 1999; Salinger and Griffiths, 2001)

Period	Circulation	Temperature	Rainfall
1930–1950	More S to SW airflows	Lower over most of country; fewer days >25°C except NE North Island	Wetter to NE of South Island; drier in N and W of South Island
1951–1975	More E and NE airflow (higher frequency of blocking highs)	Higher over most of country; more days >25°C	Wetter in north of North Island; drier to SE of South Island
1976–1994	More W to SW airflows (more ENSO events)	Little change on average; fewer days >25°C except NE North Island	Wetter over South Island; drier in N of North Island

southwest. The enhanced westerlies to the south may result in somewhat milder conditions, especially in winter. This type of circulation regime is less frequent in summer than in other seasons of the year.

During the twentieth century there were changes in the circulation pattern which can be roughly classified into two-decade periods (Salinger and Mullan, 1999). Between 1930 and 1950 anomalously high frequencies of S and SW airflow occurred compared to the overall average. From 1951 to 1976 E and NE airflows were more frequent. From 1976 to 1998 the circulation reverted to more W and SW airflows. Table A48 summarizes the impacts of these three periods on New Zealand's climate.

Western Pacific regional influences on New Zealand circulation

There are three major interacting influences in the western Pacific that affect New Zealand's circulation pattern, and therefore climate variability (Kidson and Renwick, 2002). The enhancement of convection in the tropics in locations around the dateline decreases frequency of blocking and enhances zonal circulation. If convection is enhanced over the Indonesian area, blocking frequency near New Zealand is also enhanced, and zonal circulation reduced. The frequency and movements of troughs and depressions are not significantly affected.

Shifts in the location of the South Pacific Convergence Zone (SPCZ) affect the precipitation regime over New Zealand (Sturman and Tapper, 1996). When the SPCZ shifts eastward, circulation leading to drier conditions occurs over most of New Zealand except for the W and SW, where enhanced westerlies can bring more precipitation. A westward shift in the SPCZ creates the opposite effect, enhancing precipitation over most of the country except the W and SW coasts. These variations can be subtle and difficult to detect.

Both the strength and location of convection, and the location of the SPCZ, depend strongly on the Southern Oscillation, and whether an El Niño (ENSO) or La Niña (LNSO) event is occurring (Griffiths et al., 2003). During ENSO the SPCZ is shifted toward the NE, and convection is enhanced near the dateline. ENSO encourages high pressure with drought conditions in the north, with a stronger winter anticyclone. Enhanced meridional circulation leads to anomalous strength and frequency of southerly changes. During LNSO the SPCZ is shifted toward the SW, and convection is enhanced over the Indonesia area. Zonal circulation is enhanced, creating more rapidly moving troughs and depressions. NE airflow occurs at the expense of westerlies.

Local circulations

The interaction of the mountain terrain with synoptic circulation can create significant local airflows that affect New Zealand climate. The mountains both block airflow from more westerly sources and act to channel the airflow. The result is often a Foehn wind, which blows over the eastern parts of the country, creating warm dry conditions (Sturman and Tapper, 1996). On South Island a local name for this wind is the "Canterbury Northwester". Foehn winds are strong and gusty downslope winds from the lee of the

mountain ranges, which warm through adiabatic compression. They often occur just before a cold frontal passage. Their strength and location depend on the atmospheric conditions to the windward of the mountain ranges, especially the vertical structure of the atmosphere. Foehn winds can create desiccation, very high temperatures, and damage to buildings, livestock and crops.

The Cook Straight acts a wind tunnel to encourage strong and gusty local wind passage from west to east of the country. These winds can recurve quite sharply, creating NE airflow on the E side of South Island.

Higher terrain can also create katabatic winds overnight over much of the eastern parts of New Zealand, when the synoptic situation is dominated by high pressure. The irregularity of the terrain creates complex downslope airflows, which eventually spill out over the glaciers, river valleys and plains. Low-level temperature inversions are common, especially in the winter, trapping air pollutants. A good example is wood smoke from home heating in the winter atmosphere in Christchurch, which creates highly elevated concentrations of fine particulate matter overnight.

Despite the narrowness of the islands, sea breezes occur on all coasts, especially in the summer. While these create some welcome relief from warm temperatures, their penetration inland is very much dependent on the terrain. Over very narrow areas, such as the very north of North Island, and in Auckland, sea breezes from both the Pacific Ocean and Tasman Sea can meet and interact together. Sea breeze depth ranges from 200 to 2000 m, and wind speeds can reach 15 m s^{-1} . They normally start in late morning and can extend into late evening (Sturman and Tapper, 1996).

Climatic elements (see Table A49)

The circulation variations over New Zealand, associated with changes affecting the circulation of the southwest Pacific region, significantly influence the temperature and precipitation distributions from year to year.

Temperature

Figure A92a shows the annual average temperature distribution. In summer the average temperatures range from about 18°C along the north coast of North Island to 14°C along the south coast of South Island. Particularly in South Island, the isotherm distribution is very strongly influenced by the terrain. Winter average temperatures range from 11°C in the very north of North Island to 4°C in the higher elevations below 45° latitude. Table A48 lists general changes from this average pattern as circulation periods change.

During ENSO periods the temperatures tend to be cooler over most of the country, affected by the increases in SW airflow. North Island is affected more strongly. Seasonally, this influence is weakest in summer (Kidson and Renwick, 2002). During LNSO periods the temperatures are generally milder in all areas, although the impact is less consistent on South Island. The S and W coasts are often cooler, associated with the stronger SW winds. Correlations between the South Oscillation and temperatures over New Zealand can reach 0.6 in the northern part of North Island, falling to below 0.4 along the south coast of the country and are significant.

Since 1950 the average temperatures over New Zealand have increased by about 0.5°C , in line with global increases

Table A49 Mean climatic data for selected New Zealand cities, January and July

City (Lat./long.)	Alt. (m)	Years of data	Max. temp. (°C)	Min. temp. (°C)	Mean temp. (°C)	Relative humidity (0900 (%))	Precipitation (mm)	Frost days	Daily sunshine (h)	Solar energy (MJ/m ² per day)

Data from www.niwa.co.nz.

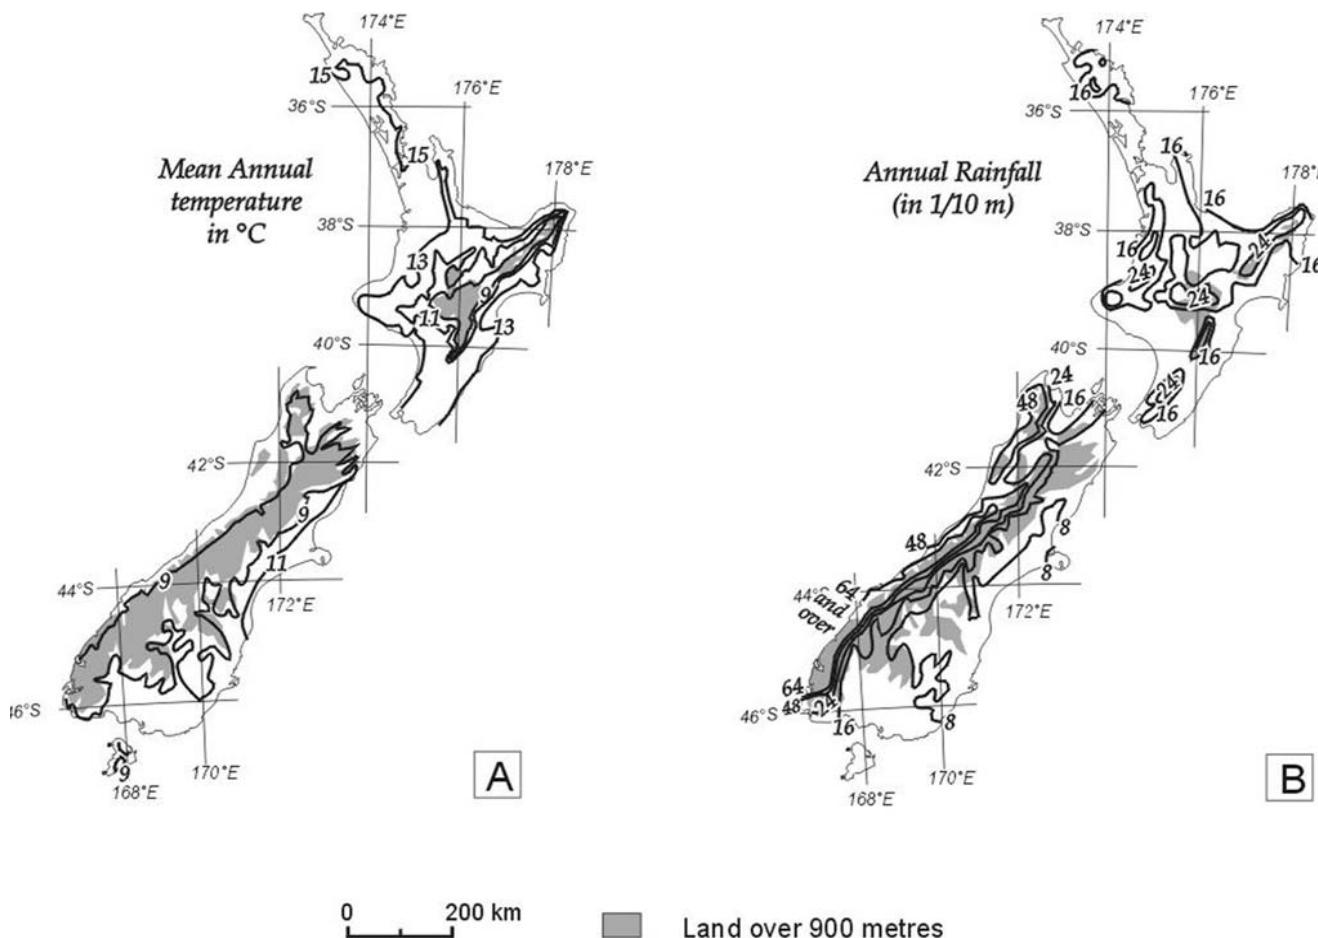

Figure A92 (a) New Zealand average yearly temperature distribution ($^{\circ}\text{C}$); (b) New Zealand average yearly rainfall (cm divided by 10) (after Kirkpatrick, 1999).

associated with **greenhouse warming** (Salinger and Griffiths, 2001). There is little evidence of change in maximum temperatures or extremes, but minimum temperatures have increased significantly. There has been a decrease in the frequency of extremely cold nights. Between 1976 and 1998 the number of days with frost was lower by an average five to 15 in each year, compared to earlier periods.

Precipitation

The precipitation distribution pattern over New Zealand is highly irregular (Figure A92b), mainly due to terrain influences. Precipitation can range from more than $12\,000 \text{ mm y}^{-1}$ on the mountain tops of South Island to less than 600 mm y^{-1} on the eastern plains, for example the Canterbury area. Particularly on South Island, snow is an important component, covering 35% of the area on average but with high variability from year to year.

The greatest source of rainfall is fronts and troughs, particularly if they are associated with cold pools of air in the mid-to-upper troposphere. These can bring severe storms and create very heavy rain. Such storms are more likely to occur in winter and spring than in summer.

Overall, increased rainfall on a seasonal or yearly basis is associated with a higher frequency of N airflows, and thus linked to LNSO. Under this pattern rainfall to the S and W is often reduced, associated with weaker westerly circulation. This varies, depending on the time of year and the strength of the LNSO event.

ENSO periods bring drier weather to the N and E, and, compared to Australia, occasional much shorter periods of drought. Droughts rarely last more than 3 weeks. Increased westerlies during this period bring higher rainfall than average to the W and S coasts of especially South Island. The SOI does not correlate significantly with rainfall over New Zealand (TPE, 2001).

Changes in rainfall associated with the major changes in circulation in 1950 and 1976 are less well defined than for temperature (Salinger and Griffiths, 2001). The eastern part of South Island and the central area in North Island show significant decreases, by 15–25%. Increases occur on the south and west sides of both islands. Otherwise, there are no significant changes in rainfall distributions. The length of dry spells over New Zealand has been reduced by 1.5 to 4.5 days since 1950.

Table A50 Extreme weather events in New Zealand

Weather event	Location	Period	Value
Rainfall (mm)			
Hourly Total	Whenuapai	16 Feb 1966	107
Daily Total	Colliers Creek (S.I.)	21–22 Jan 1994	682
Monthly Total	Cropp River (S.I.)	Dec 1995	2927
Annual Total	Cropp River (S.I.)	1998	16617
Lowest Annual Total	Alexandra (S.I.)	Nov 1963–Oct 1964	167
Temperature (°C)			
Highest Maximum (N.I.)	Ruatoria	7 Feb 1973	39.2
Highest Maximum (S.I.)	Rangiora & Jordan	7 Feb 1973	42.4
Lowest Minimum (N.I.)	Chateau Tongariro	7 Jul 1937	-13.6
Lowest Minimum (S.I.)	Ophir	3 Jul 1995	-21.6
Wind Gusts (km/h)			
Highest, North Island	Hawkins Hill	6 Nov 1959	248
Lowest, South Island	Mt John	18 Apr 1970	250

Data from <http://www.metservice.co.nz>
N.I. – North Island; S.I. – South Island.

Other climate elements

Thunderstorms are most often linked with fronts and troughs, and are higher in frequency on the west side of the islands, associated with orographic forcing. On the east coast of the islands, diurnal variations are typically a maximum in the afternoon and early evening, associated with a summertime peak in frequency and a thermal (convective) origin. On the west coast a higher frequency occurs at night, with an erratic seasonality pattern. Here wintertime thunderstorms occur more regularly, associated with friction and orographic effects. Along a north–south transect through the center of both islands, thunderstorm frequencies peak in the afternoon and early evening, but a secondary peak overnight is evident.

Hail frequencies increase from north to south, associated with the deep convection in cold fronts and troughs. New Zealand has approximately 25 tornadoes per year. North Island has an approximately three times higher frequency than South Island. Most tornadoes are relatively small by world standards, and are more frequent in the afternoon. Wind speeds can reach 190 km/h (Sturman and Tapper, 1996).

Tropical cyclones affect New Zealand rarely, creating strong winds, and heavy rain can occur on the northern and northeastern parts of North Island.

Table A50 lists extreme weather events for New Zealand. The maximum temperatures for both North and South Island are associated with a strong Foehn event, which occurred just before a cold frontal passage. Subsequently, the temperature then rapidly dropped to around 22°C. The lowest minimum temperatures occurred in snowfield stations in the winter. Short-term, high-rainfall events are associated with severe storms, and longer-term records with the higher altitudes on the western slopes of South Island mountain ranges. The lowest annual rainfall occurs at Alexandra on South Island, in the rainshadow east of the mountain ranges. In comparison with Australia (Table A45), New Zealand extremes show higher rainfall amounts but lower maximum and higher minimum temperatures.

By global standards New Zealand is basically one Köppen climate type, Cf (warm temperate climate with sufficient

precipitation during all months). On a more detailed regional scale, however, a simplified climate classification of New Zealand produces eight categories, as shown in Figure A93.

Near-future climate change in Australia and New Zealand

The climate is varying continuously, and there are concerns about near-future changes associated with greenhouse warming in Australia and New Zealand. A series of reports focusing on the results of meteorological network measurements in both countries, and global and regional climate modeling, suggest the following scenario is likely for Australia and New Zealand (www.dar.csiro.com; www.niwa.co.nz).

Higher temperatures in general across Australia are probable, 0.4–2.0°C by 2030 and 1–6°C by 2070. The extra heat capacity of the oceans will delay and minimize warming along the coast. Most of the change will most likely occur in the minimum temperature, decreasing the overall daily temperature range. Evidence that this has already been occurring comes from Queensland (Lough, 1995) and other parts of the country (Bureau of Meteorology 2003). Warmer minimum temperatures would decrease the number of days below 0°C (by up to six per year) and less snow cover would exist. However, an increase in the number of extremely hot days in summer is expected, particularly in the desert areas of Western Australia.

Rainfall zones are likely to shift southwards, leading to lower rainfall in the south and east, especially in winter and spring, but higher rainfall in summer. Winter rainfall may increase slightly in central Australia, but decrease or remain the same in most other parts of the country. There has been a downward trend in rainfall in the SW since the mid-1960s (Allen and Haylock, 1993), which may continue. The climate record already shows an increase in Australian cloud cover during this century (Jones, 1991). There may be greater frequencies of high-rainfall events, and decreased numbers of low-rainfall events, as well as increased frequencies of drought, bushfires, and fine weather (Sturman and Tapper, 1996). Potential

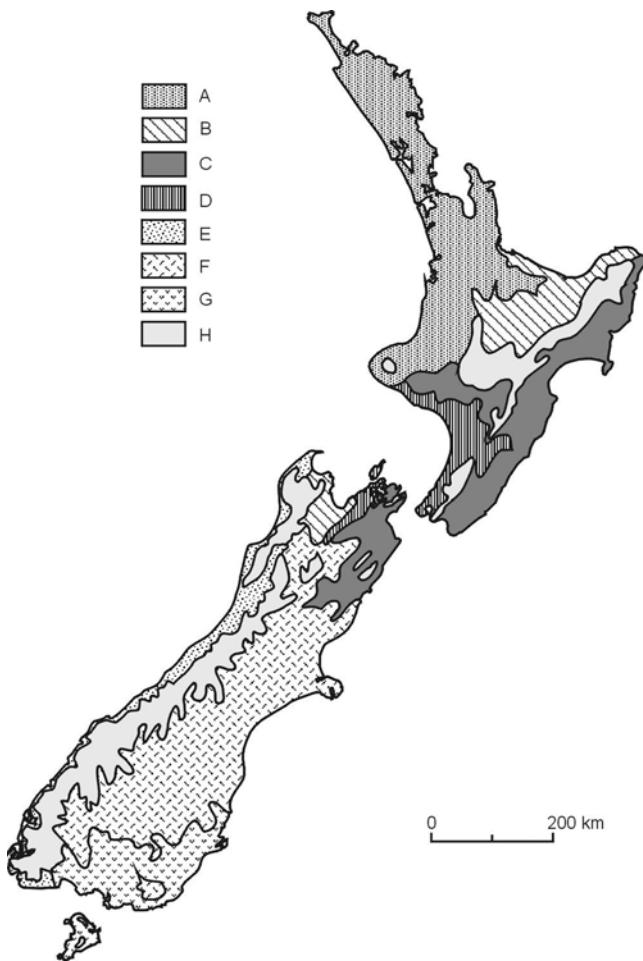

Figure A93 Simplified climate classification for New Zealand (modified from Sturman and Tapper, 1996). **A**, mild winter, warm moist summers, annual rainfall 1000–2500 mm, winter rainfall maximum, prevailing SW winds, occasional storms from E or NE. **B**, annual rainfall 1000–2000 mm, winter maximum, mild winters (but frequent frost), very warm summers, heavy rain from N or NE. **C**, very warm summers (strong Foehn effect), cool to moderate winters, annual rainfall 600–1500 mm (heavier in isolated places), winter maximum, lower and more unreliable summer rain. **D**, winds dominant from W and NW, frequent gales throughout year, annual rainfall 900–2000 mm, cooler temperatures. **E**, cool annual temperatures, range is small, prevailing SW winds, strong mountain influence on rainfall distribution (increase with altitude). **F**, cool winters, warm summers, frequent frosts, occasional snow (especially inland), annual rainfall 500–1500 mm, NE winds prevail along coast, NW winds inland. **G**, cool winters, warm summers, annual rainfall 500–1300 mm, slight winter maximum. **H**, extreme rainfall variations in mountains, cool to cold temperatures.

evaporation will increase. A greater intensity in extreme rainfall events and tropical cyclones is expected.

For New Zealand, the summer increase in temperature by the latter two decades of the 21st century may range from 1°C in the S to 1.8°C in the N. Winter increases are slightly higher,

ranging from 1.6°C in the S to 2.2°C in the N. Model results suggest decreases in precipitation of around 5% on the east coast of both islands, and an increase of up to 15% on the west coasts. Winter precipitation may change quite dramatically, with reductions of 10–15% on the east coasts and increases of more than 30% in the mountains of the South Island. These changes reflect the increasing frequency and strength of SW and W airflows.

AZORES (BERMUDA) HIGH

This is one of seven regions of year-round relatively high pressure where barometric values are typically higher than adjacent areas and where the air is drier, skies clearer, and surface wind speeds slower. The other six regions are the Siberian (Asiatic), Pacific (Hawaiian), and North American (Canadian) Highs in the northern hemisphere, and the Indian Ocean, South Atlantic (St Helena), and South Pacific Highs in the southern hemisphere.

The Azores (or Bermuda) High is a large subtropical anticyclone centered between 25°N and 35°N in the Atlantic Ocean. The high often extends westward as far as Bermuda; when this occurs it is known in North America as the Bermuda High. It extends to great elevations, with deep tropical easterlies on its equatorward side and midlatitude westerlies on its poleward side. This very persistent and quasistationary feature of the atmosphere's circulation is elongated in an east–west direction, with its center of highest pressure located over the eastern portion of the subtropical Atlantic in the general vicinity of the Azores. It is most pronounced in the summer, when land–water temperature contrasts are substantial, and has an extreme summertime position of about 34–38°N. The expanding high often gets large enough to affect hurricane trajectories, moving the storms westward toward the West Indies and the southeastern United States. In winter it is less pronounced and is located at somewhat lower latitudes.

Within the heart of the Azores High, winds are light and variable, and the high is characterized by divergence, subsidence, and fair weather. However, there is a marked contrast between the eastern and western portions of the high. The eastern side is characterized by strong subsidence and a dry climate, whereas the western side has little or no subsidence and a wetter climate. This contrast corresponds to the moisture and stability differences between the east and west sides of the oceanic trade winds.

The cause of this contrast is not clear. The longer trajectory of air over the warm waters of the subtropical Atlantic contributes to a more humid west-side climate. This circulation pattern results in hot and humid weather for the central and eastern United States in the summer. The ultimate cause is probably related to the inherent distribution of continents and oceans. Large east–west circulations exist in heating between subtropical continents and oceans. The strongly subsiding eastern portions of the Azores High coincide with the sinking branches of these east–west cells, whereas the western portion of the high is near the rising branch of the circulation cell.

The relative strength of the high is used as one variable to determine the North Atlantic Oscillation and its derived index.

B

BEAUFORT WIND SCALE

British Admiral (then Commander) Sir Francis Beaufort, KCB developed the Beaufort Wind Scale in 1805. The scale provided a practical method for estimating the force of the wind on a ship at sea by means of an arbitrary scale running from 0 (calm) to 12 (hurricanes) as shown in Table B1. In 1838 use of the Beaufort Wind Force Scale was made mandatory for log entries on all Royal Navy ships. In the scale's original form (which has been greatly altered in most current versions), there is no mention of wind velocity, it specifically being a force scale.

The scale is made up of three associated lists – a list of 13 integers (Beaufort force numbers) from 0 through 12; a list

of common words for the strength of the wind; and a list that describes the state and behavior of a “well conditioned man-of-war” (Kinsman, 1969). Beaufort, and all seafaring individuals, recognized distinct levels in the behavior of a man-of-war of the early 1800s operating under conditions of “clean full” (probably close-hauled but held just off the wind to avoid any loss of speed due to luffing or shaking of the sails) and “in chase, full and by” (carrying all possible sails, all sails full, and heading as near to the wind as possible).

The Beaufort Wind Force Scale was developed at a time when instruments that measure wind speed were unavailable; but point wind speed information would not have been helpful on a sailing ship. Wind speed would have varied considerably from the height of the quarter deck (12 feet) to the crosstrees on the main mast (120 feet). What was really needed was information on the overall effect of the wind force at all

Table B1 Beaufort's Wind Force Scale, 1831 version (probably close to the original formulation of the scale)

0	Calm	
1	Light air	Or just sufficient to give steerage way
2	Light breeze	Or that in which a man-of-war, with all sail set, and clean full, would go in smooth water from
3	Gentle breeze	
4	Moderate breeze	
5	Fresh breeze	
6	Strong breeze	Or that to which a well-conditioned man-of-war could just carry in chase, full and by
7	Moderate gale	
8	Fresh gale	
9	Strong gale	
10	Whole gale	Or that with which she could scarcely bear close-reefed main top sail and reefed fore-sail
11	Storm	Or that which would reduce her to storm stay-sails
12	Hurricane	Or that which no canvas could withstand

Source: From Fitzroy (1839), p. 40.

Table B2 Reasonable current specifications for the Beaufort Wind Force Scale

Beaufort	Descriptive term	Wind speed (knots)		Effect on sea surface
		Mean	Limits	
0	Calm	0	<1	Sea like a mirror
1	Light air	3	1–4	Ripples with the appearance of scales, no foam crests
2	Light breeze	7	5–8	Small wavelets, crests have glassy appearance and do not break
3	Gentle breeze	11	9–12	Large wavelets, crests begin to break, perhaps scattered white horses
4	Moderate breeze	15	13–16	Small waves becoming longer, fairly frequent white horses
5	Fresh breeze	19	17–21	Moderate waves, many white horses, chance of some spray
6	Strong breeze	24	22–26	Large waves form, white foam crests extensive, probably some spray
7	Near gale	29	27–31	Sea heaps up and white foam from breaking waves blown in streaks
8	Gale	34	32–36	Moderately high waves of great length, edges of crests begin to break into the spin-drift, foam blown in streaks
9	Strong gale	39	37–42	High waves, dense streaks of foam, crests of waves begin to topple, tumble and roll over
10	Storm	45	43–48	Very high waves with long overhanging crests, sea surface takes white appearance, visibility affected by spray
11	Violent storm	52	49–55	Exceptionally high waves, sea completely covered by long white patches of foam, everywhere edges of wave crests blown into froth
12	Hurricane		>55	Air filled with foam and spray, sea completely white with driving spray, visibility seriously affected

levels on the performance of the man-of-war operating at peak performance.

By the time anemometers were used to give wind speed information, men-of-war of the type utilized by Beaufort in the formulation of his scale were no longer available, so that there was no way to assign wind speed values to the Beaufort numbers. However, because of the widespread acceptance of the Beaufort Scale, later versions have included wind speeds and descriptive terms that refer to the effect of the wind on fishing smacks, on trees, and on the state of the sea (Table B2).

Wind speed values associated with specific Beaufort numbers vary considerably from scale to scale (Simpson, 1926; Verploegh, 1956). Beaufort force numbers were used as a telegraphic wind code until 1947 when the Directors of the International Meteorological Committee agreed to abandon the use of Beaufort numbers and to replace them with wind velocities in knots in meteorologic reports.

BIOCLIMATOLOGY

Bioclimatology (biometeorology) is the study of the relationships between climate (weather) and living organisms. The field is vast and brings together scientists from many disciplines. Bioclimatology is frequently divided into human, plant (agricultural and forest), and animal bioclimatology. Other subdivisions include aerobiology (the behavior of airborne living material), phenology, urban bioclimatology, air pollution bioclimatology, tourism and recreation bioclimatology, mountain bioclimatology, electromagnetic and ionization bioclimatology, and bioclimatological rhythms. However, no single classification system has been adopted universally. The American Meteorological Society, for example, has several committees with bioclimatological involvements: Agricultural and Forest Meteorology, Applied Climatology, Biometeorology and Aerobiology, and Meteorological Aspects of Air Pollution. The time intervals studied range from the daily cycle to geological times.

Bioclimatology is an interesting research field that has many important practical applications for human comfort, agricultural yields, regional land-use planning, forest management, building research, and so forth. A focus for bioclimatological studies is provided by the International Society of Biometeorology, which sponsors the *International Journal of Biometeorology* (Springer-Verlag Publishers, Heidelberg, Germany). However, research results appear in a wide range of journals.

Bioclimatologists customarily refer to an environmental stress that causes a biological response. The word stress does not necessarily imply a harmful effect; a brisk walk on a cold day may be considered invigorating by many people, for example. Over the centuries, humans have been increasing their ability to reduce unwanted environmental stresses through use of clothing, heated and air-conditioned buildings, irrigation, flood-control systems, fertilizers, and pesticides. By the year 1960 expectation was widespread that humans soon would have total control of their environment. However, beginning in the 1960s this utopian view began to be challenged, and since the 1980s it is generally believed that environmental stresses are necessary to retain the resilience of humans and supporting ecosystems. By using technology to shield living things from the rigors of the elements, the chances increase that the capacity to withstand extremes may become seriously impaired. For example, a severe ice storm in January 1998 in eastern Canada and northeastern United States caused serious damage to the power supply infrastructure, which led to electricity blackouts for several days (Higuchi et al., 2000). Communities in those regions that depended heavily on modern technology suffered more than those that were accustomed to power outages and had their own back-up alternatives. Bioclimatologists have a full agenda for the next few decades elaborating these issues, particularly in the face of global environmental change (see article in this Encyclopedia on Global Environmental Change: Impacts, by the same authors).

The field of bioclimatology is too broad to cover here; therefore, the approach taken is to discuss a few topics in sufficient detail to give the reader an idea of the flavor of bioclimatology. A list of further reading is added with respect to subjects not mentioned in the text.

Bioclimatological methods

Methods used in bioclimatological research are of three main types:

1. Statistical

Multivariate regressions or other statistical methods, in which a response characteristic is correlated with an array of possible indicators of stress. Although a significance test may indicate an association, it does not imply the existence of a cause–effect relationship.

2. Experimental

Controlled *laboratory studies* using human volunteers or greenhouses/phytotrons/biotrons in the case of plants, animals and whole ecosystems. An ethical problem with studies involving human volunteers is that the stress produced might be harmful (e.g. causing an asthma attack) for a few of the more sensitive people participating. Yet these individuals provide data for that part of the stress–response curve of most interest.

Field studies of stress–response relations, preferably under given sets of conditions, e.g. using only data when skies are clear, or when gradient winds are light.

3. Models

Mathematical statements synthesizing current understanding of stress–response relationships. For large systems, e.g. those used in integrated pest management, models can interconnect various kinds of information. Models can also be used to test the utility of various proposed management strategies.

Data sets selected for study

Biological data sets used by bioclimatologists are of four main types: (1) general biological data sets that happen to be available, e.g. census information, crop yields, insect populations; (2) data sets relating to biological indicators that are specific to conditions of extreme environmental stresses, e.g. studies of organisms existing at high elevations, studies of health effects during heat waves, cold waves, or air pollution episodes; (3) data sets relating to cycles, e.g. diurnal, annual, or life cycles; and (4) data sets that are model-dependent. In the initial stages of an investigation, e.g. with respect to electromagnetic effects, the stress–response mechanism may be obscure and only a time-series analysis will be possible.

Epidemiological (large-population) statistical regressions may suggest laboratory or field studies that should be undertaken, and models that should be tested. In the latter case the data sets must be selected with care, or new data must be collected, the specific goal being model-performance testing.

Meteorological data sets include hourly, daily and monthly records of variables such as temperature, humidity, precipitation, etc.

Some problems with bioclimatological studies

Bioclimatological studies are difficult to design for several reasons:

Lack of reproducibility

Even under controlled laboratory conditions the response of a living organism to environmental stress may vary greatly from

time to time. The response depends on the time of day (most organisms display a circadian rhythm of about 24 hours) and the frequency with which the response is imposed. Sometimes *acclimatization* (short-term physiological adjustment) may take place and may lead to long-term *adaptation*.

Variation in population responses

The response of populations to an environmental stress can vary greatly. For example, not everyone suffers from hay fever, no matter how high the concentration of pollen. The World Health Organization makes a useful distinction between an *effect* (a biological reaction) and a *response* (the percentage of exposed organisms/people who react with a specific effect.)

Existence of time lags

An environmental stress may produce an almost immediate response (e.g. exposure to H_2S causes an instantaneously detected bad smell), or the response may be lagged by days, weeks, years, or decades (e.g. up to a 20-year latency period may be required before asbestos exposure causes lung cancer; or for UV-B radiation to cause skin cancer). In the meantime the population being studied may have changed its lifestyle, making it impossible to disentangle stress-response relationships.

Multiple stresses

Living organisms frequently are subjected to several stresses at the same time. For example, during heat waves, air quality becomes poor, but it is not possible to determine whether the resulting effects on health are due to high temperatures, poor air quality or both.

Estimation of exposures

Most living things move about, and it is not easy to characterize their exposure. Many people spend most of their time indoors where the environment may be quite different from that measured outdoors at weather-observing and air-quality stations. For this reason, studies of human exposure to air pollutants often use human volunteers who wear portable pollution samplers to obtain their daily exposures (see, e.g., Silverman et al., 1992).

Failure of standard statistical methods

Many responses are curvilinear, making standard statistical methods inappropriate. Furthermore, most data sets contain time correlations rather than being random samples, causing correlation coefficients between two variables to be inflated. For more information on biometeorological methods, see Munn (1970), Houghton (1985), and Kates et al. (1985).

Human bioclimatology

Atmospheric variables that may affect humans include heat, cold, wind, humidity, solar radiation (especially UV-B radiation), air pollution, pressure, negative ions, electromagnetism, and biorhythms. In the case of the first six factors the existence of stress-response relationships has been clearly demonstrated. However, with respect to the last four factors the results

obtained are still controversial, even though studies began more than a hundred years ago, particularly at the great European health spas, where people went to seek relief from arthritis, respiratory ailments, and allergies.

Heat stress and cold stress continue to demonstrate the most obvious effects of weather and climate on people, and will be discussed in the following paragraphs as good examples of the state of the art in bioclimatology.

Warm-blooded mammals must keep their inner body temperature within a very narrow range (around $37^\circ C$) or irreparable harm ensues. The body gains heat by its own metabolism; gains (or loses) heat from (or to) its surroundings by radiation, conduction, and convection; and loses heat by evaporation (breathing and sweating). There are two types of metabolic heat stress: *basal metabolic heat* (released when the body is at rest) and *muscular metabolic heat* (released, in addition to basal metabolic heat, during periods of work or body exercise).

Basic heat transfer models can predict the heat balances of simple volumes such as spheres or cylinders. However, the human body has a complex shape and some parts of the body – such as nose, cheeks and earlobes – are fully exposed whereas other parts are covered with clothing. Therefore, the study of heat and cold stress is not a straightforward problem in thermodynamics. Recently, more advanced heat transfer models have been developed and are being tested for use in a wide range of environmental conditions (see, for example, Fiala et al., 2001; Huizinga et al., 2001; Tanabe et al., 2002; and the International Society of Biometeorology: <http://www.biometeorology.org/>).

Heat stress is associated with various combinations of the following conditions: (1) high muscular activity; (2) high solar radiation, particularly in the tropics at high elevations; (3) high infrared radiation, e.g. near a blast furnace in a steel mill; (4) air temperatures greater than body temperature ($37^\circ C$), producing a net gain in body heat from convection; (5) high humidity, reducing the rate of evaporational cooling from the body; and (6) strong winds in combination with (4) and (5), increasing the convective heat gains of the body.

The *physiological* (involuntary) mechanisms used to cope with heat stress are (1) dilating of blood vessels near the surface of the skin, increasing the flow of blood near the skin and increasing the heat exchange from the body to its surroundings; (2) increased sweating, resulting in evaporational cooling; and (3) increased respiration (equivalent to panting of dogs). The *voluntary* mechanisms are (1) avoiding strenuous activity; (2) avoiding direct sunlight and strong infrared sources; (3) switching to lightweight clothing; (4) changing diet to reduce basal metabolic heat production; and (5) remaining in air-conditioned buildings.

An indicator of heat stress is *effective temperature*, the temperature at which motionless saturated air would induce the same degree of comfort/discomfort as that associated with ambient conditions of temperature, humidity, and wind. Although the words “comfort” and “discomfort” are subjective terms, some consensus on their meaning has been achieved through physiological studies of volunteers walking on treadmills in controlled conditions. During each experiment, measurements are made of skin temperature, sweat rate, and body weight, and the volunteers are asked about their degree of discomfort. In other kinds of studies the learning rates of students or work outputs of office employees are examined in relation to room temperature and humidity. The results of these types of studies have been summarized in tables of discomfort.

Table B4 Relation of Humidex with comfort

Humidex	Degree of discomfort
20–29	Comfortable
30–39	Varying degrees of discomfort
40–45	Almost everyone uncomfortable
46 and over	Many types of labor must be restricted

Source: Data obtained from the Meteorological Service of Canada, Downsview, Ontario.

An example of a simple empirical discomfort index (*Humidex*), used by the Meteorological Service of Canada, is shown in Table B3, and the associated discomfort ranges are given in Table B4. *Humidex* is derived from air temperature and humidity (Masterton and Richardson, 1979). For example, air temperature of 30°C and relative humidity of 90%, giving a *Humidex* value of 46, are an extremely uncomfortable combination.

Cold stress occurs during exposure to low temperature, strong winds, and thin or wet clothing. It is not always realized that severe cold stress can occur at temperatures well above freezing if clothing becomes saturated with moisture (see, for example, Pugh, 1966).

The *physiological* (involuntary) mechanisms activated to cope with cold are (1) contracting of blood vessels near the surface of the skin; and (2) shivering. The *voluntary* mechanisms are (1) switching to warmer and drier clothing; (2) moving indoors or to locations sheltered from wind and rain; (3) exercising; and (4) changing diet to increase basal metabolic heat production.

A widely used method of expressing cold stress is by calculating *wind chill*. One of the early empirical methods was

derived from 89 sets of measurements made in Antarctica by Siple and Passel (1945), who recorded temperature, wind speed, and the time required to freeze a plastic cylinder of water. However, this method was found to exaggerate the effect of cold due to certain assumptions that do not apply for the human face (Bluestein and Zecher, 1999; Osczevski, 2000; Tikuvisis and Osczevski, 2002). More complex but also more realistic approaches for calculating wind chill, as well as the full range of thermal stress, are based on heat budget models of the whole body (see, for example, Steadman, 1984; Hoeppke, 1999; Fiala et al., 2001; Huizenga et al., 2001; Laschewski and Jendritzky, 2002; Tanabe et al., 2002). However, these models have not yet been widely tested or used, and a coordinated international effort is currently under way to develop a universal thermal climate index (see International Society of Biometeorology: <http://www.biometeorology.org/>). A simpler approach has recently been developed and implemented in Canada and the United States, based on the cooling effect of wind on the human face, and was validated on a group of healthy volunteers (see Meteorological Service of Canada: <http://www.msc-smc.ec.gc.ca/education/windchill/index.cfm>). The data are shown in Table B5, together with explanatory notes concerning the risk of frostbite. The table is developed for the dry human face in the shade and may not represent the discomfort of a warmly dressed person, a person exposed to sunshine or a person with wet skin.

The thermal insulation of clothing is expressed in *clo* units, where 1 *clo* is the insulation that maintains comfort in a resting person indoors at an air temperature of 21°C with relative humidity of less than 50%. Experimentally, 1 *clo* has been estimated to be equal to 0.18°C m² h/kcal. The insulating efficiency of clothing can be measured, and the results can be used

Table B5 Wind chill, where T_{air} = Air temperature in °C, and V_{10} = Observed wind speed at 10-m elevation, in km/h

in conjunction with joint climatological frequency distributions of temperature and wind speed to produce clo climatologies. For example, at Yellowknife in the Canadian Northwest Territories in January, the numbers of clo required to maintain comfort outdoors are 5.2, 4.1, 2.7, and 1.2 for metabolic rates of 80, 100, 150 and 300 kcal m⁻² h⁻¹, respectively (Auliciems et al., 1973).

That heat stress and cold stress indeed cause increases in morbidity and mortality has been amply demonstrated. See Macfarlane (1977, 1978) for reviews of relevant epidemiological studies on mortality. In one particularly interesting investigation, Clarke and Bach (1971) found that the number of deaths caused by heat in St Louis, Missouri, in July of 1966 could be fitted by a straight line when plotted against average temperature of the previous day; no deaths at 32°C (assumed to be the critical level) rising to 73 cases at 35°C. A more recent heat wave during 12–15 July of 1995 caused over 500 excess deaths in Chicago, Illinois (WMO, 1999; Klinenberg, 2002). The average daily maximum and minimum temperatures during the 4-day heat wave exceeded 38°C and 26°C, respectively, coupled with very high dewpoint temperatures during day and night (Kunkel et al., 1996). The high number of deaths was blamed on several factors, including an inadequate heat-wave warning system, power failure, inadequate health-care and air-conditioned facilities, an aging population, and poor home ventilation due to poverty or fear of crime (Changnon et al., 1996). A much more dramatic heat wave in Western Europe in August 2003 caused between 22,000 and 35,000 excess deaths (Schär and Jendritzky, 2004), over 14,000 of them in France alone (Allen and Lord, 2004).

This review of human bioclimatology admittedly is incomplete. However, the following list will lead the reader into the literature on specific topics:

Plant bioclimatology (agricultural and forest)

Humans have been managing (or in some cases mismanaging) renewable resources for many centuries. The goal is to increase crop and timber yields without causing long-term degradation of soils and forests. Climate has a direct effect on plants; it provides the primary source of energy; it governs the temperature of plant organs; and it controls water loss by transpiration. The main climatological stresses that adversely affect vegetation are drought, flood, hail, strong winds, and frost. However,

atmospheric processes are indirectly important in seed dispersal, pest outbreaks, air pollution concentration (including acidic rains), soil erosion, and soil moisture. Because many cash crops are grown outside their normal climatological ranges, they must be irrigated and protected from frost and strong winds. The bioclimatologist assists in this latter regard, either by modifying the landscape (e.g. with shelterbelts) or by providing advice on how to optimize the use of terrain irregularities (*topoclimatology*). For example, a forest clearing can create a frost pocket, making it difficult for young seedlings to survive. The forest industry therefore has a need to evaluate topoclimatological features in order to assure regeneration of clear-cut areas.

A single example, apple-growing in Britain, will illustrate some of the factors considered in a bioclimatological study (Landsberg, 1980). First, the life cycle of apple trees must be described: from seedlings to mature orchards and from bud production (late summer and early fall) through blossoming (spring) to fruiting (late summer). Next, the sensitivity of an orchard to environmental stresses must be evaluated with respect to each phenological stage of development of the tree and of the fruit. The main stresses are drought, unseasonably mild winters, spring frost, wet and cold summers, and weather-sensitive pest outbreaks. These several stresses have an effect on both quantity and quality of the harvest. Landsberg reviews the work that has been done to understand the effects of weather on the apple orchards of Britain. He asserts that part of the problem has been solved: the annual total dry matter produced by apple trees can be estimated satisfactorily, given the daily weather throughout the year being studied. But orchards are grown for their fruit, not for their biomass. An empirical relationship has therefore been developed that relates dry matter production to quantity and quality of apples.

Agricultural and forest bioclimatology has become increasingly significant in the recent climate change debate. Agricultural lands and forests sequester large amounts of carbon; therefore improved management practices are needed to partially offset the rising levels of atmospheric CO₂. Climate change may also alter the pattern of food and timber production, either for the better in some regions, or for the worse in others. Plant bioclimatology will therefore continue to play a major role in understanding the impacts of climate change, and in formulating mitigation and adaptation measures (see Global Environmental Change, in this volume).

For more information on agricultural and forest bioclimatology, consult the following references. For crop-weather relations, see Baier et al. (1976), Skjelvag (1980), Burt et al. (1981), Parry (1985), and Parry et al. (1986); for topoclimatology, see Skaar (1980), and Utaaker (1980); for shelterbelts, see Rosenberg (1975); for UV radiation, see Grant (1997); for ozone effects, see Krupa et al. (2001); for effects of nitrogen compounds, see a series of articles in *Environmental Pollution* (2002), vol. 118, issue no. 2, pp. 165–283. In general, see the journal *Agricultural and Forest Meteorology*, published by Elsevier Publishing Company, Amsterdam, and the book *Forest Microclimatology* (Lee, 1978).

Animal bioclimatology

Bioclimatologists seek to quantify the direct and indirect impacts of climate on animals, particularly domestic ones. In the case of farm animals the objective is to improve the quality and quantity of meats and dairy products, as well as to increase the work output of “beasts of burden”. Direct effects involve

heat exchanges between the animal and its environment, which are linked to air temperature, humidity, wind speed, and thermal radiation. These linkages affect animal health, growth, milk and wool production, reproduction, and performance in general. For example, heat and cold stress can have marked effects on milk yield of lactating cows, depending on breed, feed intake and degree of acclimatization. Conception rates of dairy cows are also sensitive to seasonal fluctuations. Climatic extremes such as droughts, floods, violent winds, heat waves, and severe winter storms can result in injury and death of vulnerable animals. Indirect effects include climatic influences on quantity and quality of feedstuffs such as pastures, forages, and grains, as well as the severity and distribution of livestock diseases and parasites.

Bioclimatologists also undertake studies on wild animals to determine the effects of atmospheric stresses such as acidic deposition, long-range transport of toxic chemicals, weather disasters, and more recently UV-B radiation and climate change. Ecologists need this information to help understand population changes, species diversity and ecosystem health. Biodiversity has become a fast-growing field of study linked in many ways to bioclimatology.

Animal bioclimatology is a vast field and only a few references are listed here. For general information, see Tromp (1980), and Johnson (1997). For heat transfer from animals, see Cena and Monteith (1975), and Tracy (1977); for bioclimatology of domestic animals, see Bianca (1976), Dragovich (1981), Christianson et al. (1982), Igono and Aliu (1982), and Starr (1983); for bioclimatology of wild animals, see Shkolnik (1971), and Picton (1979).

Phenology

Blooming wildflowers, falling leaves, migrating birds and insects, spawning fish, hibernating animals, freezing ponds and rivers, and the like, are all influenced primarily by climatic conditions. Bioclimatologists undertake phenological studies to understand the role of climate variables in the dynamics of plant and animal natural cycles. The relationships between climate variables and the timing of these phenophases provide useful information to farmers, gardeners, horticulturists, and beekeepers, e.g. first growth and flower dates, last frost of spring or first frost of fall, planting and harvesting dates, and appearance of insect or weed pest species. Wildlife managers also need information on bird and animal migration dates, growth stage dates of various plant and animal species, dates of critical lake and soil temperatures, and breeding activities and nesting/denning dates (see, e.g., Lieth and Schwartz, 1997).

Phenological studies have become increasingly valuable in recent years, because trends in phenology may serve as natural indicators of global climate change (IPCC, 2001; Lechowicz, 2001; Van Noordwijk, 2003).

Aerobiology

Airborne living material is transported by the wind, sometimes for thousands of kilometers. Field naturalists are interested in bird and insect migrations, and in large-scale movements associated with the life cycles of pollen, rusts, and spores, which are of economic and health significance. For example, pollen and other allergy-causing materials may be transported from countryside to city, or from state to state, causing health problems at

considerable distances from the source regions. (A question often asked is how large an area surrounding a city should be cleared of ragweed in order to provide effective relief to hay fever sufferers?) Other examples include the potato blight, wheat rust, locusts, the gypsy moth, and spruce budworms. A final example is that many viruses and other substances that harm animals and/or people can also be transmitted by the wind, e.g. foot-and-mouth disease, rinderpest, influenza viruses, etc. In 2001 a severe outbreak of foot-and-mouth disease spread in the UK, leading authorities to destroy several million livestock. Computerized models are often used to predict the dispersion, movement and deposition of viruses and other biological agents.

Aerobiology contributes to understanding the atmospheric part of the life cycles of the pests mentioned above, and to an activity called *integrated pest management*. A good example is the study by Fleming et al. (1982), who examined the effect of field geometry on the spread of crop disease. Using reaction-diffusion models, rectangles of various dimensions were studied. The models suggest that the greater the perimeter-to-area ratio, the slower the increase of disease within a field. Assuming that a constant proportion of a region is allotted to a particular crop, the models also indicate that decreasing field size and elongating fields in the cross-wind direction will reduce disease losses.

There are, of course, many other types of aerobiological studies (see, e.g., Edmonds, 1979; Pedgley, 1982; and Isard and Gage, 2001).

Climatic adaptation

Finally, mention should be made of climatic adaptation. Because the time scale involved is of the order of centuries or longer, it is difficult to demonstrate stress-response relationships. Yet the presumption of climatic adaptation seems to be justified in many cases. For example, the shape of the Arctic igloo is optimal for minimizing heat losses. Similarly, small insects often have spherical or cylindrical bodies to reduce heat loss on cold nights. As another example, vegetation has "learned" to survive along the coastline of the Arctic Ocean at a site (the Smoking Hills) where SO₂ concentrations and soil pH values should be lethal; in this case the cliff has been burning naturally for at least several centuries (Havas and Hutchinson, 1983). Some of the species have been successfully transplanted on mine tailings near the Sudbury copper smelter.

Other examples of adaptation include desert plants and animals, which have minimized their water consumption and water losses through physiological mechanisms (Smith, 1978), and bird, insect, and animal migrations, which depend on the regularity of annual climatic cycles. Black people in the tropics have skin pigments that protect them from sunburn and skin cancer, while native people in the Arctic have adjusted diet and body fat to cope successfully with the long northern winters.

On the global scale, the *Gaia* theory of Lovelock (1979) asserts that the biosphere played an essential role in the evolution of the Earth over a geological time-scale. Once established, the primitive vegetation cover was able to control the oxygen and CO₂ concentrations of the atmosphere, the temperature of atmosphere and oceans, and the salinity and pH of oceans.

For a recent discussion of the *Gaia* theory, see a collection of papers in *Climatic Change* (2002), vol. 52, issue no. 4, pp. 383–509. See also the exchange of views between J. Lovelock and T. Volk in *Climatic Change* (2003), vol. 57, pp. 1–7.

Conclusion

Although the bioclimatologist has been studying stress-response relations for more than a century, nature unlocks its secrets slowly. Nevertheless, future prospects for meaningful research are good. The main problem to be overcome is the difficulty that specialists encounter when working with specialists in other fields. For example, medical doctors and climatologists have traditionally not communicated with one another except at the non-specialist level. It is hoped that interdisciplinary educational and research programs will be encouraged in all parts of the world.

BLIZZARD CLIMATOLOGY

The most extreme form of a winter storm is the blizzard, which combines strong winds with falling or blowing snow to cause low visibility, deep snowdrifts, and intense wind chill. This combination of strong winds and blowing snow causes a general cessation of routine societal activities, making the blizzard the most dangerous of winter storms (Schwartz and Schmidlin, 2002).

The National Weather Service (NWS) defines a blizzard as winds over 16 m s^{-1} [35 miles per hour (mph), (30 knots)] and falling or blowing snow reducing visibility to less than 400 m (0.25 miles) lasting for at least 3 hours (Branick, 1997; NSIDC, 1999; NWS, 1999). An additional criterion for temperatures below 20°F (-7°C) was used for many years but was abandoned in the 1970s. Blizzards in Canada have regional-dependent definitions with one definition for the Northwest Territories and Nunavut and another for Alberta, Saskatchewan, and Manitoba (Lawson, 2002). Also, the Meteorological Office in Great Britain has another definition (Wild, 1997).

The term “blizzard” was first used by Henry Ellis along Hudson Bay in 1746 (Black, 1971) although Ellis’s meaning at the time was ambiguous according to Wild (1997). Ludlum (1968) reported that the term was first used in the United States to describe the winter storm of March 1870 in Iowa; however, Wild (1997) reported use in South Dakota newspapers in 1867. By the 1880s the term was in general use according to Wild (1997).

Blizzards require interactions of meteorological processes that are vital for storm development. First, a cyclonic storm or low-pressure system that forms along frontal boundaries is usually the focal point for storm development and cyclogenesis. Important components include the position of the jet stream as the trough aloft often follows the 500 mb level flow. Cold polar air and a source of moisture are also necessary for the snow (Kocin and Uccellini, 1990). Deepening (strengthening) cyclones are another ingredient of a blizzard. The intensity is dependent on strength and positioning of the jet stream relative to the other upper-air disturbances along with the availability of moisture and strength of horizontal temperature gradients. Additionally, the upper-level trough/ridge pattern is important as this gives vorticity, upper-level divergence, and diffuseness with a negatively tilted trough. The upper-level jet streaks or short waves increase divergence and vorticity, which gives the necessary uplift for heavy snow as described by Black, 1971; Dupigny Giroux, 1999; Ellis and Leathers, 1996; Kocin and Uccellini, 1990; Leathers and Harrington, 1999; and Mote et al., 1997 (see references in Schwartz, 2001).

The physical geography of North America allows a favorable environment for blizzards as the Rocky Mountains run north–south, effectively isolating the Great Plains from comparatively warmer Pacific air (Rauber et al., 2002). Flat terrain in central North America provides an “open door” for cold polar and Arctic airmasses from the north, and moisture from the Gulf of Mexico is transported from the south. Some of the source regions for blizzards in North America originate in the Pacific Ocean (Westerly Lows), Alberta (Alberta Clippers), the Texas–Colorado Panhandle (Panhandle Hooks), the Louisiana Delta (Gulf Coast Low), and the Atlantic Ocean off the North Carolina coast (East Coast Low or Nor’easter). These were described by Doeskin and Judson, 1996; Goddard, 1998; Kocin and Uccellini, 1990; and Morgan and Moran, 1997.

There were 438 blizzards identified for the 41 winters from 1959/1960 to 1999/2000 in the conterminous United States. The annual number of blizzards per winter averaged 10.7 and ranged from 1 blizzard in 1980/1981 to 27 blizzards in 1996/1997 (Figure B1) (Schwartz, 2001; Schwartz and Schmidlin, 2002).

The frequency of blizzards by county over the period 1959–2000 is shown in Figure B2. Forty of the 48 states reported a blizzard during the study period. The number of states with blizzards was 26 in the 1960s, 37 in the 1970s, 31 in the 1980s, and 39 in the 1990s. Blizzards were most common in the northern Great Plains where 17 counties in North Dakota and eight counties in South Dakota had more than 60 blizzards during 1959–2000. Traill County, North Dakota, had 74 blizzards in the 41-year period, the most of any county in the conterminous United States. An apparent region described as the United States “blizzard zone” occupied all of North and South Dakota and 34 counties in western Minnesota. Each county in the blizzard zone had 41 or more blizzards in the 41 winters, for an average of one or more blizzards per winter (Schwartz, 2001; Schwartz and Schmidlin, 2002).

Outside of the blizzard zone there were 21–40 blizzards per county during 1959–2000 in the rest of Minnesota, northern and central Iowa, most of Nebraska, northwest Kansas, eastern Colorado, southeast Wyoming, and eastern Idaho. The blizzard frequency decreased to 11–20 per county in the northern and central Rockies, central Great Plains, and the western Midwest. Other areas with 11–20 blizzards during the period were in Erie County (Buffalo), New York; Garrett County, Maryland; all of Maine; and portions of southeastern New England. Hancock and Washington counties in Maine had 18 blizzards, the largest number in the eastern United States. There were 4–10 blizzards per county during 1959–2000 across the remainder of the northeastern United States, the Great Lakes region, the High Plains of Texas and New Mexico, and the Sierra Nevada Mountains (Schwartz, 2001; Schwartz and Schmidlin, 2002).

Monthly frequency of blizzards peaked during January in the blizzard zone and most other parts of the United States. However, blizzards were most frequent during December in the Sierra Nevada; during March in the central High Plains of western Nebraska, eastern Colorado, and Kansas; and during April in Montana. The blizzard frequency in western South Dakota showed a second peak during April, matching the January peak frequency. Early and late season blizzards generally occurred in the upper Plains and mountainous areas (Schwartz, 2001; Schwartz and Schmidlin, 2002).

The mean population was 2 462 949 people affected per blizzard. Additionally, the average total population affected

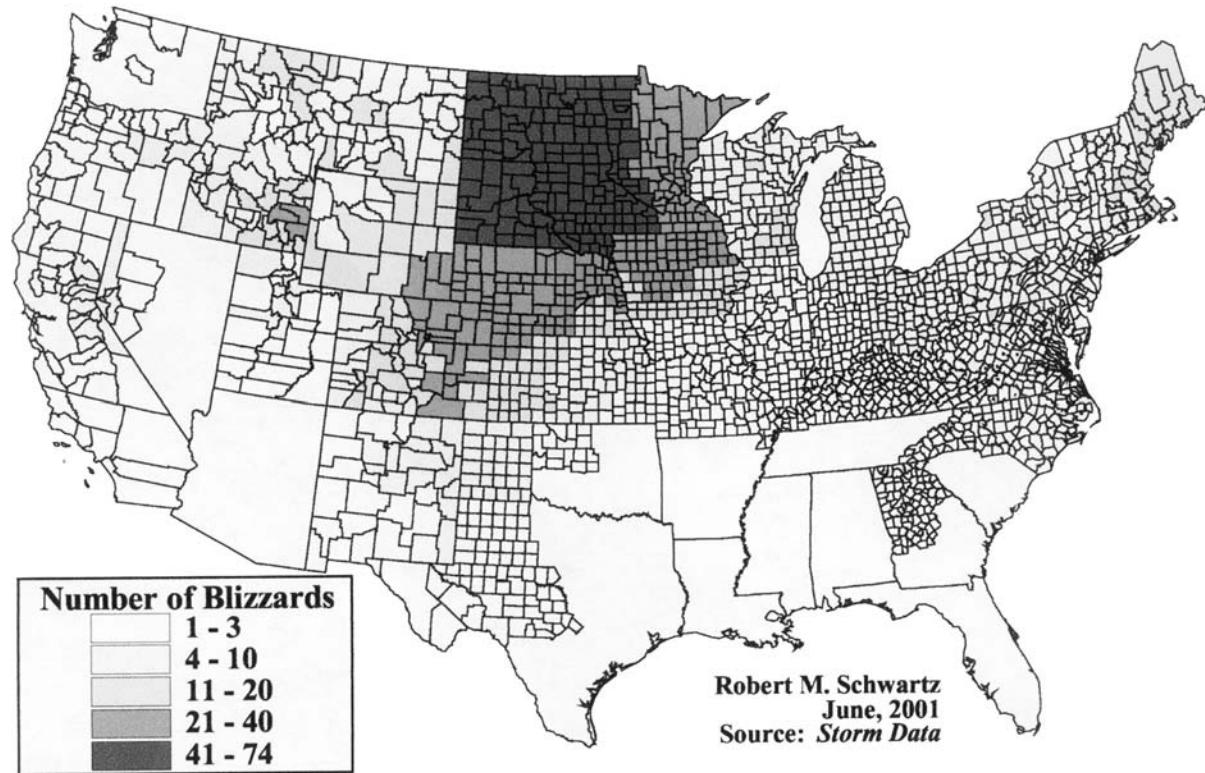

Figure B1 Number of blizzards in the United States from 1959/60 to 1999/2000 (courtesy of the American Meteorological Society).

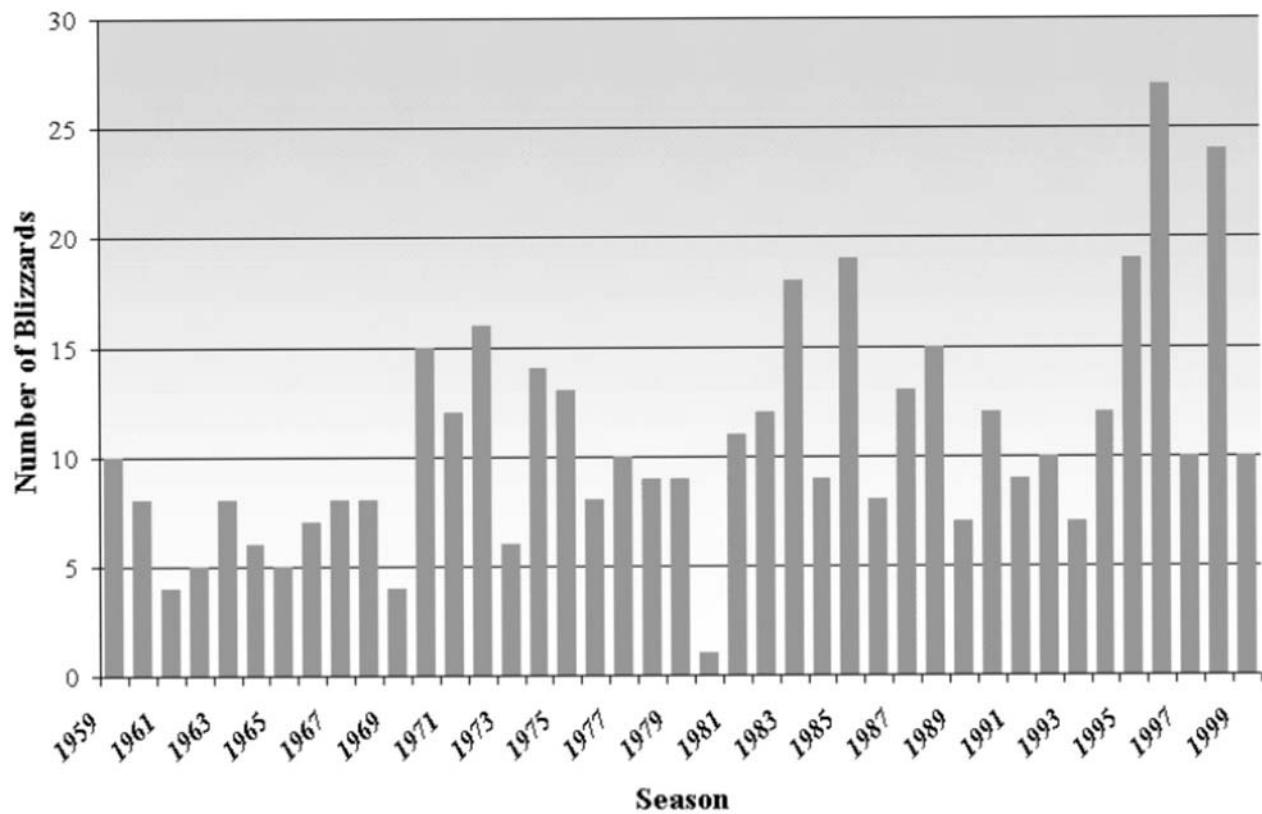

Figure B2 Blizzard frequency in the United States, 1959–2000 (courtesy of the American Meteorological Society).

per winter during the study period was 26 311 505. Population in the continental United States for 1960 through 1990 rose by 68 728 426 persons. In spite of the increased population, the population affected by blizzards did not increase. Although the number of blizzards increased, the affected population did not increase. The likely reason for no linear time trend is that the population decreased by 30 737 in the core blizzard region (Schwartz, 2001).

There were 679 reported fatalities directly associated with blizzards during the 41-year period, which is a mean of 1.55 fatalities per blizzard. Fatalities ranged from zero in several cases to 73 during the Midwest Blizzard of January 1978 (Schwartz, 2001).

During the study 2011 injuries were reported as direct results of blizzards. The mean was 4.59 per event and the minimum number was zero while the maximum was 426, with the Superstorm of March 1993 (Schwartz, 2001).

Total property damage adjusted to 2001 dollars was reported at \$22 600 000 000 or a mean of \$51 593 998 per blizzard. No damage was reported for several blizzards. The greatest property damage was \$4 550 000 000 (unadjusted) or \$12 300 000 000 (adjusted) from the Midwest Blizzard of January 1978 (Schwartz, 2001).

Even though many agricultural areas are affected by blizzards, crop damage was often not reported by *Storm Data*. In unadjusted dollars, \$439 542 000 in crop damage was reported (\$1 080 000 000 adjusted). The mean crop damage per blizzard was \$1 003 520 unadjusted and \$2 466 324 in adjusted dollars. Maximum reported crop damage was \$227 250 000 (unadjusted) and \$613 575 000 (adjusted) from the January 1978 Midwest Blizzard (Schwartz, 2001).

There were 25 disaster declarations associated with blizzards in the study period. The 1960s had no declared blizzard disasters while the 1970s had eight declarations, the 1980s had three, and the 1990s had 14 (Schwartz, 2001).

BLOCKING

Middle-latitude circulation is classically represented by belts of high- and low-pressure systems that are approximately parallel to the equator. Winds associated with these systems also have their major components parallel to the equator and are said to be zonal. Periodically, this zonal flow breaks down and wind components perpendicular to the equator become more important. Such flow is said to be meridional. Meridional flow often results from the blocking action of a persistent anticyclone.

Blocking action is a diminution of the zonal circulation at all levels of the troposphere, with retardation of zonal flow tending to spread westward. The phenomenon may last from 3 days to a month and is often associated with a warm anticyclone in high latitudes and cold cyclonic circulation in lower latitudes. It may result in significant temperature and precipitation anomalies.

Various types of blocking patterns have been recognized. The most common is the omega block, resembling the Greek letter Ω . An example is shown in Figure B1, which provides a sequence of the 1000–500-mb thickness charts that illustrates the change from high-index zonal circulation to meridional circulation to the low-index pattern in which cut-off lows are separated by a deep circulation high – a blocking high. Note that, although pressure cells or ridges are usually cited as the blocking phenomena, cut-off lows can also act as a block to zonal circulations.

The Climate Prediction Center (CPC) utilize a blocking index (Tibaldi and Molteni, 1990) to consider the frequency of “blocked days”. This index, shown as Table B6, has been used to calculate seasonal frequency and location of blocking highs for the northern hemisphere through reanalysis.

John E. Oliver

Table B6 Blocking index used by Climate Prediction Center (after CPC), northern hemisphere

For each longitude the southern 500 hPa geopotential height gradient (GHGS) and the northern 500 hPa geopotential height gradient (GHGN) are computed as follows:

$$\text{GHGS} = \left[\frac{Z(\phi_o) - Z(\phi_s)}{\phi_o - \phi_s} \right]$$

$$\text{GHGN} = \left[\frac{Z(\phi_n) - Z(\phi_o)}{\phi_n - \phi_s} \right]$$

where

$$\phi_n = 80^\circ\text{N} + \delta, \phi_o = 60^\circ\text{N} + \delta, \phi_s = 40^\circ\text{N} + \delta, \delta = -5^\circ, 0^\circ, 5^\circ.$$

A given longitude is said to be blocked at a given time if the following conditions are satisfied for at least one value of δ :

$$(1) \text{GHGS} > 0$$

$$(2) \text{GHGN} < -10 \text{ m/deg latitude.}$$

A 5-day running mean can be applied to the 500 hPa height field prior to calculating both GHGS and GHGN to isolate potential blocking episodes of sufficient duration.

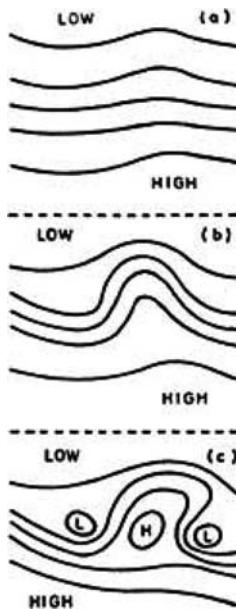

Figure B3 Typical successive 1000–500-mb thickness patterns during the formation of cut-off lows and blocking high. (a) High-index zonal circulation; (b) meridional circulation; (c) blocking high (after McIntosh and Thom, 1973).

BOUNDARY LAYER CLIMATOLOGY

Near the Earth’s surface the wind interacts with an endless variety of ground covers, each of which has distinctive surface properties that condition the air above, imparting to it distinctive characteristics. As the wind moves the air across the edge of a new area of ground, characteristics that were acquired upwind of the edge begin to change in response to new surface properties. The modified air grows in thickness as the distance downwind of the edge, or fetch, increases. The process continues until a boundary layer a few meters thick is established, its climate clearly linked to the nature of the surface boundary (Figure B4).

Boundary layer climatology is the study of the processes that link the surface of the Earth to the boundary layer, as well as the boundary layer response. The study of process is rooted in the field of micrometeorology, from which the theoretical basis is established. The more descriptive aspects of the response, such as wind speed, temperature and humidity profiles, are derived from the traditions of early investigators who studied microclimatology from the viewpoint of the case study (Geiger, 1966). This perspective still exists, but now the emphasis is directed more toward energy exchanges and their attendant processes (Bailey et al., 1997).

The term “boundary layer” was borrowed from the field of fluid mechanics by micrometeorologists who used it in their

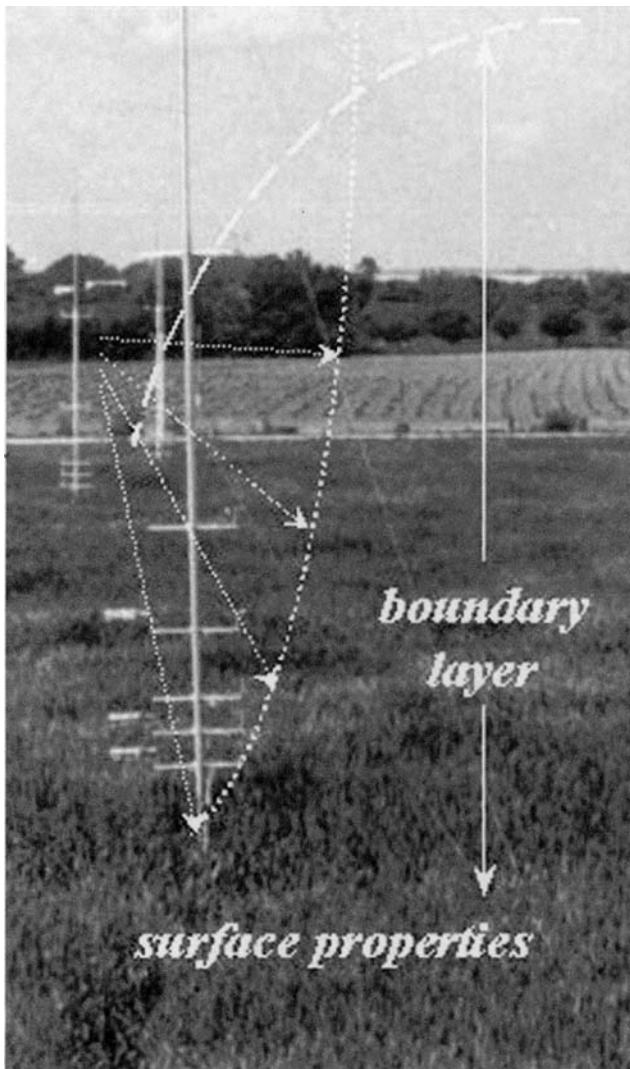

Figure B4 Boundary layer development over an instrumented wheat field, Simcoe, Southern Ontario, Canada. A new boundary layer begins where the wind (dotted arrows) encounters the wheat, after passing over upwind surfaces. The top of the boundary layer (broken line) marks the transition between upwind air and boundary layer air, where the degree of modification increases toward the base of the wind profile (dotted line).

investigations of the lower atmosphere. Some investigators focused attention on experimental studies of boundary layer growth downwind of a change in surface type (Elliott, 1958; Rider et al., 1963; Bradley, 1968). Such studies provided evidence that atmospheric data must be obtained at a considerable distance from the border if the data are to be linked accurately to energy exchanges at the surface. It has since become good practice to collect data at fetches that are at least 100 times the height of measurement above the surface.

Subsequent adoption of the term “boundary layer” in small-scale climatological work occurred gradually, as microclimatologists developed an increasing interest in processes that

shaped the climate near the ground. The emphasis on process has become such that the casual observer may see little that differs from micrometeorology. However, the meteorological focus is clearly on improving the physical theory behind the processes at work. The climatological focus rests on the application of theory to gain a better understanding of how surface properties interact with the boundary layer to create distinctive surface *boundary layer climates* (Oke, 1987).

Energy balance at the boundary

The influence of the surface boundary is established by the way in which the surface responds to the transfer rate per unit area, or flux density, of global radiant energy supply, K_{\downarrow} (Figure B5). Surface reflectivity initially reduces this to K_{\ast} , the net shortwave radiation supply, which in turn is reduced by L_{\ast} , the net longwave radiation loss, thus leaving the net radiative flux density, Q_{\ast} , to force a surface response (Figure B5a). The response to Q_{\ast} occurs in the form of other energy exchanges that are balanced against Q_{\ast} (Figure B5b):

$$Q_{\ast} = Q_H + Q_E + Q_G, \quad (1)$$

where Q_H refers to sensible heat transfer between air and ground, Q_E to latent heat transfer due to surface evaporation or condensation, and Q_G is heat transfer between the surface and the underlying medium, which changes the surface heat storage. The transfers are the result of radiative heating or cooling, which causes the boundary temperature to differ from that of the air above and the ground below, thus invoking Q_H and Q_G . It also establishes humidity differences across which the moisture transfer associated with Q_E takes place. The wind and the roughness property of the surface play an active role in the process, mixing the air as momentum is transferred to the surface.

The example in Figure B5 provides a representative picture of the major energy exchange components for a moist, vegetated boundary, where Q_H , Q_E and Q_G use the net radiation supplied during the day, when Q_{\ast} is positive, then compensate for net radiative loss at night. The energy flow induces atmospheric responses (Figure B5c), the most prominent features of which are the diurnal cycles of temperature, T , wind speed, u , and the persistent rise in atmospheric vapor pressure, e , until such time as the weather changes. Examples from other types of surfaces (Bailey et al., 1997; Geiger, 1966; Sellers, 1965) show considerable variation in the magnitudes and relative contributions of the energy balance components, as well as the need to modify some of the components or to add new terms to the equation. Thus, one finds that the calculation of Q_G in water may require the inclusion of horizontal heat transfer due to currents, that the energy used in melting may replace Q_G for melting ice and snow (Munro, 1990), or that anthropogenic heating may be important in cities (Oke, 1987). The negligibly small amounts of energy involved in photosynthesis are investigated as part of the increasingly important theme of carbon cycling, wherever the requirement of measuring atmospheric carbon dioxide concentrations can be met (Monteith and Unsworth, 1990; Soegaard, 1999).

Although geographic location and ambient weather conditions are recognized as major determinants of the overall magnitude of energy exchange, it appears that characteristics of the surface medium control the distribution of energy among the various components in equation (1). Water is well known for its relatively high amounts of heat storage and small diurnal temperature

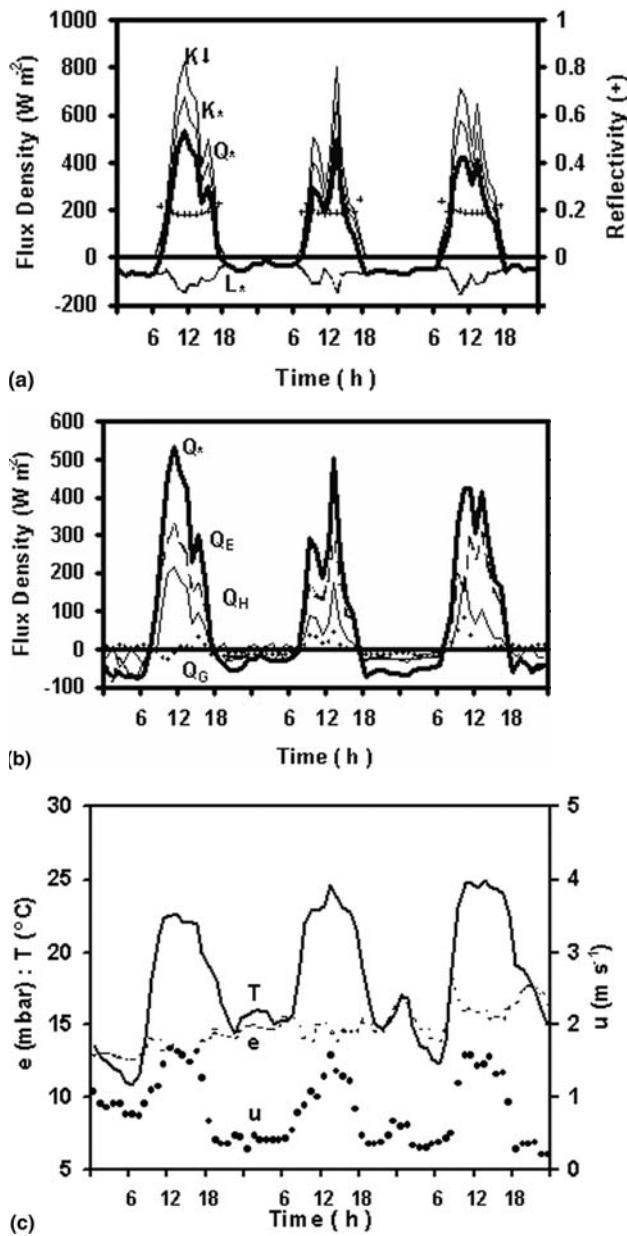

Figure B5 Hourly variations of (a) radiation terms, (b) energy balance components and (c) atmospheric properties for sawgrass marsh during the dry season, Everglades National Park, Florida (16–18 February 1999). Data source: author. (See Appendix for explanation of symbols and units.)

ranges in comparison with land. The proportion of net radiation used in evaporation over land tends to decrease as the amount of moisture in the soil decreases. Net radiation itself tends to be small for snow in comparison with its value for vegetation-covered or bare ground in similar locations. Such knowledge has been obtained by adapting micrometeorological theory to flux estimation, an exercise that often provides insights into the explicit role that surface properties play in energy transfer between the surface and the boundary layer.

Flow of energy at the boundary

Radiative exchange

The role of surface properties in determining net radiation at the boundary may be appreciated by separating Q_* into its shortwave and longwave radiation components in such a manner as to include the shortwave reflection coefficient, α , and the surface emissivity, ε_s :

$$Q_* = K_{\downarrow}(1 - \alpha) + \varepsilon_s(L_{\downarrow} - \sigma T_s^4), \quad (2)$$

in which K_{\downarrow} is incoming shortwave (global) radiation from the sun, L_{\downarrow} is incoming longwave radiation from the atmosphere, and T_s is the absolute temperature of the boundary. Part of the expression, σT_s^4 , is the longwave radiation leaving the surface, where σ is the Stefan–Boltzmann constant. Because σT_s^4 is almost always greater than L_{\downarrow} , net longwave radiation exchange amounts to a perpetual energy loss, which ensures that Q_* is generally less than net shortwave radiation, $K_{\downarrow}(1 - \alpha)$, and is therefore negative during the night (Figure B5a).

The respective values of α and ε_s control the shortwave and longwave radiation exchanges. Their values must be derived experimentally (Monteith and Szeicz, 1961; Buettner and Kern, 1965), as there is no theoretical basis on which to make estimates. Tabulations of experimental results from various sources (Monteith and Unsworth, 1990; Oke, 1987) show little variation in ε_s , its value being close to 0.98 for most surfaces. On the other hand, α varies over a wide range, from less than 0.1 for water to nearly 0.9 in the case of freshly fallen snow. The value for most vegetated surfaces is close to 0.2, slightly less for forests, somewhat greater for bare soil and ice. Furthermore, α is known to increase rapidly with decreasing solar elevation over water (Nunez et al., 1972), a feature that is repeated to a lesser degree over land (Arnfield, 1975). Seasonal variation may also be important: the reflectivity of sawgrass during the dry season (Figure B5a), typical as it is of vegetated surfaces, is likely to be more characteristic of a water surface during the wet season.

Given reliable values of K_{\downarrow} , L_{\downarrow} , α , and ε_s , equation (2) might be used to calculate Q_* if it were possible to measure T_s . However, the measurement of surface temperature is difficult, except in the case of water, where thermometers submerged slightly below the surface have been shown to closely estimate T_s (Davies et al., 1971), or melting snow and ice, where T_s is the melting point temperature (Munro, 1990; Oerlemans, 2000). Since the invention of a reliable net radiometer, however, it has been possible to measure Q_* directly (Funk, 1959).

Heat storage in the boundary

Part of the difficulty in obtaining surface temperature arises from the fact that the surface boundary, though active as the principal site of energy exchange (Oke, 1987), is not a physical entity in itself. It is simply the point where the ground and the atmosphere meet. Moreover, the position of such a point is difficult to define, particularly over tall vegetation where individual leaves become the main sites of energy exchange activity, such that the soil surface no longer forms an appropriate zero reference level. In such cases the zero plane, d , is effectively displaced upward, so that Q_G now applies to the plant mass and intervening air space, as well as the soil. Following a customary rule of thumb (Oke, 1987), one may estimate $d \approx 2/3h$, where h is the vegetation height. This does not amount to much plant mass and air space heat storage for short vegetation covers, such as wheat and sawgrass. For tall, dense vegetation,

such as is found in forested wetland, plant and air space heat storage may constitute $1/3 Q_G$ (Munro et al., 2000).

Although surface heating effects quickly diminish with increasing soil depth (Figure B6), they form an interesting topic for study (Monteith and Unsworth, 1990). Also, the diffusion of heat through soil and other components of the surface may be viewed as one of the necessary steps in the evaluation of $Q_* - Q_G$, the amount of energy available to balance Q_H and Q_E .

Heat transfer in soil is controlled by the thermal conductivity, k_s , the thermal diffusivity, κ_s , and the volumetric heat capacity, C_s , which are surface properties that apply to layers beneath the surface:

$$Q_G = -k_s \frac{\partial T'}{\partial z'}, \quad (3a)$$

$$\frac{\partial Q_G}{\partial z'} = -C_s \kappa_s \frac{\partial^2 T'}{\partial z'^2}, \quad (3b)$$

$$\Delta Q_G \approx -C_s \frac{\Delta T'}{\Delta t} \Delta z', \quad (3c)$$

where T' refers to soil temperature, $\Delta z'$ is the thickness of a particular layer at some depth, z' , and t refers to time. It is clear from equation (3b) that Q_G undergoes substantial variation with depth; in other words a flux divergence, which accounts for the rapid reduction in temperature change with time as depth increases (Figure B6). The latter is incorporated into equation (3c), an approximation which constitutes a practical procedure for estimating heat transfer if a sufficient number of $\Delta z'$ layers is summed to calculate Q_G .

Although k_s , κ_s , and C_s are properties of the medium, soil is a mixture of solid, air, and water in which properties vary with depth and soil moisture conditions. Therefore, it has become

standard procedure to follow the practice of Fuchs and Tanner (1968) in which equation (3a) is replaced by soil heat flux plates buried just below the surface, usually at a depth of 50 mm, and the remaining portion is obtained by employing equation (3c), inserting temperature measurements taken near the surface. Such an approach does not work in semitransparent media such as ice, snow, and water where shortwave radiative transfer penetrates the surface to act in conjunction with the conductive process (Schwerdtfeger and Weller, 1967). However, C_s is easily specified in such media, so equation (3c) can be applied to temperature profile data to obtain reasonably good results, particularly for water (Dutton and Bryson, 1962). Heat storage in vegetation can be estimated by means of suitable adaptations of equation (3c) (Monteith and Unsworth, 1990).

It is rare that Q_G amounts to more than 10% of net radiation for most surfaces, thus minimizing the significance of estimation errors. The notable exception is water, where the proportion may be substantially greater, depending on the season. This is due to a number of factors, notably its transparency to solar radiation and the large values that can be assigned to C_s and κ_s . The latter may be combined with density, ρ_s , to define the conductive capacity, or thermal admittance (Oke, 1987; Priestley, 1959): $\rho_s C_s \kappa_s^{1/2}$. Thermal admittance is generally greater for water than for land surfaces due to large C_s and mixing by wave action. Therefore, water boundaries are generally more effective than land boundaries in moving heat to and from storage.

Flow of energy through the boundary layer

Energy exchange and turbulence

Although boundary layer temperatures vary considerably over time (Figure B6), flux divergence due to heat storage is negligible

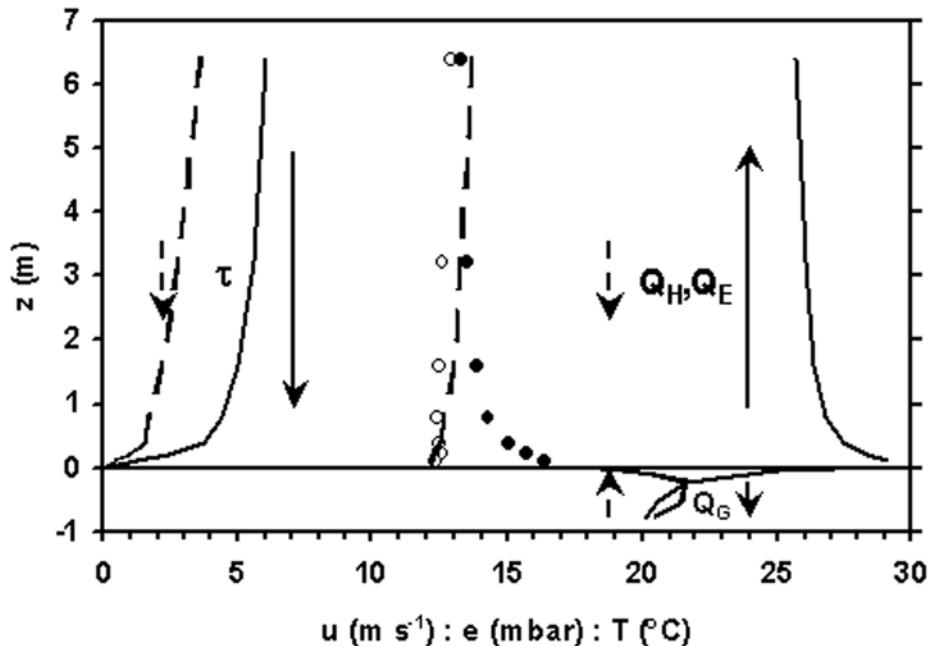

Figure B6 Profiles of wind speed (lines), vapor pressure (circles), air and soil temperature (lines) for late night (0235) and afternoon (1435), O'Neil, Nebraska (19 August 1953), where solid lines, circles and arrows denote afternoon profiles and flux directions. Data source: Great Plains Turbulence Field Program (Lettau and Davidson, 1957).

because the heat capacity of air is extremely small. Divergence due to horizontal gradients in u , T , and vapor pressure, e , poses a potentially greater problem, hence the interest in keeping measurement height, z , small in relation to fetch. The assumption of negligible flux divergence with height is crucial in developing procedures for estimating transfers from atmospheric data.

The development of transfer procedures lies at the heart of the rapidly evolving field of micrometeorology (Monteith and Unsworth, 1990; Priestley, 1959; Thom, 1975). A convenient starting point is to outline the convective transfer equations for Q_H , Q_E , and momentum, τ :

$$\tau = \rho K_M \frac{\partial u}{\partial z}, \quad (4a)$$

$$Q_H = -\rho c_p K_H \frac{\partial T}{\partial z}, \quad (4b)$$

$$Q_E = -\frac{\rho L_v \epsilon}{p} K_V \frac{\partial e}{\partial z}, \quad (4c)$$

in which one finds ρ , the air density, c_p , the specific heat of air at constant pressure, L_v , the latent heat of vaporization, ϵ , the ratio of the weight of water vapor to dry air, and p , the air pressure. The quantities, K_M , K_H , and K_V are referred to as eddy diffusivities for momentum, heat, and water vapor, respectively, by analogy to the molecular diffusivities for conduction in solids. Although the conduction process is at work

in air, its contribution to the task of transporting heat within the boundary layer is negligible in comparison with that of convection.

The use of the term "eddy" recognizes that convective transfer is a turbulent process. The nature of the turbulence may be appreciated by noting that air, being a fluid, is subject to mixing, and that the increase of wind speed with height imparts a circular motion to the flow (Figure B7a). The motion is sensed as an almost random series of upward and downward velocities, w' , or eddies, which decrease in size but increase in frequency, as momentum passes down the wind profile toward the ground. The effect of the eddies is to cause small fluctuations, u' , T' , and e' , from mean values of u , T , and e at any given height above the ground whenever the properties of air at adjacent levels are different, as is normally the case (Figure B6).

Schematically (Figure B7b), the pattern of u' or w' is similar in shape and sign to that of T' and e' at night. During the day the similarity in shape for T' and e' remains, but the sign is reversed, because temperature and humidity now decrease with height (Figure B6). Given sufficiently precise measurements it is thus possible to define an eddy correlation procedure for flux estimation:

$$\tau = -\rho \overline{w' u'}, \quad (5a)$$

$$Q_H = \rho c_p \overline{w' T'}, \quad (5b)$$

$$Q_E = \frac{\rho L_v \epsilon}{p} \overline{w' e'}, \quad (5c)$$

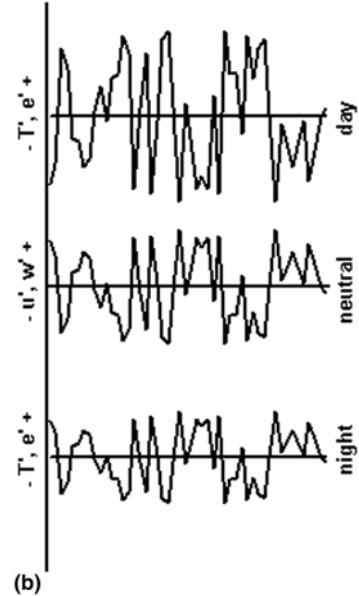

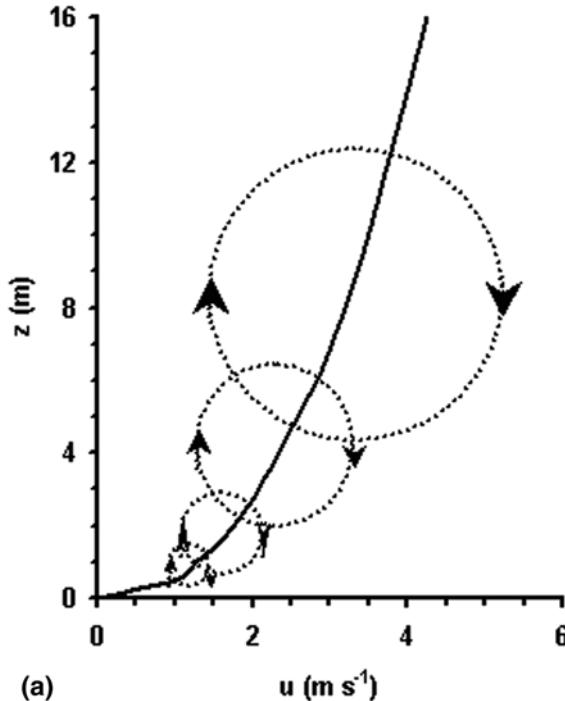

Figure B7 (a) Wind profile at Kerang, Victoria, Australia (17 February 1962), with representation of circular nature of eddy motion and scale in relation to height; (b) schematic depiction of variations from mean values (horizontal lines) due to turbulence, where velocity fluctuations expand beyond the neutral range during the day but contract at night, in accordance with T' and e' . Data source: Webb (1970).

where the overbars denote an average taken over a period of time. Since the time of successful field trials in Australia (Dyer, 1961), the method has been used in a variety of situations (Wesley et al., 1970; Yap and Oke, 1974; McKay and Thurtell, 1978). The great care and expense involved in the methodology once meant that the procedure was beyond the reach of most investigators. Recent developments in instrumentation have, however, given the procedure a much wider range of application (Campbell and Unsworth, 1979; Munro, 1989).

Eddy fluctuations are far more intensive during the day than they are at night (Figure B7b). The more intensive activity during the day is due to the increased amount of energy available at the surface, but only a part derives from the increase in wind speed. The remainder is obtained from the temperature gradient and, to a much lesser extent, the humidity gradient. Warm temperatures at the ground during the day lead to a strong lapse of temperature with height, causing the air to be relatively buoyant and therefore unstable. At night, cold temperatures near the ground invert the profile, resulting in relatively heavy, stable air. Consequently, instability enhances turbulence during the day but suppresses it at night, situations that can be visualized by rendering the circles in Figure B7a as a set of ellipses that have their long axes oriented vertically during unstable conditions; horizontally when the atmosphere is stable (Figure B8). The circular portrayal of eddy motion is appropriate for neutral conditions, when the temperature gradient is equivalent to that which would be expected from adiabatic cooling, a gradient that is virtually zero over small height intervals.

Stability effects are of minor concern in eddy correlation work, but they become important in understanding how fluxes are related to profiles. Therefore it is useful to obtain a numerical

measure of stability such as the Richardson number, R_i , or the z/L stability parameter (Thom, 1975):

$$R_i = \frac{g}{T_a} \frac{\Delta T / \Delta z}{(\Delta u / \Delta z)^2}, \quad (6a)$$

$$\frac{z}{L} = \frac{g}{T_a} \frac{k z Q_H}{\rho c_p u_*^3}, \quad (6b)$$

where g denotes the gravitational acceleration, k is von Kármán's constant, and T_a is the absolute temperature of the air. The friction velocity, u_* , is defined by setting $u_* = (\tau/\rho)^{1/2}$. L , the Obukhov length scale, defines the height of the sub-layer of dynamic turbulence (Obukhov, 1971).

Equation (6) is negative in unstable conditions but positive in stable conditions, with zero signifying neutrality. Although equation (6a) is preferred for its simplicity, in that the gradients can be obtained from measurements at two elevations above the ground, it assumes that eddy diffusivities for heat and momentum are similar. The assumption is not required in equation (6b), which has the advantage of explicitly showing that stability effects increase with height above the boundary.

Calculation of fluxes from profiles

The calculation of fluxes from profiles requires the integration of equation (4) between any two measurement levels near the surface, in order that differences may be substituted for the gradients. The requirement is not simple because, unlike molecular diffusivities, the eddy diffusivities are properties of the turbulence. Therefore, they change according to height, wind speed, and stability. Taking the example of K_M , micrometeorological theory suggests a model for eddy diffusivity:

$$K_M = \frac{ku_* z}{\phi_M}, \quad (7)$$

where the stability correction factor, $\phi_M = f(z/L)$, is one in neutral conditions.

Taking $\tau = \rho u_*^2$ and substituting equation (7) into equation (4a) leads to a relationship that may be integrated across any height interval, $\Delta z = z_2 - z_1$, to give

$$\Delta u = \frac{u_*}{k} \left[\ln \left(\frac{z_2}{z_1} \right) + \Delta \psi_M \right], \quad (8)$$

in which z_1 and z_2 are the respective lower and upper limits of the height interval in question, and ψ_M is the integrated form of ϕ_M . For neutral conditions, $\Delta \psi_M = 0$ and equation (8) becomes the well-known logarithmic wind profile, where the slope of the profile is equal to u_*/k (Figure B8). The purpose of introducing $\Delta \psi_M$ into the equation is to correct for curvature due to stability effects (Figure B8).

The profiles may also include a correction for the zero-plane displacement, d . Failure to include the correction over any vegetated surface other than short grass introduces curvature to the logarithmic wind profile. Because height is plotted logarithmically, zero wind speed is found at a height, z_0 , the roughness length. It tends to be an order of magnitude smaller than the vegetation height, and has often been regarded as an artifact of the analysis, but there is good reason to treat it as a physical property of the surface. Lettau (1969) showed how an

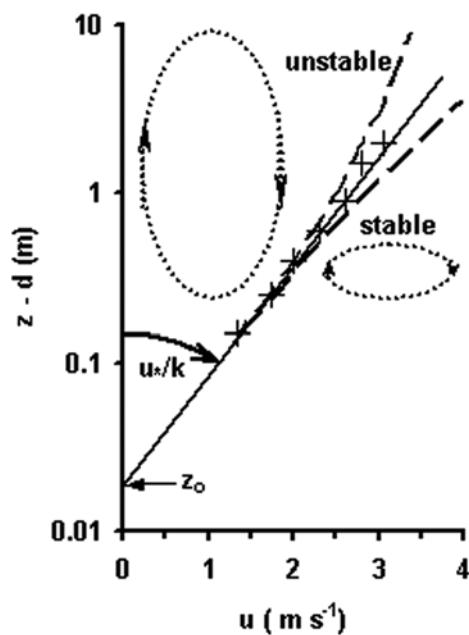

Figure B8 Logarithmic wind profile plot for Davis, California (9 May 1967), showing possible curvatures due to stability effects. Note the roughness length, z_0 , and the height correction for zero-plane displacement, d . Data source: Morgan et al. (1971).

independent z_0 calculation can be made from careful measurements of surface dimensions, a technique which works especially well over non-vegetated surfaces (Munro, 1989; Raupach, 1992; Smeets et al., 1999).

It is possible to rearrange equation (8) to estimate u_* and, therefore, τ by means of an aerodynamic approach that may be extended to Q_H and Q_E :

$$\tau = \frac{\rho k^2 (\Delta u)^2}{[\ln(z_2/z_1) + \Delta \psi_M]^2}, \quad (9a)$$

$$Q_H = -\frac{\rho c_p \Delta u \Delta T}{[\ln(z_2/z_1) + \Delta \psi_M]^2}, \quad (9b)$$

$$Q_E = -\frac{\rho L_v \epsilon k^2 \Delta u \Delta e}{p [\ln(z_2/z_1) + \Delta \psi_M]^2}, \quad (9c)$$

where all differences correspond to Δz . The expression for Q_E was first proposed by Thornthwaite and Holzman (1939), without the inclusion of ψ_M , and subsequently received much attention in evaporation studies. However, the inclusion of ψ_M in the denominator of each expression requires the assumption of similar eddy diffusivities for momentum, heat, and water vapor.

The similarity assumption was treated with suspicion by micrometeorologists, but experimental evidence remained vague until the publication of a stability analysis undertaken by Swinbank and Dyer (1967). They demonstrated that the functional form for K_M in unstable conditions is different from that for K_H and K_V , which were found to be equivalent quantities. Subsequent work (Dyer and Hicks, 1970; Webb, 1970) addressed the problem of integrating the stability corrections with height and demonstrated the numerical equivalence of R_i and z/L when the atmosphere is unstable.

In principle, the structure of equation (9) can be improved by means of suitable modifications to the denominators of equations (9b) and (9c). In practice this leads to a cumbersome structure that places great demands on measurement accuracy. Furthermore, investigators have produced a variety of different stability correction functions (Andreas, 2002; Dyer, 1974).

The finding that $K_H = K_V$ means that, regardless of the form that stability modifications might take, the denominators of equations (9b) and (9c) are equal. Thus, it becomes a simple matter to extract the Bowen ratio, $\beta = Q_H/Q_E$ from temperature and humidity data:

$$\beta = \gamma \frac{\Delta T}{\Delta e}, \quad (10a)$$

$$Q_E = \frac{Q_* - Q_G}{1 + \beta}, \quad (10b)$$

where equation (10b) is obtained by rearrangement of equation (1) and $\gamma = c_p p / L_v \epsilon$ defines the psychrometric constant. This is the Bowen ratio, or energy balance approach, in which Q_H can be obtained as a residual in the surface energy balance, or as a different rearrangement of equation (1).

The energy balance approach has become very popular in boundary layer work because it reduces the problem of obtaining fluxes from profiles to the task of obtaining good measurements of ΔT and Δe . The task can be difficult where temperature and humidity differences are small, as for forest boundaries. Thus, effort has been directed toward the construction of reliable

measurement systems for ΔT and Δe (Black and McNaughton, 1971; McNeil and Shuttleworth, 1975).

The Bowen ratio itself is a quantity of considerable climatological significance because it characterizes the surface partitioning of energy exchange with the boundary layer (Oke, 1987). As surface conditions become colder, β increases to values approaching 10, a value which is characteristic of dry desert surfaces. Also, β sensitivity to surface moisture content is well known, the value changing from a low of approximately 0.1 over water to a range of 0.5 to 4.0 over vegetated surfaces, where the higher values apply to drier boundary conditions.

Incorporating the boundary into boundary layer work

The incorporation of the boundary in flux calculation procedures is essentially a matter of substituting the surface for the lower measurement level in equation (9). The substitution is desirable on both operational and conceptual grounds. Operationally, it relaxes the stringent measurement requirements for profile measurements, thus allowing the use of standard measurements of wind speed, temperature, and humidity, such as might be obtained from a climatological station. Conceptually, it poses the stimulating problem of characterizing the boundary in such a way that it plays a useful role in the flux estimation scheme.

In attempting to characterize the boundary, one may consider the problem of defining surface temperature, T_s , and humidity, e_s , over a vegetative surface. One solution, proposed by Monteith (1963), is to plot temperature and humidity against windspeed, defining T_s and e_s at $u = 0$ (Figure B9). The approach was criticized by Tanner and Fuchs (1968) on the grounds of uncertainty regarding source levels for heat and

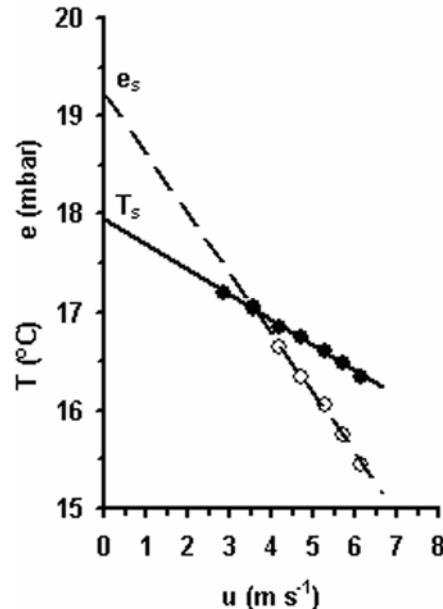

Figure B9 Plots of temperature and vapor pressure against wind speed to estimate surface values, Davis, California (9 May 1967). Data source: Morgan et al. (1971).

water vapor. Thom (1975) has since shown that reference levels for heat and water vapor differ from that for momentum, so z_0 is not the appropriate roughness length for temperature and humidity profiles. In fact, temperature and humidity roughness lengths may exceed z_0 by a factor of two for forest (Mölder et al., 1999), but are likely to be two to three orders of magnitude smaller than z_0 for ice and snow (Andreas, 2002).

Modifying the aerodynamic procedure to include the boundary in calculations of Q_H and Q_E causes equation (9) to take the form of a bulk transfer equation:

$$Q_H = -\frac{\rho c_p k^2 u (T - T_s)}{[\ln(z/z_0) + \psi_M] [\ln(z/z_H) + \psi_H]}, \quad (11a)$$

$$Q_E = -\frac{\rho c_p k^2 u (e - e_s)}{[\ln(z/z_0) + \psi_M] [\ln(z/z_V) + \psi_V]}, \quad (11b)$$

where the subscripts, H and V , apply to the appropriate roughness lengths and stability corrections for sensible heat and water vapor. Nevertheless, it is assumed that $\psi_H = \psi_V$ and $z_H = z_V$, pending strong experimental evidence to the contrary.

The difficulty in defining T_s and e_s severely restricts the use of a bulk transfer procedure over land, though there is a long history of its use over water (Deacon and Webb, 1962). The method is especially attractive for the special case of melting ice and snow on glaciers, where one may assume $T_s = 0^\circ\text{C}$ and $e_s = 6.11 \text{ mb}$ (Munro, 1990; Oerlemans, 2000). In such cases, however, turbulence is generated by katabatic winds, such that alternative flux estimation approaches are required (Oerlemans and Grisogono, 2002). Also, regardless of surface cover type, $z_{H,V}$ is proportional to z_0 , the proportion changing with the degree of turbulence (Andreas, 2002; Garratt and Hicks, 1973).

A more generalized approach to the problem of incorporating the boundary into flux computations arose from the initial work of Penman (1948) which, following subsequent work (Monteith, 1981), led to the development of the Penman–Monteith (PM) model for surface evaporation:

$$Q_E = \frac{S(Q_* - Q_G) + \rho c_p D_a / r_a}{S + \gamma(1 + r_c / r_a)}. \quad (12)$$

The air temperature may be used to determine S , the slope of the relationship between saturation vapor pressure, e' , and temperature. The quantities r_a and r_c are respectively known as aerodynamic and surface (or canopy) resistances to water vapor movement from the surface to the boundary layer, while $D_a = e' - e$ is the saturation deficit of the air.

Monteith (1981) explains how the PM model combines diabatic, $S(Q_* - Q_G)$, and adiabatic, $\rho c_p D_a / r_a$, energy contributions to evaporation. The relative importance of each contributor depends upon the extent to which surface roughness results in coupling between the surface and the boundary layer (Jarvis and McNaughton, 1986). The adiabatic contribution is dominant where coupling is strong, as it is for tall, rough forest, such that Q_E may be modeled solely according to D_a and the resistances (Infante et al., 1997). The diabatic contribution prevails over smoother, weakly coupled short vegetation, such that D_a and the resistances may be expressed as a coefficient (Priestley and Taylor, 1972), or ignored altogether, leaving the equilibrium form of equation (12) which may be useful for cropped surfaces (Davies and Allen, 1973). The full PM model applies to most surfaces, however, because the degree of coupling is typically between these extremes.

The PM aerodynamic resistance is a function of turbulence, and may be obtained from the logarithmic wind profile, incorporating the correction for d :

$$r_a = \frac{1}{k^2 u} \left[\ln \left(\frac{z - d}{z_0} \right) \right]^2. \quad (13)$$

Some error may be introduced in ignoring a stability correction, and in using z_0 rather than z_H , but the error is likely to be small because r_a appears in both the numerator and the denominator of equation (12). Thus, if Q_* and Q_G are known, estimates of Q_E follow from measurements of T , D_a , and u above the ground provided the value of r_c can be defined.

Over water, r_c can be taken as zero, an assumption that has also been shown to work well for wet vegetation canopies (Stewart, 1977). Otherwise, it has been demonstrated that r_c is a physiologically sensitive parameter because r_c values obtained by rearranging equation (12), knowing the value of Q_E , closely follow patterns of stomatal resistance, r_s , obtained from direct measurements on the leaves of plants (Figure B10). The r_s to r_c ratio in Figure B10 reflects the leaf area index of the plant cover (Tan and Black, 1976), which suggests that r_c may be obtained from the rule of parallel resistances:

$$\frac{1}{r_c} = \sum_{i=1}^n \frac{\text{LAI}_i}{r_{si}}, \quad (14)$$

in which i is any of n leaves or leaf layers. Conceptually, this compresses a multi-level plant cover into one big leaf, treating r_c to represent a full canopy which covers the whole surface.

Depending upon the plant root structure, r_c is sensitive to the availability of soil moisture (Figure B11), the sensitivity being strong for field crops, with their temporary root systems, but much weaker for the well-established root system of a forest (Szeicz and Long, 1969). Given the extensive work done with the PM model, it is now possible to generalize about r_c where soil water supply is not severely restrictive: ranges of 5 to 50 s m^{-1} for crops, 5 to 125 s m^{-1} for forests, where the low end of each

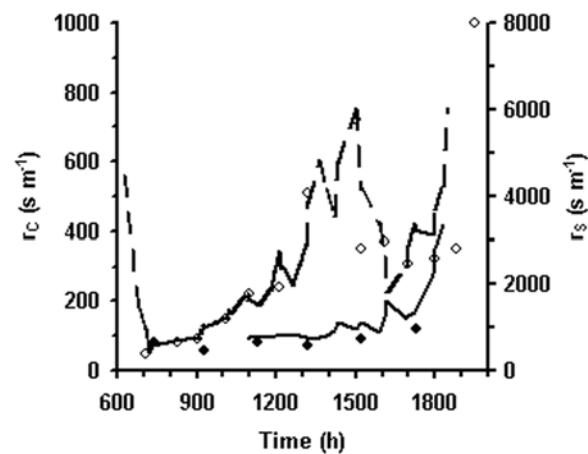

Figure B10 Hourly variations of surface (lines) and stomatal (circles) resistances for a Douglas fir forest, Courtenay, British Columbia, Canada, where solid lines and circles refer to relatively moist soil, broken line and open circles to drier soil (after Tan and Black, 1976).

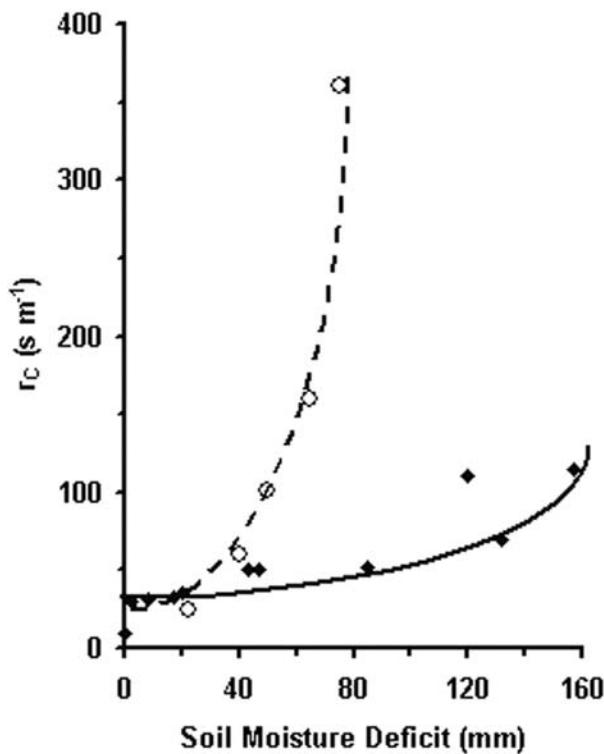

Figure B11 Surface resistance responses of grass–clover vegetation and forest vegetation (solid line and circles) to soil moisture deficits, where the deficit refers to the depth of water required to raise soil moisture to field capacity (from Szeicz and Long, 1969).

range applies to wet canopies (Oke, 1987). Thus, there is now sufficient experimental evidence to develop a climatology of r_c (Thom and Oliver, 1977), and to incorporate vegetation layers into simulation models of basin hydrology (Sellers and Lockwood, 1981).

Once the PM model had been well established for the full big leaf canopy, attention turned to evaporation from sparse canopies (Figure B12), where the ground appears between rows or patches of ground cover (Shuttleworth and Wallace, 1985). The approach taken here is to apply the PM model separately to each surface category, such that the ground itself has a surface resistance, r_g (Figure B12b). Thus Q_E is composed of canopy evaporation, Q_{Ec} , and ground evaporation, Q_{Eg} , each of which is obtained from the PM model (Wallace, 1995):

$$Q_E = f_c Q_{Ec} + f_g Q_{Eg}, \quad (15)$$

where the proportional contributions of each evaporation source, f_c and f_g , are functions of the aerodynamic and bulk resistances of canopy and ground.

Hence, the PM model will continue to be a powerful, adaptable operational tool and a conceptual stimulus in a number of environmental fields which involve boundary layer climatology. Operationally, it minimizes the need for sophisticated measurement procedures, such that basic weather station data are useful. Conceptually, it stimulates interest in the structure of the surface boundary, comprised as it may be of full or sparse vegetation cover, thus allowing scholars to consider greater variability in the surface properties which shape the many climates of the boundary layer.

Appendix: Symbols and units

- C_s = surface volumetric heat capacity ($\text{J m}^{-3} \text{C}^{-1}$)
 D_a = vapor pressure deficit of air (mb, Pa)
 $K_{M,H,V}$ = eddy diffusivities for momentum, heat, water vapor ($\text{m}^2 \text{s}^{-1}$)
 K_{\downarrow} = incoming shortwave, or global, radiation (W m^{-2})
 L = Obukhov length (m)
 L_v = latent heat of vaporization (J kg^{-1})
 L_{\downarrow} = incoming longwave radiation (W m^{-2})
 LAI = leaf area index
 Q_E = latent heat transfer (W m^{-2})
 Q_{Ec} = leaf canopy latent heat transfer (W m^{-2})
 Q_{Eg} = bare ground latent heat transfer (W m^{-2})
 Q_G = heat transfer to the surface medium (W m^{-2})
 Q_H = sensible heat transfer (W m^{-2})
 Q_* = net radiative transfer (W m^{-2})
 Ri = Richardson number
 S = slope of the saturation vapor pressure curve (Pa C^{-1})
 T = air temperature (C, K)
 T_a = absolute temperature of the air (K)
 T' = soil or water temperature
 T_s = surface temperature (C, K)
 c_p = specific heat of air at constant pressure ($\text{J kg}^{-1} \text{C}^{-1}$)
 d = zero-plane displacement (m)
 e = vapor pressure of air (mb, Pa)
 e' = vapor pressure of air (mb, Pa)
 e_s = surface vapor pressure (mb, Pa)
 $f_{c,g}$ = proportion of evaporation due to canopy, ground
 g = acceleration due to gravity (m s^{-2})
 k = von Kármán's constant (≈ 0.4)
 k_s = surface thermal conductivity ($\text{W m}^{-1} \text{C}^{-1}$)
 p = air pressure (mb, Pa)
 r_a = aerodynamic resistance (s m^{-1})
 r_c = surface, or canopy resistance (s m^{-1})
 r_g = ground resistance (s m^{-1})
 r_s = stomatal resistance (s m^{-1})
 t = time (s)
 u = wind speed (m s^{-1})
 u_* = friction velocity (m s^{-1})
 z = height above ground (m)
 z' = depth in soil (m)
 $z_{0,H,V}$ = roughness length for wind speed, temperature, humidity (m)
 α = reflectivity for shortwave radiation
 β = Bowen ratio
 γ = psychometric constant ($0.66 \text{ mb C}^{-1}, 66 \text{ Pa C}^{-1}$)
 ε = ratio of molecular weight of water vapor to dry air (0.622)
 ε_s = surface emissivity
 κ_s = thermal diffusivity of soil or water ($\text{m}^2 \text{s}^{-1}$)
 ϕ_M = gradient stability correction for momentum
 σ = Stefan-Boltzmann constant ($5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$)
 τ = momentum transfer (N m^{-2})
 ρ = air density (kg m^{-3})
 ρ' = ice, soil or water density (kg m^{-3})
 $\psi_{M,H,V}$ = integrated stability correction for momentum, heat, water vapor

BOWEN RATIO

Net radiation at a surface – an expression of incoming less outgoing radiation – must be divided between energy that goes to sensible heat flow and to latent heat flow. The Bowen ratio (β) is used to express the partitioning of net radiation at a surface. Thus:

$$\beta = \frac{\text{Sensible heat loss to atmosphere } (C)}{\text{Latent heat loss to atmosphere } (LE)}.$$

Theoretically, in the absence of an atmosphere, β can vary from infinity (for a dry surface with no evaporation) to zero (for a wet surface with no sensible heat loss). Practically, measurements of surfaces with an atmosphere do not experience such extremes. Typical values are $\beta = 0.1$ for world oceans and $\beta = 5.8$ for desert–semidesert areas.

The derivation of values needed to determine the Bowen ratio has been outlined by Lockwood (1979), who notes that both the sensible and latent heat fluxes (C and LE , respectively) can be expressed in almost symmetrical form:

$$C = -\rho C_p K_H \frac{\partial T}{\partial z}$$

$$LE = -\rho \frac{C_p}{\gamma} K_V \frac{\partial e}{\partial z}$$

where ρ is the density of moist air; C_p is the specific heat of air at constant pressure; K_V and K_H are the eddy diffusivities for water vapor and heat, respectively, e/z and T/z are the vertical gradients of vapor pressure and temperature, respectively; and L is the latent heat of vaporization of liquid water.

The thermodynamic value of the psychometric constant, γ , is given by:

$$\gamma = \frac{C_p \rho}{0.621L}$$

If the following typical values are introduced into the above equation, γ becomes 0.66: $C_p = 0.240 \text{ cal}^{\circ}\text{C}^{-1} \text{ g}^{-1}$; $L = 585 \text{ cal g}^{-1}$; and $\rho = 1000 \text{ mb}$ (ρ = pressure).

Therefore, from the above equations it is possible to write for the Bowen ratio:

$$\beta = \gamma \frac{\partial T K_H}{\partial e K_V}.$$

Often the convenient simplification is made that $K_H = K_V$, giving:

$$\beta = \gamma \frac{\partial T}{\partial e}$$

The dimensionless Bowen ratio is a useful value in climatic analysis of energy balance studies. For example, it is interesting to compare β values of areas that have been modified through human activities. The change from a natural to an urban environment results in an increase in β , with the value for an urban area in humid climates approaching similar values to those of deserts. A decreasing ratio occurs in irrigated areas in dry regions where the β value is similar to that found in oases.

BUDYKO, MIKHAIL IVANOVICH (b. 1920)

Unquestionably, Mikhail Ivanovich Budyko was one of the greatest climatologists in the Soviet Union and is the most respected in Russia today. He has received worldwide recognition for his work. Budyko was born in 1920, at a time of civil war and famine, in Gomel, Belarussia (now Belarus). Educated in the Soviet system, he received his Master of Science degree from the Leningrad Polytechnic Institute in 1942. Budyko was assigned immediately to Leningrad Main Geophysical Observatory as a researcher in 1942. During the German Army siege of the city he experienced the travails of the famine of 1941–43. Then in 1951, Budyko received his PhD from the Observatory, became Deputy Director in 1954, and advanced to Director in 1972.

A respected and highly qualified scientist, Budyko was dismissed from his director's position in 1954 for not cooperating

with the Communist Party's Leningrad Committee. Eventually he was reinstated. His brilliant research and major scientific contributions enabled him to be appointed Head of the Division of Physical Climatology at the Observatory in 1972, Head of the Division of Climatic Change Research at the State Hydrological Institute at Leningrad in 1975, and later, Academician of the Russian Academy of Science in 1992 (Pacchioli, 2001). To many scientists Budyko is the father of physical climatology, and he is noted for raising the level of precision of global climatic research.

Budyko became deeply involved in researching the Earth's heat budget and regional heat balances in the 1950s. The first systematic measurements of solar radiation had begun in the nineteenth century. Improved instrumentation, better communication between scientists, and exchange of data led to new insights into heat balance Arctic climatology during the Second International Polar Year in the 1930s. After World War II, investigation of the radiation balance of the Earth was stimulated by an expansion of actinometric observation and advanced computational methods. Dr Budyko postulated that the sun's energy was the most important factor in climatology. He calculated the heat balance of selected climatic regions, verified his numerical models with observational data, confirmed that his heat balance calculations were accurate, and published his conclusions in his seminal book, *The Heat Balance of the Earth's Surface*, in 1956. This book revolutionized the way climatology was taught, provided a base for research not considered before, and remolded climatology into a more quantitative and physical science. A few years later, in 1963, Dr Budyko's team of researchers produced a very sophisticated atlas, depicting the energy balance of the Earth as viewed from space (Budyko, 1963).

In 1970, supported by an excellent team of researchers and concerned about the role of biological organisms and human activities on climate, Dr Budyko began research on climatic change (Budyko, 1971). He believed that the Earth would enter a period of warming that would increase the global average temperature a few degrees Celsius. His research into the composition of the atmosphere in the geologic past indicated that a significant factor in global temperature changes in the past was the amount of carbon dioxide in the atmosphere. In 1973 Dr Budyko published a remarkable article entitled, "Atmospheric carbon dioxide and climate". He noted that a relatively small increase or decrease in the amount of carbon dioxide could change climatic conditions on Earth. Also, he observed that the atmosphere has retained approximately one-half of the carbon dioxide gas formed as a result of human activities (Budyko, 1973). Humans, through their actions, and in particular the burning of fossil fuels, were changing the climates of the Earth. This article stimulated much research throughout the world, and Dr Budyko continued his studies on the relationships between climate and human activity. He published a book entitled *Climate and Life*, in 1974. In this book he correlated climatic changes and the extinction of animal species, plus the effect of climate on all forms of life on earth (Budyko, 1974).

Realizing that any changes, whether large or small, in the stable and unstable components of the Earth's atmosphere impact world climate, Dr Budyko began to focus his attention on the atmospheric ramifications of a nuclear war. He postulated that if a nuclear exchange between the United States and the Soviet Union were to occur, large amounts of aerosol particles would be released into the atmosphere. Coordinating what was known

about past climate and weather changes resulting from volcanic eruptions and collisions with meteorites, he concluded that a nuclear weapon exchange would threaten life in all forms on our Earth. His publications and presentations on a potential “nuclear winter” impacted Soviet military planners and decision-makers in the 1980s and are believed to have contributed to the decision of the Soviet Union and the United States to sign a treaty to reduce the number of nuclear missiles in their arsenals.

Recognized by the United Nations and the recipient of the Blue Planet Prize in 1998, Dr Budyko outlined in his Commemorative Lecture his charge for climatologists in the world. He firmly believes that there should be more research into climatic change, climate and global food problems, climatic change’s effect upon natural zonality, global warming and permafrost, temperature increases and reduction of energy consumption in winter, hydrological response to climatic change, and a rise in the sea level. He has been the recipient of the Lenin National Prize in 1958, the Gold Medal of the World Meteorological Organization in 1987, the Professor R. Horton Medal of the American Geographical Union in 1994, the A. A. Grigoryev Prize of the Russian Academy of Science in 1995, and others. Mikhail Ivanovich Budyko personifies the best in atmospheric research, climatic change identification, and concerned scientist involvement in critical global issues. His research and publications represent major contributions to

scientific work, focused upon seeking solutions to global environmental problems (AGF, 1999).

CARBON-14 DATING

The introduction of the carbon-14 (^{14}C , radiocarbon) dating method in 1947 (for which Willard F. Libby received the Nobel Prize for Chemistry in 1960) transformed many aspects of environmental science by permitting numerical dating of fossils, artifacts and deposits whose age previously had to be estimated. Organisms and events could now be put into chronological order and correlated objectively, and the search for mechanisms of change placed on a sounder footing, leading to a better understanding of such matters as the viscosity of the Earth's mantle, the mechanisms of climatic change, processes of organic evolution and extinction, and climatic history, within the 70 000 or so years spanned by the method.

Three isotopes of carbon are present in the atmosphere in the ratio 100 : 1 : 0.01, of which two, ^{12}C and ^{13}C , are stable. The third, ^{14}C , is radioactive and thus subject to decay, but it is continually replenished by the action of cosmic rays, which interact with ^{14}N atoms in the upper atmosphere to form ^{14}C . The radiocarbon is oxidized to form CO_2 , which is then incorporated into plants by photosynthesis or dissolved in the ocean and used to build carbonate structures by mollusks and corals. The current estimate of the half life ($t_{1/2}$) of ^{14}C is 5730 ± 30 years, but Libby's original value of 5568 ± 30 is used in many date lists for consistency. The "Libby" age can be adjusted to the new value by multiplying by 1.03. His use of BP for Before Present (= 1950) also persists.

Originally Libby analyzed his samples as solid carbon. Nowadays in most radiocarbon laboratories ^{14}C content is measured by converting the sample into CO_2 , whose radioactivity relative to a modern standard is counted in a gas-proportional counter or by synthesizing benzene (C_6H_6) from the gas and using a liquid scintillation counter. A third method, accelerator mass spectrometry (AMS), allows ^{14}C atoms to be counted directly and thus requires much smaller samples, typically 15 mg as opposed to 1 g of carbon. The \pm value that follows the age is generally a statement of the counting error at 1 s.d., but some laboratories include analytical and other error estimates.

The method can be used for any organic material but some substances have proved less troublesome than others. Wood, charcoal and peat, suitably pretreated, are often favored, but bone collagen and unrecrystallized shell and coral yield reliable ages. Besides exercising great care in field attribution and handling, the collector can check the sample for contamination by old or young carbon by means of microscopy (both optical and SEM), X-ray diffraction and the $^{13}\text{C}/^{12}\text{C}$ (stable isotope) ratios measured by mass spectrometry. Corrections need to be made for ^{14}C contributed to the atmosphere by thermonuclear weapons testing after 1952 and by dead CO_2 produced from the burning of coal and oil fuels (the Suess effect).

Variations in the ^{14}C reservoir (the de Vries effect) can be allowed for by reference to calibration curves based on tree ring ages for sequoia (*Sequoia gigantea*) and bristlecone pine (*Pinus aristata*), which are available for the last 8000 years. The main sources of variation are the intensity of the cosmic ray flux, the strength of the Earth's magnetic field and changes in the Earth's carbon reservoir stemming from climatic changes. The solution of parochial dating errors is thus proving a source of information on environmental change both on Earth and on the sun.

Further information on carbon-14 dating can be gained from Bradley (1985, Ch. 3), Worsley (1981), and Raaen et al. (1968). Practical applications can be found in Ozer and Vita-Finzi (1986).

CENTERS OF ACTION

If there were no continents and seasonal variation on the Earth, an ideal atmospheric circulation system would be denoted by: (1) an equatorial belt of low pressure; (2) polar centers of high pressure; and (3) two intermediate belts, one of high pressure (the Horse Latitudes) at about 30 degrees and the other of low pressure in the vicinity of 60 degrees. The low-pressure zones would be centers of convergence and the high-pressure zones centers of divergence. Since the Earth is rotating, wave patterns would develop along the convergences and these would become the great storm-generating belts. However, the critical modification in this ideal pattern is the asymmetric presence of continents; meridional land masses and mountain belts block the 60 degree convergence zone in the northern hemisphere, but in the southern hemisphere this is a clear waterway – the Southern Ocean – all around the Earth.

Due to the different thermal characteristics of continents and oceans, semipermanent centers of high and low pressure tend to build up and remain along the zonal (east–west) pressure belts, with greater contrasts in the northern hemisphere as it contains most of the world's land mass. Over the oceans the sign of the pressure extremes remains constant in each pressure mass, but over continents it tends to alternate in summer (low) and winter (high), the so-called monsoon effect. Since the surface winds diverge from high-pressure areas, the semipermanent highs are known as source regions for airmasses. These semipermanent or regularly recurring pressure centers are known, as Rossby (1945) says, “by the somewhat misleading name” of centers of action. It is important to recognize that these centers are the result and not the cause of global circulation.

The semipermanent centers of action in the northern hemisphere are: (1) low pressure: Aleutian Low, Icelandic Low; and (2) high pressure: Azores or Bermuda High, Hawaiian or North Pacific High (Figure C1).

The continental highs in the northern hemisphere winter are the North American or Canadian High and the Siberian or Asiatic High; in summer these tend to be replaced by lows, but are more complicated by the zonal circulation, especially in the case of the smaller land mass of North America.

With the exception of the South Polar High over Antarctica, comparable centers of action are not as well developed in the southern hemisphere, though well-defined oceanic high-pressure centers occur: the South Atlantic or St Helena High, the Indian Ocean High, and the South Pacific High. In summer, lows develop over the continents and are replaced by highs in the winter; this is similar to, but not so marked as, the Siberian Low and High. These differences occur due to the continuous waterbody of the Southern Ocean symmetrically surrounding Antarctica, which is itself symmetrical about the South Pole, and because the other three southern continents occupy only minor fractions of the total area, the steady circulation is striking. Indeed, Gentilli (1949) found that the maximum zonal index was 6 (i.e. well-marked westerlies) and there was never a negative (easterly) reading between 35°S and 55°S; in contrast, the index varied from +15 to -5 over a 12-month period in North America.

It is known that large-scale phenomena such as the El Niño/Southern Oscillation (ENSO) and the North Atlantic Oscillation (NAO) affect the climate over a large part of the Earth on time scales that range from years to centuries. Kirov and Georgieva (2002) compared the century-long variability of ENSO and NAO with variations of solar activity, and suggest that the influence of solar activity on these phenomena is mediated by the atmospheric centers of action which react by changes in intensity and location.

CENTRAL AMERICA AND THE CARIBBEAN, CLIMATE OF

Central America and the Caribbean span the deep tropics and subtropics. Because of the tropical maritime location temperature changes throughout the region are generally small, and rainfall is by far the most important meteorological element. In general the climate of the region is controlled by the migration of synoptic features, and the mean climate strongly reflects the annual cycle of these features.

The most dominant synoptic influence is the subtropical high of the north Atlantic. Subsidence associated with the spreading of the subtropical high from the north Atlantic to the north American landmass dominates during boreal winter, as do the strong easterly trades found on its equatorward flank. Coupled with a strong trade inversion, a cold ocean and reduced atmospheric humidity, the region is generally at its driest during the winter. With the onset of boreal spring, however, the subtropical high moves offshore and trade wind intensity decreases, with convergence characterizing their downstream. Especially for Central America, the variation in the strength of the trades is an important determinant of climate throughout the year. There is also a high and weak trade inversion, the ocean warms and atmospheric moisture is abundant. The region is consequently at its wettest in the northern summer half-year.

The contrast in summer and winter rainfall defines most climate classifications of the region. For example, Rudloff (1981) suggests that the climate of Central America and the Caribbean can be classified as dry-winter tropical. The contrast proves an important control for agricultural and tourism activity, water resource allocation, hydrological considerations and fishing – activities which are of utmost importance to the region.

The dry winter/wet summer regime, however, only broadly defines the climate of the region as orography and elevation are significant modifiers on the subregional scale. The region is one of complex and diverse topography including continental territories, island chains, and mountain ranges of varying orientations and elevations. The topography interacts with the large-scale circulation to produce local variations in the climate, including significant variations in annual rainfall totals, length of the rainy season, and the timing of maxima and minima. As examples, the windward slopes of the larger mountainous islands of the Greater Antilles have significantly higher rainfall totals than the smaller flatter islands in the eastern Caribbean Sea. Similarly, the Caribbean coastal stations of Honduras, Costa Rica and Panama possess a strikingly homogeneous

rainfall regime (i.e. in stark contrast to the dominant dry winter/summer regime) due to strong interactions of low-level winds with the topography. The subregional variations make generalizations about the climate of the region difficult – a fact which must be borne in mind when considering the general overviews presented in the following sections.

Besides the subtropical high, other significant synoptic influences include: (a) the seasonal migration of the Intertropical Convergence Zone (ITCZ) – mainly affecting the Pacific side of southern Central America; (b) the intrusions of polar fronts of midlatitude origin (called “Nortes” in Spanish) which modify the dry winter and early summer climates of the northern Caribbean and north Central American; and (c) westward propagating tropical disturbances – a summer season feature associated with much rainfall especially over the Caribbean region.

Central America

Temperature

Temperature ranges during the course of the year in the Central America region are generally small. They may exceed 4°C to the north, from the Yucatan to Honduras, but drop to less than 2°C in the south and along the coastal zones. Maximum temperatures are dependent on altitude given the mountainous interior of the region. The common usage of the terms *tierra caliente* (“hot land”), *tierra templada* (“temperate land”), *tierra fria* (“cold land”), and *tierra helada* (“frozen land”) suggests a longstanding recognition of the effect of altitude on temperatures. The terms loosely denote shifts in the mean temperature regime with increasing altitude, but their usage is relative (varies with location), with no consistent assignment of a temperature to elevation. Minimum temperatures similarly exhibit dependence on altitude, but also show the effect of the winter intrusions of cold air from North America, and can dip as low as 7°C.

Portig (see Schwerdtfeger, 1976) classifies the annual cycle of air surface temperature in Central America as tropical, predominantly maritime, with small annual changes and dependent on cloud cover and altitude. The dominant annual cycle of the Central American region (excepting the Atlantic coasts of Honduras and northern Nicaragua) is monsoonal, with highest temperatures occurring just before the summer rains (Figure C2). Temperatures are at their lowest during January, largely due to the cooling effect of the strong trade winds (Figure C3). Maximum temperatures occur during April and are associated with a decrease in trade wind strength, lower cloud coverage and higher values of solar radiation (Alfaro, 2000a). There is a temperature minimum in July which coincides with the onset of the midsummer drought (or in Spanish the *veranillos* or *caniculas* – see below). During this period the trade winds briefly increase in intensity (see again Figure C3), the subtropical ridge over the Caribbean intensifies, and there is a second minimum and maximum in cloud coverage and radiation respectively.

Precipitation

Mean annual rainfall totals vary over a wide range in Central America in keeping with the diversity in topographic conditions. Annual totals of less than 100 cm are typical of the plains of Guatemala, Honduras and northwestern Nicaragua, and portions of the Pacific coast of El Salvador, Honduras and

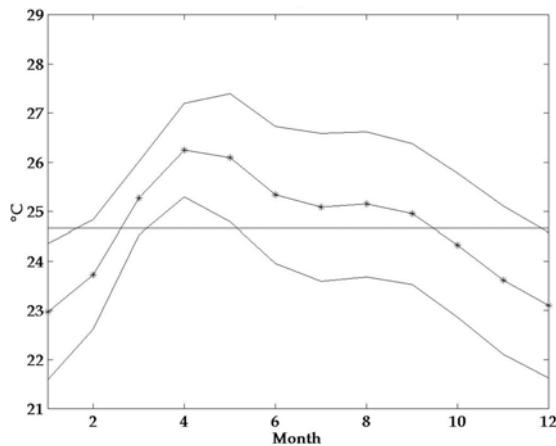

Figure C2 The central line (with asterisks) depicts the mean annual cycle of temperature over Central America as determined from principal component analysis. The upper and lower solid lines represent one standard deviation. The horizontal line is the annual mean of 24.7°C.

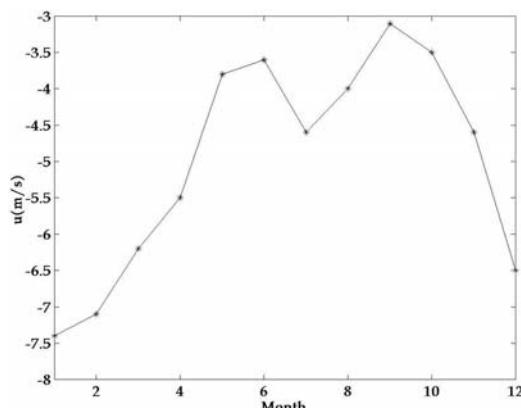

Figure C3 Annual cycle for zonal wind component (u) at the 900 hPa level. Monthly values are from Juan Santamaría synoptic station ($10^{\circ}00'N$, $84^{\circ}12'W$, from Alvarado, 1999), period used: 1972–1989. The annual average value is -5 m s^{-1} . Notice that negative values are westward winds.

Panama. In contrast the northern and southern mountain ranges of Guatemala and the low mountains between Costa Rica and Panama receive large amounts of rainfall (in excess of 250 cm), as do the Atlantic coastal regions from Belize through Guatemala, the south coast of Costa Rica and a section of Panama's Atlantic coast. In general the Caribbean seaboard receives more rainfall than the Pacific side, reflecting the influence of tropical disturbances from the Caribbean Sea and the windward interaction of the trade winds with the mountains chains.

Fernandez et al. (1996) explored the variability of rainfall with altitude in Central America by examining the vertical rainfall distribution in Costa Rica along a topographic profile which crossed the country from the Pacific to the Caribbean coasts. The mountain profile, with highest peak of approximately 3000 m, is

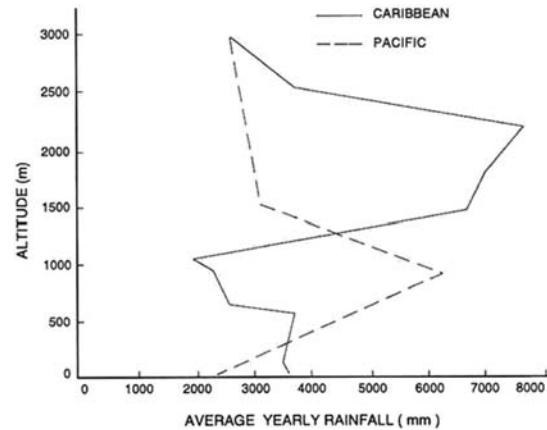

Figure C4 Distribution of average yearly rainfall with altitude on the Caribbean and Pacific sides of a topographic profile in Central America. The periods of analysis are 1966–1984 and 1981–1984 for the Caribbean and the Pacific sides respectively. (After Fernandez et al., 1996.)

oriented parallel to the prevailing large-scale northeasterly trade winds. Their analysis of rainfall amounts and the seasonal and diurnal variations at 14 rain-gauge stations located on or close to the topographic profile reveals considerable variation with altitude. Maximum rainfall on both the windward (Caribbean) and leeward (Pacific) sides of the main mountain range occur at intermediate altitudes rather than on the mountain tops. (See also the work of Chacon and Fernandez, 1985.) Average yearly maxima of 7735 mm on the windward side and 6692 mm on the leeward side were observed at about 2000 m and 800 m respectively (see Figure C4).

Analysis of the mean annual cycle of precipitation reveals two dominant modes (Figure C5). The first and more representative mode is characterized by two rainfall maxima in June and September, an extended dry season from November to May, and a shorter dry season in July–August. Figure C5a suggests this regime as characteristic (with a few exceptions) of the entire Central America. This regime is largely explained by the seasonal migration of the subtropical north Atlantic high and the ITCZ.

The dry season of winter and early spring accounts for less than 20% of the annual precipitation total of Central America. It is more intense on the Pacific slopes of the isthmus, possibly due to an additional drying effect caused by the seasonal reversal of the winds on the Pacific side which blow offshore during winter. The ITCZ is also at its maximum southeast position during February and March. The season is further characterized by strong Atlantic trades (Figure C3), high values of total radiation (direct plus diffuse radiation) and sunshine hours in the low troposphere levels, despite the fact that radiation at the top of the atmosphere is at minimum. Cortez (2000) shows that there is no evidence of deep convection during the period as mean OLR values are greater than 240 W m^{-2} , and that there is poor humidity convergence over almost all the isthmus excepting the southeast.

The onset of the rainy season is in May. There is a latitudinal variation of onset dates with earlier onset (early May) in the south and late onset (late May) in the north. The latitudinal variation may be partially explained by the northward migration

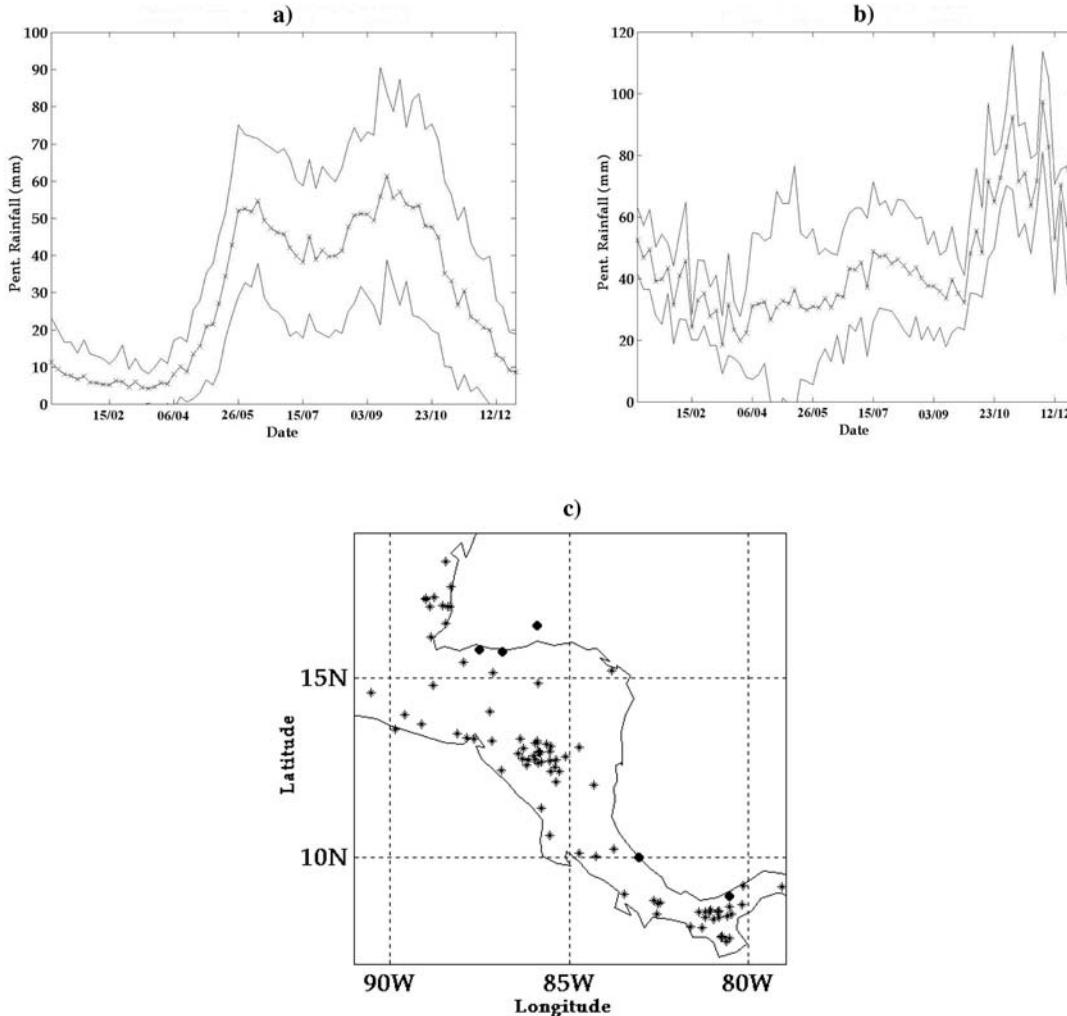

Figure C5 Lines with asterisks are the (a) first and (b) second pentad rainfall dominant annual cycle patterns, using empirical orthogonal function analysis of 94 gauge stations. Bands are given for one standard deviation (solid lines). (c) Asterisks (solid circles) are locations at which the first (second) mode dominates.

of the ITCZ that causes instability and humidity convergence in southern Central America from boreal late spring to early fall. As noted by Alfaro (2000b), however, the migration of the ITCZ cannot explain the generalized deep convection over the entire region during the rainy season as the ITCZ is not normally found at latitudes higher than 10–12°N. The first rainfall peak occurs in mid-June, and during this period (and for the entire rainy season), the trade winds are weak (Figure C3), allowing for the formation of mesoscale systems such as sea breezes, though mostly on the Pacific side.

By the middle of July there is a distinct decrease in rainfall over much of Central America. The brief dry period is known as the *veranillo*, *canícula*, or the midsummer drought (MSD, see Magaña et al., 1999). Again there is some latitudinal variation in the onset dates of the MSD, with earlier onset in the Southern-Pacific slope and later onset in the Northern-Caribbean slope. During the MSD there is an increase in the trade wind intensity associated with a brief retrogression of the north Atlantic subtropical high.

The second rainfall maximum occurs in mid-September/October, and is wetter than the first. The subsequent demise of the rainfall season also shows latitudinal variation with the tendency for earlier end dates in the north Pacific sector and later end dates in the south. This latitudinal behavior is only partially explained by the southward migration of the ITCZ, since latest end dates are found on the north Caribbean coast. The reason for such late end dates in the north is unclear. It could reflect the influence of cold fronts over the North-Caribbean Central American coast during boreal winter and/or the intensification of the winter trade winds which transport humidity and produce precipitation on the windward side.

The Caribbean coasts of Honduras, Costa Rica and Panama (Figure C5c) exhibit a second rainfall mode, different from the dominant dry-winter/wet-summer regime. It is difficult to define a dry season for this region as rainfall is nearly homogeneous between January and the middle of October, with typical accumulations of between 180 and 300 mm per month. The period accounts for approximately 60% of the annual total in

this region. From mid-October onwards there is a marked increase in precipitation accumulation until the end of the year, with a maximum in the beginning of December. This is related to a maximum in humidity convergence at the end of the year in the southeastern region. Significantly, there is no rainfall minimum in July, with instead a relative maximum characterizing the mode 2 regions. This might result from the low-level jet influence and the interaction between topography and the low-level wind (Amador, 1998). Interestingly it is the same mechanism (i.e. the intensification of the trades) which both yields the MSD over most of Central America and makes the Caribbean slope wetter than the Pacific slope during July.

The Caribbean

Temperature

Temperatures on the islands of the Caribbean remain fairly constant throughout the year, with a small annual range of only 2–7°C (see Figure C6). As opposed to the dominant monsoonal type variation of Central America, the annual cycle of temperature for the Caribbean exhibits a summer–winter variation similar to that of more northern latitudes, but with high tropical temperatures and in the context of the small range. In the mean, temperatures steadily increase from May and peak in August–September. The summer months are the warmest with mean temperatures peaking in the upper 20s Celsius, but rarely exceeding 37°C for any station. For the smaller islands of the Lesser Antilles, the summer heat is tempered by the easterly trades.

Coolest temperatures occur during boreal winter and early spring (December to April) with values generally in the low 20s for sea-level and coastal stations. Temperatures, however, never generally fall below 18°C. The summer–winter variation becomes more pronounced for territories at increasingly higher latitudes, which also come under the occasional influence of intruding polar fronts in winter. Inland, on the larger islands of the Greater Antilles, the cooling influence of the sea breeze is lost, though in some cases this is compensated for by increasing altitude.

Precipitation

The differences in size, shape, topography, and orientation with respect to the trade winds greatly influence the amount of rainfall received by the island territories of the Caribbean. The larger and more mountainous islands of the Greater Antilles (Cuba, Jamaica, Hispaniola, Puerto Rico) receive rainfall amounts of up to 160 cm per year, with in excess of 500 cm on the highest peaks. There is, however, a distinct rainshadow effect on their southern coasts, which are distinctly arid. To their east the northern Windward Islands (as far as Antigua) receive lower rainfall amounts, tending to be slightly drier. Precipitation increases with southerly latitude and the Windward Islands, Trinidad and Barbados tend to be well watered. Normal yearly rainfall is between 180 and 230 cm for the Windward Islands (from Montserrat through Grenada), 150 cm for Trinidad, and 125 cm for Barbados. The dry belt of the Caribbean is found over the southwestern islands of the Netherland Antilles (Aruba, Bonaire, Curacao), which possess a semiarid climate and receive less than 60 cm per year on average. In general the eastern sides and windward slopes of the

Caribbean islands receive more rainfall because of the prevailing northeasterly trade winds, while the lee slopes and interior portions of the mountainous islands are drier.

Except for the Netherland Antilles, the Caribbean islands generally receive most of their yearly rainfall in the summer months (Figure C6). This reflects the influence of the migrating north Atlantic subtropical high, the warming of the Caribbean Sea, a reduction in trade wind strength, and the appearance in mid-June of easterly waves/tropical disturbances which leave the west coast of Africa and traverse through the Caribbean region. These easterly waves are convection centers carried by the trades that frequently mature into tropical storms and hurricanes under conducive atmospheric and oceanic conditions such as warm sea surface temperatures and low vertical shear. They represent the primary source of Caribbean rainfall, and their onset in June and demise in early November roughly coincide with the mean Caribbean rainy season. Unlike Central America, the southernmost Caribbean territories lie too far north ($\sim 11^{\circ}\text{N}$) to come under the direct influence of the ITCZ.

The northwestern Caribbean territories (Jamaica, eastern Cuba, and Hispaniola) possess a distinct midsummer break in rainfall similar to the MSD of Central America (see Figure C6). Onset, however, tends to be later than in Central America, with the MSD for the Caribbean territories occurring in mid to late July/early August. Consequently the annual cycle of rainfall for the northwest Caribbean is bimodal with an initial peak in May/June and a second greater maximum in October. The islands of the Lesser Antilles generally lack the earlier maximum, with rainfall totals increasing from the onset of the rainy season in May to a late fall rainfall peak. The eastern side of Dominica and Martinique has one long rainfall season with a peak in November, while Barbados has a broad minimum in February and March, and a broad maximum between September and November. This lack of an early rainfall season peak in the eastern Caribbean might be accounted for by the fact that only the western Caribbean Sea is warm enough to support convection (i.e. exceeds the 27°C convection threshold) at the onset of the rainy season (Wang and Enfield, 2001, 2003), and it is only the southwestern Caribbean which is conducive to tropical cyclogenesis at the start of the rainy season.

A slightly different rainfall regime characterizes the flat islands of the Netherland Antilles, which have their main rainy season from October through January, with the “small rains” from June to September. The islands are at their driest between February and May, with an absolute minimum in April.

Outside of the rainy season, rainfall in the Caribbean dry season can occur from the southern tip of intruding cold fronts from North America. The influence of the fronts is particularly noticeable in northern Caribbean territories (especially the Bahamas) but rarely extends below Jamaica or east of Puerto Rico.

Hurricanes

Tropical storms and hurricanes are seasonally common in the northern Caribbean and Gulf of Mexico. They merit brief discussion due to the significant loss of life, the extensive infrastructural damage, and the disruption to the Central American and Caribbean economies and way of life that occur with hurricane landfall or even passage nearby. In the mean eight hurricanes will pass near or through the Caribbean region in a year, but this number can vary significantly from year to year. Global climatic phenomena such as the El Niño Southern

Oscillation (ENSO) seem to play a role in determining the number of storms which will develop and pass through the Caribbean. During the warm phase there is an apparent decrease in the frequency of tropical storms due to an increase in wind shear over the Caribbean during the hurricane season (Banichevich and Lizano, 1998). There is also evidence of decadal variation in storm activity with some decades on average being less active (1970s to 1990s) than others (1920s to 1960s) (Goldenberg et al., 2001).

The hurricane season runs from June to November with a peak in activity in September. The peak occurs prior to the rainfall maximum of the Caribbean, suggesting that although hurricanes are significant they are not the primary rainfall mechanism for the Caribbean territories, as is often thought, mainly because their effects over specific locations depend on the cyclone's relative position and their velocity over the Caribbean Sea. The coincidence of hurricane peak activity and maximum tropical wave activity is, however, not surprising given the importance of the waves to cyclogenesis. Most (though not all) of the tropical cyclones that ply the Caribbean Sea originate from tropical waves in the easterlies. A warm ocean and low vertical shear fuel their development. Development during the peak period generally occurs in the 10–20°N latitudinal band (termed the main development region or MDR) just east of the Lesser Antilles in the eastern north Atlantic. Early in the hurricane season, however (June), the development region resides in the Caribbean and Gulf of Mexico.

Hurricane development is suppressed in July leading to a bimodal distribution of the annual cycle of north Atlantic hurricanes. This suppression coincides with the previously noted

intensification of the trades in July, which yields upwelling in the southwestern Caribbean and lower sea surface temperatures, high vertical shear and reduced convection.

Sometimes (as with Joan in 1988), hurricanes pass over Central America and continue their activity in the eastern tropical Pacific. The eastern tropical Pacific is itself an important region of hurricane development but these affect mainly the Pacific coast of Mexico, and occasionally the northern part of Central America (Guatemala and El Salvador).

CLIMATE AFFAIRS

Climate affairs is a multidisciplinary concept that encompasses climate science, climate impacts on ecosystems and on societies, climate politics, policy, law and politics, climate economics, and climate ethics. While individual and societal concerns about climate have existed for millennia, the notion of climate affairs is new and is designed to meet the growing educational needs related to climate-related issues.

Climate in its various forms – variability, fluctuations, change, extremes – is appearing at the top of governmental lists of concern about global environmental and technological change. Aside from specific weather and climate phenomena that are of concern in their own right, there is a deep concern about what the adverse effects might be of those phenomena on human activities or on the resources on which societies depend: food production and security, water resources, energy, public health, public safety, economy and environment. Running through each of these categories are ethical and equity issues.

One could argue that global change represents a version of a new Cold War; only this time the conflict is between societal activities and natural physical and biological processes, instead of between two nuclear superpowers.

Rich and poor societies alike have increasingly come to realize the extent to which their activities (e.g. industrialization processes and land-use practices) can affect the local and global atmosphere as well as be affected by it. In addition, an increasing number of government, individual, and corporate decisions are being made for which a knowledge of climate affairs is required. As a result, there is a growing awareness among educators in many disciplines of the need for a better understanding of just how climate variability, change and extremes affect the environment and the socioeconomic affairs of people, cultures and nations.

Climate issues have become increasingly important to governments, corporations, and the public. One could surmise that this sharp increase in interest in climate issues and weather has been a result of the end of the Cold War in the early 1990s. At the same time various storms and anomalies have been labeled as the “storm of the century”, the worst hurricane, the most costly drought, the longest El Niño, and so forth, in history. Some observers have linked “blockbuster” weather and climate episodes to human-induced global warming of the atmosphere, while others have argued that these are random extreme events under normal global climate conditions.

Since the late 1980s, scientific and government interest in human-induced influences on the naturally occurring greenhouse effect has increased steadily and to new heights, leading up to serious international negotiations to control the emissions of greenhouse gases (carbon dioxide, nitrous oxides, CFCs, methane). The perception about the global climate regime is that climate anomalies have become more frequent, more costly and more deadly. The negative impacts of a changing climate on food, water, energy, health and public safety of a human-induced global warming loom large in the 21st century.

For our purposes, climate encompasses *variability* from season to season and from year to year, *fluctuations* on the order of decades, *change* on the order of centuries and beyond, and *extreme meteorological events*.

Climate variability

Although climate varies on several time scales from seasons to millennia, most people are most concerned about climate variability within a season, from one season to the next, and from one year to the next. These are the time scales that are perceived by people and societies to directly, as well as indirectly, affect them and resources such as food, water, energy, ecological and human health. People everywhere are aware of growing seasons, hunger seasons, rainy seasons, fire seasons, hurricane seasons, planting seasons, harvest time, and so on. Forecasters are now focused on producing reliable seasonal forecasts well in advance of the season, as these forecasts are most useful to societies and individuals, affording them time to take strategic evasive action. When the natural flow of the seasons is disrupted, social and economic problems arise for individuals as well as governments. Year-to-year climate variability is also of concern to society. The El Niño–Southern Oscillation (ENSO) cycle of warm–neutral–cold episodes operates on an annual basis with El Niño events recurring on the order of 2–10 years, often interspersed with the cold episodes.

There is a major difference in societal and environmental impacts in the way annual climate is sequenced. For example, if a dry year is followed by a wet year, societal (and individual) responses will differ from a dry year followed by a second and a third dry year. The same applies to wet years. As an example, in an arid area, societal coping strategies are designed to cope with one or two dry years but not with a third.

Climate fluctuations

Fluctuations refers to variability on the order of decades. For example, the frequency of hurricanes in the tropical Atlantic has changed over periods of decades: 1930–1960 was a very active period, whereas 1960–1995 was relatively inactive. Some researchers suggest that we are about to enter a multi-decadal period with an increase in the frequency of tropical storms on the order of the earlier (1930–1960) active hurricane period.

As another example, El Niño events were less frequent than La Niña between 1950 and 1975, but have become more frequent in the last quarter of the twentieth century. While this time scale is of interest to certain specialists dealing with long-range issues, such as engineers who deal with the planning of water resources and structures that have to last for many decades, they are apparently of much less concern to individuals and policy makers. The decadal scale is one about which societies should be more concerned and knowledgeable than they are at present.

Climate change (new global climate state)

Climate change is a euphemism for global warming. Scientific reports strongly suggest that human activities such as the burning of fossil fuels, tropical deforestation and the emission of other greenhouse gases are responsible for enhancing the naturally occurring greenhouse effect.

Political leaders in many countries have become directly involved in and concerned about the global warming issue. It relates to international energy politics as well as domestic energy debates. Governments equate the use of energy with economic progress. The popular source of energy derives from fossil fuel use (coal, oil and natural gas). These gases when emitted alter the radiative balance of the atmosphere, trapping outgoing longwave radiation in the Earth's atmosphere, which leads to global warming.

Furthermore, in order to prepare society to cope with the projected global and regional changes in climate, societies must evaluate how well they cope with variability and extremes today.

Extreme meteorological events (EMEs)

Societies everywhere worry about particular extreme weather, climate and climate-related events. Although each society faces its own subset of such extremes – droughts, floods, cyclones, heat waves, vector-borne infectious disease outbreaks, etc. – it does not have to face the same set of extremes as other societies with different climate regimes. While Floridians are concerned about hurricanes and fires, Californians are concerned about El Niño-related coastal storms and torrential rains in the southern part of the state. States in the Great Plains and the Gulf states are concerned about tornadoes and severe weather to a much greater extent than states in other parts of the US. There are, however, many similarities in the way that societies prepare for or cope with extreme events.

Researchers concerned about climate variability and those concerned about climate change are interested in EMEs, but for different reasons: the former community wants to forecast their onset and prepare society for their impacts, whereas the latter community of researchers wants to identify changes in frequency, intensity, duration or location of such extremes.

In order for a climate affairs activity (education, training, research) to be complete it must incorporate information about climate science, climate impacts, climate politics, policy and law, climate economics and climate ethics and equity.

Climate science

The objective of a climate science section of climate affairs is threefold:

1. To understand the climate system.
2. To understand its components.
3. To recognize society as a component.

It is important that climate affairs students and professionals understand the workings of the climate system. That system has numerous components. The shells of mollusks, for example, retain carbon for millennia. Termites produce methane, as do animals in feedlots, and so forth. The system's major components are sea ice, forests, oceans, deserts, clouds, the sun, topography, rangelands, and wetlands. Human activities have become a notable forcing factor as far as atmospheric processes are concerned and are now an integral part of the climate system along with its physical components. Social scientists are increasingly recognizing the importance of understanding the physical conditions under which societies they study must operate.

Climate impacts

Climate variability, change and extremes have positive and negative impacts on environment and society. Those impacts can vary over time even in the same location, depending on changes in the vulnerability of ecosystems and societies. The level of vulnerability or resilience of a society or an ecosystem is not just dependent on the intensity of a weather or climate anomaly.

Attributing a specific impact to a climate anomaly is not easy, as there are often several factors that have to be taken into consideration in doling out "blame". Often, the way attribution is done by the public is as follows: a major anomaly – drought, flood, frost, fire, severe storm, cyclone – occurs and most adverse impacts that happen to take place are identified; almost immediately they are attributed to it. However, a more considered assessment is necessary, so that appropriate safeguards can be developed to enable a society to cope with similar events in the future. Wrongly attributing climate-related impacts to a specific cause can prove to be wasteful of scarce resources. It can also lead to false expectations about the level of protection that a society might have from climate-related anomalies.

Climate impacts on terrestrial and marine ecosystems

For the most part the media concentrate their attention and coverage on visible climate and climate-related impacts on land-based ecosystems, both managed (irrigated, dryland, rangeland) and unmanaged (forested and other wilderness areas). Droughts and floods capture the most attention. More correctly, premature concern during dry spells about drought

often fill the airwaves and the printed media, only to have that concern evaporate as a timely rain saves a crop. For example, in the midst of a devastating El Niño-related drought in 1997 in Australia, timely rains occurred over a few weeks and prevented a devastating agricultural production year.

Climate impacts on marine ecosystems receive much less attention for a variety of reasons: fishing activities take place where most people do not live; the fishing sectors in most countries involve a relatively small number of workers; it is an economic problem for the most part, rather than one of life and death; the relationship between the viability of living marine resources and variability in air-sea interactions in different parts of the world's oceans are much less studied and not well understood. There are notable examples, however, of climate-marine life interactions: the Peruvian anchoveta, Ecuadorian shrimp, Pacific Northwest Salmon, Pacific Sardine, among others.

The impacts of climate anomalies in industrialized countries are economic issues, for the most part, whereas in developing countries the impacts of anomalies on societies tend to create life-death situations for relatively large segments of their populations. In other words, rich countries have the economic (and therefore technological) wherewithal to minimize or mitigate climate impacts on their populations.

The public now knows that human activities can affect atmospheric chemistry and atmospheric processes at all levels from local (i.e. urban heat island effect) to regional (i.e. tropical deforestation, desertification, and SO₂ emissions), to global (i.e. ozone depletion as a result of CFC emissions and global warming as a result of greenhouse gas emissions). Research on human activities that can affect the atmosphere continues, as researchers seek to reduce scientific uncertainties surrounding their impacts on the atmosphere. Improved understanding of this interaction could provide a sound, non-controversial basis for societal actions to minimize human influences on the atmosphere at various spatial levels.

Attempts to identify human impacts on the atmosphere and the impact of atmospheric processes on society depend on both qualitative and quantitative methods of assessment. It is likely that there will always be some level of scientific uncertainty that surrounds society-atmosphere interactions and, as new methods are developed, a refining of our understanding of those interactions will take place. However, there may be useful qualitative measures to identify how societies might be affected by climate variability, change and extremes. Even the use of anecdotal information can be instructive about climate impacts in certain societies. Historical accounts of impacts and responses to climate-related problems can be very instructive.

One qualitative approach has been referred to as "forecasting by analogy". While the future impacts of a climate anomaly will not likely be a mirror image of a recent past anomaly, this approach can help decision makers identify the strengths and weaknesses in societal and especially institutional responses. The strengths can be maintained or enhanced, and the weaknesses can be addressed.

Climate politics, policy and law

Climate politics refers to the process to achieve (or not achieve) certain objectives by way of climate and climate-related policies and laws. The outcome of politics is climate policies and laws. There are many climate-related political issues in need of discussion and resolution. Politics related to climate issues occurs at local, national, regional and global levels.

Climate has become a highly charged (politically and economically) aspect of environmental change at local to global levels. Climate as a scientific concern is not only important to comprehend in its own right, but understanding it and its various aspects helps us to cope more effectively with other issues considered to be climate-sensitive (fisheries, health, history, war, economy, policy, disasters, institutional change, etc.).

Today, the international community is negotiating the development of what could be called a "Law of the Atmosphere", through the IPCC (Intergovernmental Panel on Climate Change) process. Coupling together international agreements related to the atmosphere that have been developed over time, a body of laws related to the chemistry of the atmosphere and atmospheric processes is being accumulated: the Vienna Convention, the Montreal Protocol, the Convention on Long-Range Transboundary Air Pollution, and the UN Framework Convention on Climate Change (UNFCCC) and subsequent Kyoto Protocol and the entire set of Conference of Parties (COP) conferences. In the process of developing what will essentially become a Law of the Atmosphere, negotiators continue to seek assistance from experts in the physical, biological, and social sciences. Thus, expertise on climate-related issues has been emerging within educational, governmental and non-governmental institutions around the world.

Actions have been taken since the mid-1970s to reduce and, later, to eliminate ozone-depleting chemicals from industrial use in both the industrialized and developing countries. The Montreal Protocol in 1987 (and later amended several times) has sharply reduced CFC emissions. Since the late 1980s to the present, there have been several international conferences on global warming. The most noteworthy is the UNFCCC and the various Conferences of Parties to develop a protocol for the effective control of greenhouse gas emissions.

Acid rain has also generated international discussions, conferences and agreements on the science and impacts. Transboundary acid rain concerns have led to a dilemma. The SO₂ output of industrialization processes has been found to counteract the warming of the atmosphere regionally caused by the burning of the suite of fossil fuels. Recently, considerable renewed concern has focused on water issues and how those issues are or can be affected by climate variability, fluctuations, change and extremes (e.g. the Water Forum in 2001 in Japan).

Climate economics

What was the cost of that storm, drought, flood, frost or El Niño event? When people think of climate economics, this is most likely what they will think about – cost or benefit of a climate-related impact. To do this properly, however, researchers have to get a better handle (e.g. understanding) on "attribution" or what impacts can appropriately be blamed on or associated with a weather or climate event. A climate anomaly affects a society that is also affected at the same time by other factors, such as poverty, poor land management, inappropriate land use, conflict, trans-boundary air or water disputes, bureaucratic rivalries, domestic political rivalries, and so forth. A researcher has to take great care in teasing out of this situation, what was the contribution of the climate anomaly. Sometimes the anomaly may not have been the most important factor by itself but became important when it combined with some of these other factors.

Financial loss or gain as the result of climate variability, change or extremes, in fact, is only one aspect of climate economics. Economic researchers are also concerned about the following, when it comes to assessing climate-society-environment

interactions: risk analysis, discount rates, externalities – present vs. future generation welfare, forecast value, free market vs. government intervention, prevent, mitigate or adapt, climate variability and economic development.

Climate ethics

Of all the aspects of a climate affairs activity, the most neglected has been that of climate ethics and equity. This aspect encompasses a wide range of ethical and equity issues, such as the following, that are directly or indirectly affected by climate variability, change or extremes.

Inter- vs. intra-generational equity

Governments everywhere face the same question in the face of a climate issue: Who to help in the event of climate-related problems, present generations or future ones? For example, should the Brazilian government preserve Brazil's tropical rainforests, for example, for potential discovery of pharmaceuticals or cut them down to clear the land for cultivation and livestock and sell the timber? There is a desire also on the part of many to pass something of value on to future generations. As a result, they want to manage the Earth's resources (soil, vegetation, water, air) with the needs and welfare of future generations in mind.

Environmental justice

It is usually the poor and elderly in society who are most adversely affected by a drought, a flood or a heat wave. They are the ones whose living space has been relegated to precarious regions or areas or conditions: flood plains, steep slopes, arid lands, swampland, short growing seasons, and so forth. A forecast issued on the Internet gives those who have computers an advantage to receive that timely information before those who do have that access to the information highway. The rich in society have other options that the poor do not have available to avoid climate-related harm. Seldom are the upper classes in a society in harm's way to the same extent as the poor.

North-south cleavages and climate change

Today, there is considerable debate over responsibility for the global warming of the Earth's atmosphere. The developing countries argue forcefully and effectively that the industrialized countries were able to develop rapidly as a result of their burning of fossil fuels during *their* industrial revolution. As a result, the rich countries have saturated the atmosphere with radiatively active greenhouse gases. They argue that it is the responsibility of the industrialized countries to take the first steps – unconditionally – to reduce their greenhouse gas emissions. To counter, the industrialized and the coal- and oil-producing countries argue that the developing countries will be supplying the lion's share of greenhouse gases emissions in future decades.

There are several sayings that relate to the ethical aspects of climate, broadly defined: the “polluter pays principle”, the “precautionary principle”, and “common but differentiated responsibilities”. Each of these notions generates concerns about equity among competing countries, companies and ideologies. Thus, climate ethics and equity is an integral part of climate affairs.

In sum, climate affairs is an integrator of disciplinary interests in issues that are directly or indirectly affected by the behavior (as well as perceptions of the behavior) and impacts of

climate on environment and on society. It can also serve to stimulate new ways of thinking about traditional issues of disciplinary scientific research; conflicts over climate-related resources; political, economic, and technological development; famine; and political instability.

CLIMATIC CHANGE AND ANCIENT CIVILIZATIONS

Climatic change during the postglacial period

The Quaternary period is characterized as a glacial age. The coldest period of the last glaciation was about 18 000 years BP (based on uncalibrated ¹⁴C estimate), when margins of ice sheets and glaciers began to retreat in northern Europe, North America, and regions of the Eurasian continent. The end of that glacial age brought great changes in the landscape, due not only to the retreat of ice sheets and glaciers but also to the rise in sea level caused by melting ice. The rise in sea level occurred not only in the post-glacial period but also between 17 000 and 14 000 years BP and between 10 000 and 7 000 years BP. The latter phase was drastic in northern Europe particularly rapid, and north America because of glacio-isostatic rebound. Worldwide rise in sea level from the last glaciation to the present is estimated to be 140 m in total.

The hypsithermal

The last glacial stage ended about 10 000 years BP, after which the climate became warmer and reached a peak period called the

Climatic Optimum or the Hypsithermal, about that lasted about 6000 to 4500 years BP. Lamb (1982a) reconstructed average latitudes of the lowest and highest air-pressure axes at sea level in the European sector of the northern hemisphere. In winter, during the Hypsithermal, the dry belt under the subtropical high was located at around 40–45°N (around 30°N today) and the wet belt under the subpolar low at around 57–58°N (about 50°N today). On the other hand, in summer the dry belt under the subtropical high was located at around 50°N during the Hypsithermal (around 33–35°N today); the wet belt under the subpolar low has not fluctuated greatly since 8000 years BP. Suzuki (2000) compiled the climatic change curves during the last 10000 years all over the world, which were based on the continuous data analyzed, as shown in Figure C7. Even though the ranges of fluctuations and the local differences are different from place to place, and for the climatic elements, the general tendency mentioned above can be observed. Circulation patterns over Africa of 8000 years BP were reconstructed by Messerli (1980), as shown in Figure C8. The difference between Hypsithermal and present-day circulation patterns is strikingly clear in this illustration. Climatic fluctuations in the arid belt of the “Old World” since the last glacial maximum, taking examples in Africa, were discussed by Flohn and Nicholson (1980), Nicholson and Flohn (1980), Tyson (1986), and Tyson and Lindberg (1992).

In most parts of the world the climate between 7000 years BP or earlier and by 5000 years BP was warmer by 1–3°C than it is today (Harding, 1982). The middle latitudes enjoyed a warm climate and the Intertropical Convergence Zone (ITCZ) shifted northward in the northern hemisphere (Suzuki, 1975, 2000). One result of this shift was that the arid regions from the Sahel to northwestern India, which today lie in the Subtropical High-Pressure Zone (STHP) area, during the Hypsithermal experienced a moister regime south of the STHP. Europe experienced a warm, moist climate, and extensive beech and oak forests covered England and the Scandinavian peninsula. Overall mean temperatures in Europe and North America seem to have been up to 2°C higher than at present (Lamb et al., 1966; Lamb, 1977). In East Asia it was 5–8°C colder 10000 years BP but 2–3°C warmer 5000–6000 years BP than today (Yoshino and Urushibara-Yoshino, 1978).

In the middle latitudes, glaciers on the mountains almost disappeared during the Hypsithermal. Ice in the Arctic Sea melted away and the ice sheets and glaciers in Greenland and Antarctica shrank in this period. The minimum reconstructed 1000–500-hPa-layer thickness of 5150–5200 gpm was found over Arctic North America (Lamb, 1974). By 6000 years BP thermal gradients had weakened and the area of steep gradient shifted north of its current position. The great cold trough had broadened, weakened, and shifted east, out over the Atlantic in summer. It appears that the trough was located farther east than where it had been over North America in winter at 8500 years BP (Lamb et al., 1966). In short, the circulation became weaker on the whole, more zonally oriented, with its action centers located farther north. The North American cold trough was displaced eastward and the wavelength was increased, associated with a spread of westerlies at surface level.

Post-Hypsithermal

After the Hypsithermal the climate deteriorated once more. Large forests disappeared from England and Scandinavia during 3500–3000 years BP. (These dates “BP” are all uncalibrated.) This tendency was observed not only in Europe but in

all parts of the world. Suzuki (2000) concluded that there is evidence of a sharp decrease in air temperature around 3500 years BP in the Mediterranean region, East Asia, Australia, North America and South America. Of course, the decrease in temperature did not occur at the same time all over the world but it can be summarized that in 3500–3000 years BP temperature dropped by 2–3°C from the maximum of the Hypsithermal period. In the Near East this period was characterized by a mild dryness and in northwestern India a sharp dryness. Such severe desertification at the zone around 25–35°N was caused by the northward shift of the subtropical high-pressure zone in this period. The polar frontal zone also shifted poleward and wet conditions prevailed along both zones. There are other indications that the climate became slightly wetter in the tropical zone during this period, which may have been caused by the intensification of tropical westerlies. In short, in the period 3500–3000 yr BP the temperature decrease and the change in wet and dry conditions caused by the shifting of frontal zones and the subtropical high-pressure zone were striking features.

By 2500 years BP the renewed cooling trend of climates in the north had steepened the thermal gradient again, resulting in stronger circulation, longer wavelength, and more penetration of the westerlies over Europe (Lamb et al., 1966). Around 2850 years BP, glaciers in northern Europe and the Alps advanced suddenly and rivers were frozen in many parts of Europe due to the cold climate. East Asia was also cold during this period.

Suzuki (2000) compiled also the climatic change curves during the last 1100 years all over the world, as shown in Figure C9. The fluctuation ranges and phases are rather different region to region. Roughly speaking, however, the fourth to fifth centuries AD were colder and wetter in most regions. The evidence of climatic changes has been clarified recently (Bradley and Jones, 1992).

Ancient civilizations

After the climax stage of the last glaciations, the climate became warmer and reached its peak of the Hypsithermal as mentioned above. Until 12000 years BP, human inhabitants in the northern part of the Near East had lived in caves and hunted wild game in mountain areas. With the climatic change to warmer conditions they came down to open living sites in the foothills where the ground was more favorable for cultivation (Wright, 1968). A northward shift in the tree line (tundra boundary) was seen in Europe. In accordance with the invasion of woodland-type vegetation, insects, birds, and fish extended their ranges.

During the warmest postglacial time, between 6500 and 5000 years BP, the Sahara was much more humid than today. Animals and humans could roam about and cross what is now the world's greatest desert. The moist condition of the Sahara is supported by the study of the change in water levels of Lake Chad and other lakes (Messerli, 1980). Although the levels fluctuated severely in the beginning of the postglacial time, they reached their highest levels about 8000 years BP, with a second peak about 5000 years BP.

Cooling first occurred in higher latitudes after about 5500 years BP. Especially after 4800 years BP the moist regime began to decline. The drier conditions confined human settlement and animals to oases and river valleys such as the Nile, Mesopotamia, Indus, and Hwang-ho (Yellow River). In this period, summer temperatures were 1–3°C higher than today's but winter temperatures were variable. The drying tendencies from about 5500 to 4800

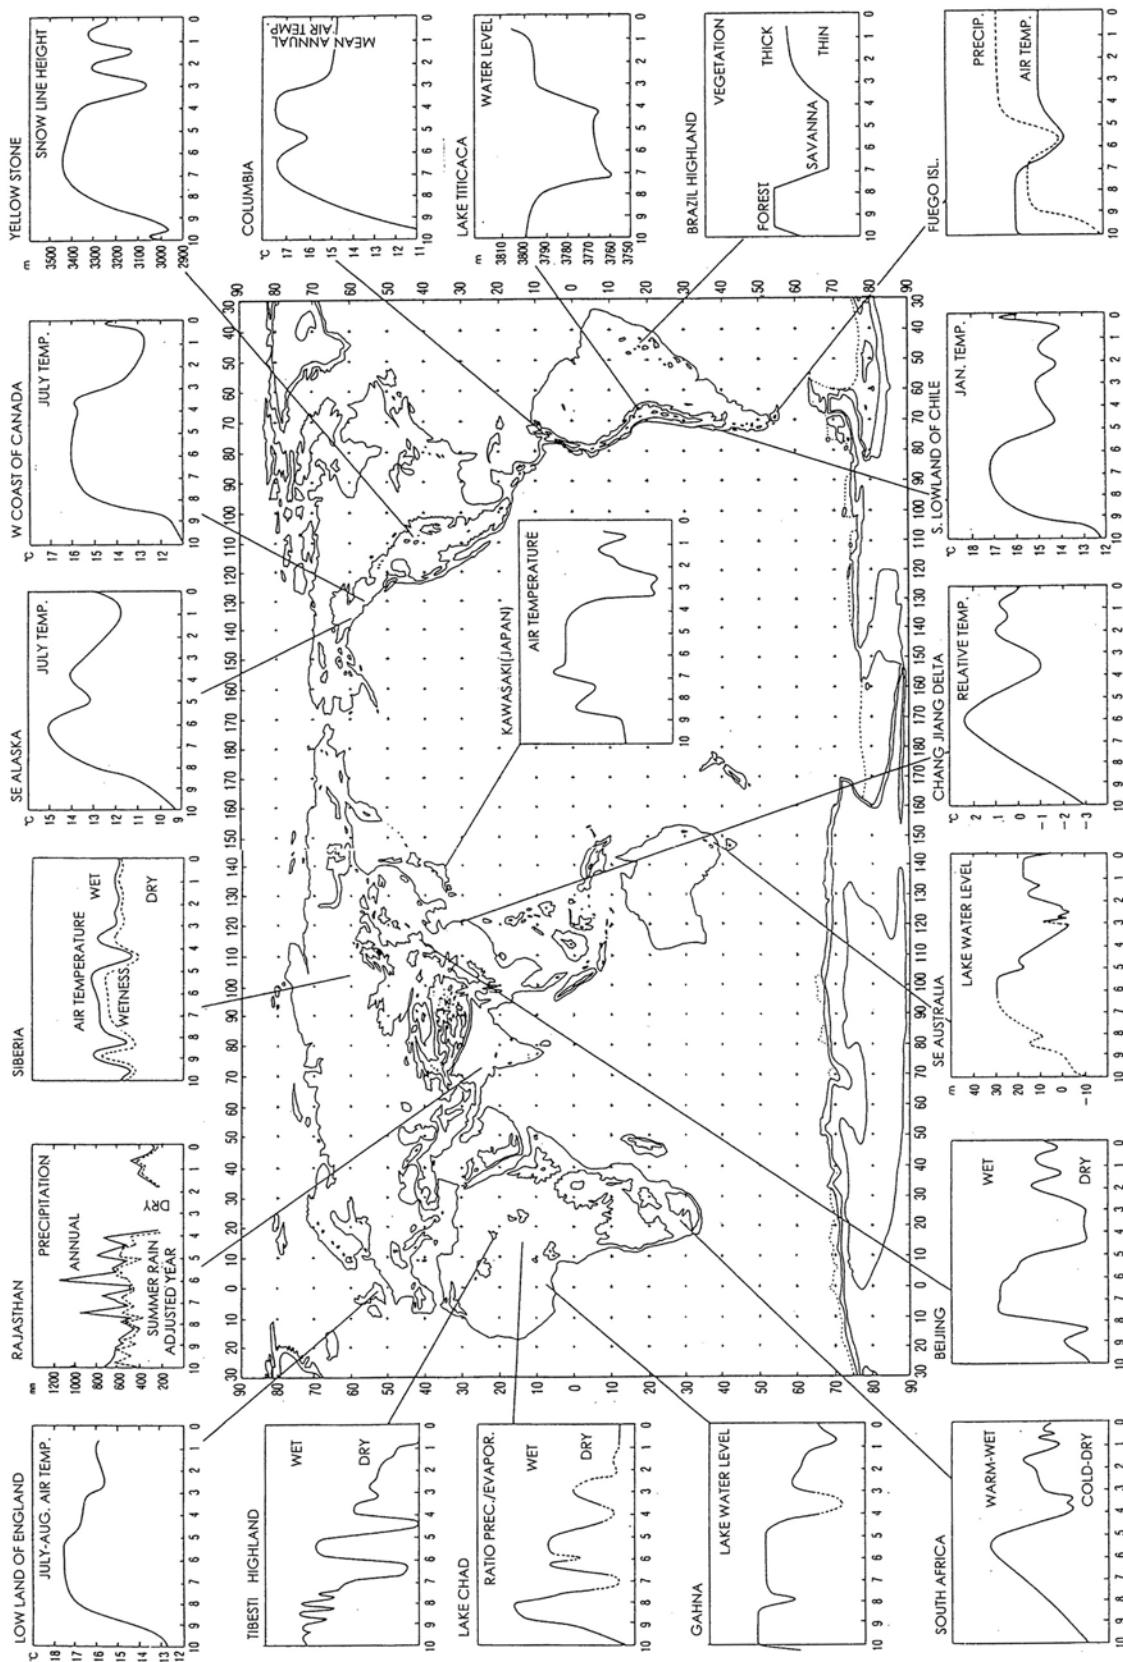

Figure C7 Climatic change curves during the last 10 000 years (after Suzuki, 2000, pp. 8–9).

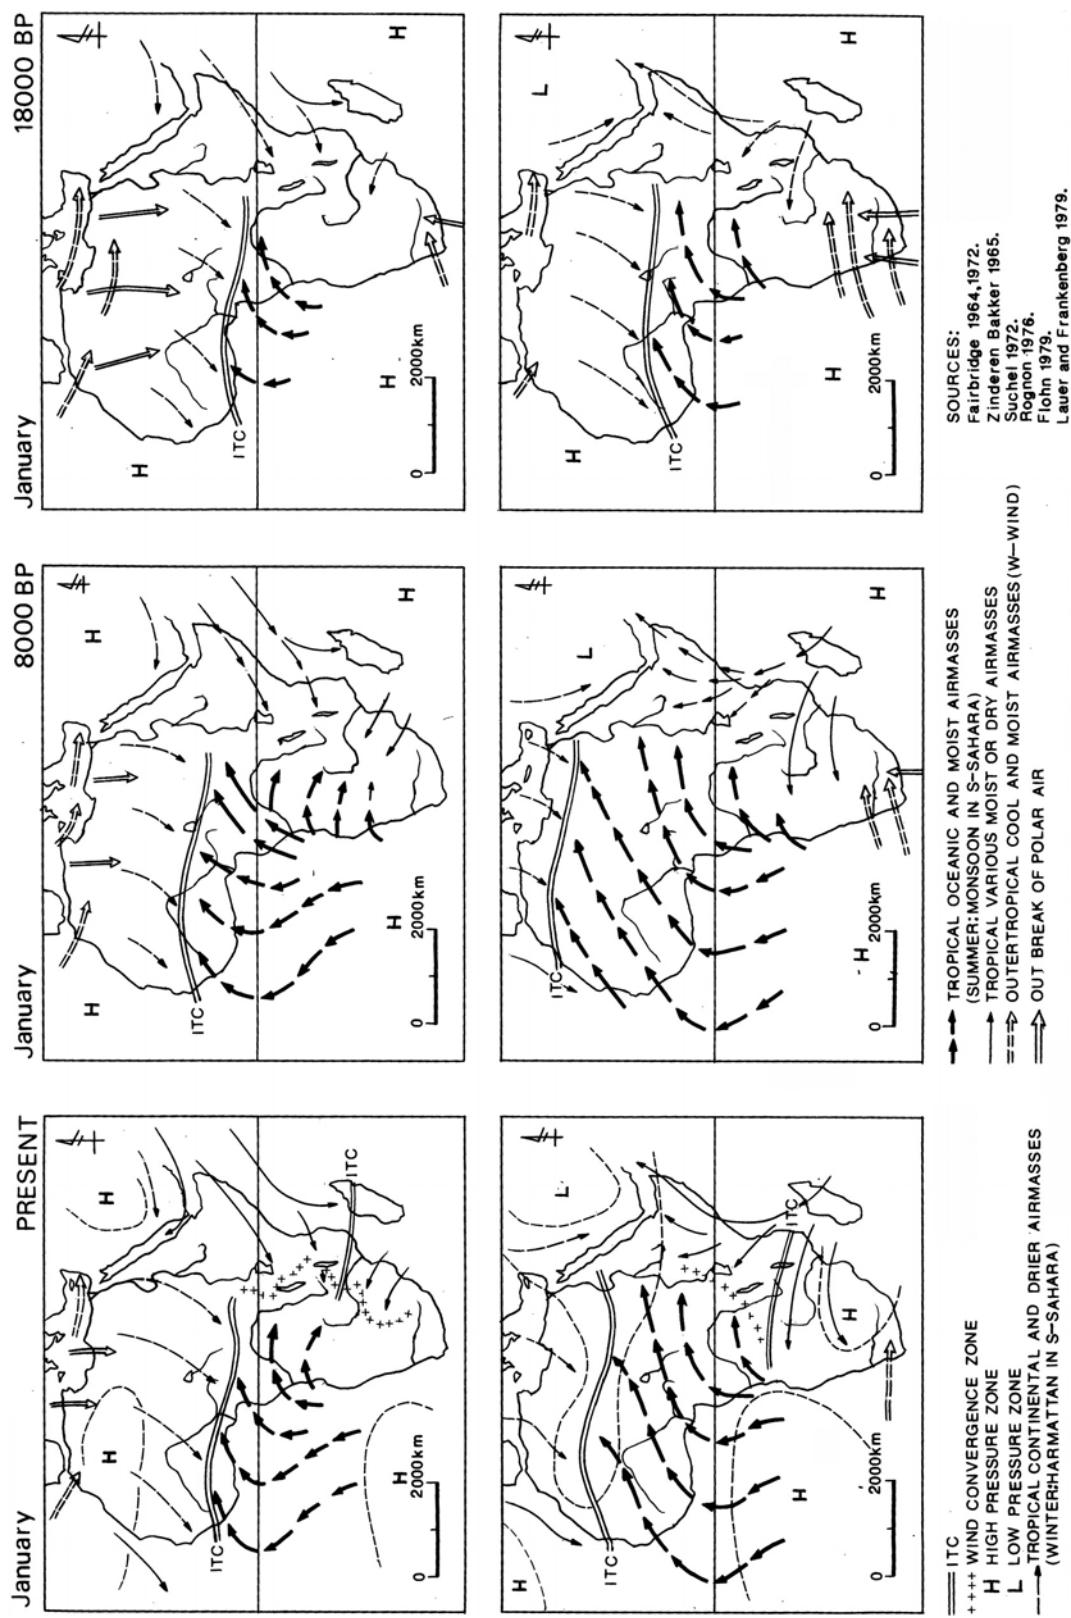

Figure C8 Circulation patterns in Africa at present, 8000 years BP, and 18000 years BP (after Messerli, 1980, p.84).

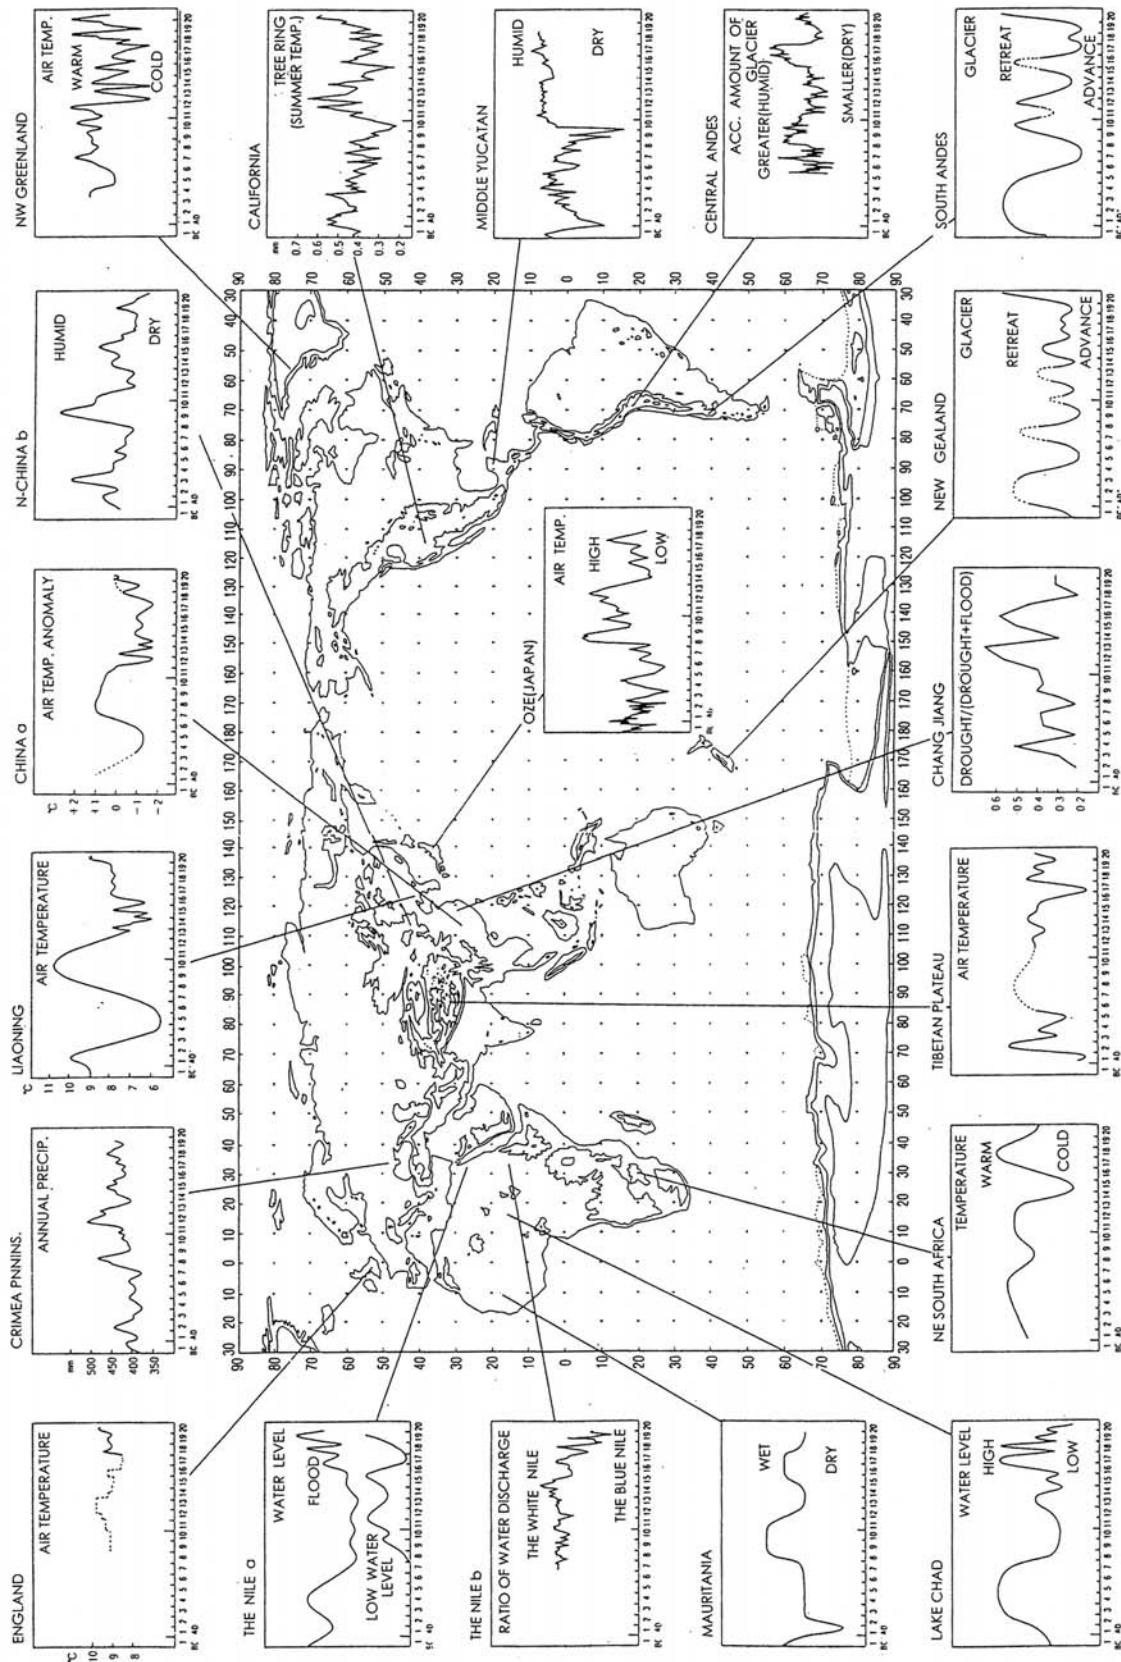

Figure C9 Climatic change curves during the last 2100 years (after Suzuki, 2000, pp. 126-127).

years BP onward seem to have been related to a climatic development of hemispheric, and probably global, extent (Lamb, 1982a). Butzer (1966) also suggested that the Sahara recorded a moister subpluvial period between about 5500 and 2350 BC (with interruption by one or more dry spells) and a hyperarid oscillation between 2350 and 870 BC. This can also be observed on the curve of ratio for precipitation/evaporation in Lake Chad in Figure C7.

The dry and wet conditions also differed, from region to region during the Hypsithermal, as also shown in Figure C7. The regional change in cultural practices during the postglacial period is closely related to the climatic change, mainly due to the change of hunted animals. Irwin-William and Haynes (1970) reported changes in Paleo-Indian cultural areas in the southwestern United States since 11 500 years BP. After the last glacial period the dryness increased gradually and the Hypsithermal period was the driest in the Paleo-Indian region. Accordingly, their cultural area retreated owing to the decrease in the number of bison. Then, in the period between 5000 and 4500 years BP, a wet condition pervaded this region and a dramatic increase in population took place.

In Egypt, between the first and the second Dynasty (2152–2040 BC), and between the second and the third Dynasty (1552–1069 BC), periods of chaos prevailed. As one of the causes for confusion, Bell (1975) pointed out the anomalous changes of flood levels of the River Nile; which have a close relation to Egypt culture. These periods coincide roughly with the water-level changes of Lakes Faiyum and Moeris (Hassan, 1986), and the sea-level change of the Mediterranean (Fairbridge, 1965) as well as water-level changes of lakes in East Africa (Butzer, 1976) which were of course related to the monsoon rainfall and evaporation changes of the region.

In China, during the Hypsithermal period, the overall average temperature may have been about 2°C warmer and the mid-winter temperature about 5°C higher than today. This enabled the cultures of the Yanshao and Yin-Hsu periods to flourish, because there were rich subtropical fauna and flora concentrated around old cities such as Sian (Xi'an) and Anyang (Chu, 1973). It is assumed that, at the beginning of the Chou Dynasty (1066–256 BC), the climate was warm enough to grow bamboo extensively in the Hwang-Ho valley. The cultivation was destroyed, however, and when protracted droughts followed, as well as freezing up of the Yangtze River region.

The first Chinese Neolithic agricultural civilization developed in the northern China plain. The sudden advance to a Bronze-Age culture and the cultivation with irrigation of wheat and millet seem to suggest some contact with the European culture across Central Asia, possibly during a moist period.

In Japan the Hypsithermal corresponded with the early and middle Jomon (Jomon) period (Fukui, 1977). The Jomon culture seems to have been established by the people who came from the west during the warmer Jomon period. After about 4000 years BP the climate tended to deteriorate; it was warm but unstable. In the second half of the latter stage of the Jomon period a cooler climate affected northern Japan: the wetter region retreated to southwestern Japan due to the southward shift of the polar frontal zone during the warm season (Yasuda, 1995). There is evidence that the Jomon culture developed first in the east, then migrated to the southwest. This may be attributed to the shifting of wetter regions in Japan (Yasuda, 1997).

The Yayoi period in Japan began about 2500 years bp, when the climate became cooler. This cooler period coincided with the above-mentioned cool period of the Chou Dynasty in China. There was a warm stage between 800 and 400 bc. Air

temperature in the Yayoi period seems to have been 1.0–1.58°C lower than today. In northern Japan it was cooler and wetter than today, with its peak in about 2500 years bp (Yasuda, 1978, 1995). Paddy rice cultivation spread from southwestern to northeastern and northern Japan and established the basis of Japanese culture today, even though the climatic conditions were not friendly in this period. It is interesting that even among the different cultures in different periods there are similar phenomena; namely, the coincidence in timing of the rise of a new culture with the decline of the prevailing favorable climate, as in the timing of the rise of the stone age culture in the Old World and its decline during the Hypsithermal.

A question is, why were flourishing civilizations not in the valleys of other great rivers such as the Ganges, the Yangtze, and the Mississippi, as they were in the Nile, Hwang Ho, etc.? At least one reason for this absence can be attributed to the climate. It seems that the drier conditions in the less inhabited valleys during the Hypsithermal did not experience the passage of the ITCZ or polar frontal zones in this period.

Summarizing the relationship between the beginning of ancient civilizations and their climates, we may conclude that the ancient major civilizations began around 5000 years BP – this was the time after the peak of the Hypsithermal. Strictly speaking, civilization began in the valleys along great rivers located in the marginal regions that started to experience cool and dry conditions. The rise of Egypt and the organized cultivation of the Nile valley by the use of early floods for irrigation may have been the necessary response to the increased food demand in a newly habitable region. In other words, civilization came about through the need to organize irrigation systems to produce food for the increased population, while the refugees presumably provided slave labor (Suzuki, 1979; Lamb, 1982a). The disruption of established ways, which the climatic events caused, provided the challenge and stimulus for undertaking deliberate cultivation and invention of new tools.

The decline of ancient civilization took place around 3500 years BP, which was a turning point in postglacial climatic history. It is obvious that the ancient civilizations were not able to continue in the valleys along great rivers because increasingly drier climates caused limited crop production.

The agricultural areas had been greatly reduced by 3500 years BP, and agricultural production was influenced by the decreased rainfall, e.g. several hundred millimeter decreases in rainfall in the Indus valley. Outside the agricultural areas, people had to shift to regions to live in accordance with the retreat and advance of grassland. The climate change was the cause of decline in the ancient civilizations and the migration of peoples.

In Roman times (Rome was founded in 753 BC) the Mediterranean world had a cooler climate with more winter rains (primarily from 600 to 200 BC). This period was one of great fertility for Greece, northern Africa, the Carthaginian, and later Roman croplands. For a few hundred years there was a warming tendency and increasing dry weather until about AD 400.

During the days of early Babylonia and Egypt there were two great inventions. One was the art of fashioning iron into tools with a cutting edge, and the other was the building of seagoing ships. The first invention meant that humans could now live quite comfortably in colder or more humid climates than those of Babylonia or Egypt. The second, shipbuilding, can be considered in relation to forest management. During the greatest days of Greece, the contrast between wet winters and dry summers was less marked than today. Such conditions were favorable for the growth of forests.

Viewpoints

There are several viewpoints on the relationship between climate and civilization (Pittock et al., 1978). In particular, the rise and fall of ancient civilizations seems to have been closely related to the change in climate. The ancient civilizations were built up on the basis of hunting and nomadism, which depended on the distribution of vegetation and animals. The flourishing of the ancient civilizations was supported by agricultural production and a definite form of organized village life.

Huntington (1945) wrote on the role of climate in developing civilizations in the Babylonian and Mesopotamian regions. He pointed out rightly that "the real problem [in developing civilizations] is to determine the exact nature of the [climatic] influence, its magnitude, and the extent to which its favorable and unfavorable aspects have counteracted one another". Because of his general deterministic treatment of the relationship between climate and human activities, including civilization, his descriptions are not accepted by many people today. However, at least as far as his account of the ancient civilizations is concerned, his description is a sophisticated one. As pointed out by Spate (1952) and Oliver (1973), the historian Toynbee presented many similar ideas, although in a much more literary fashion.

It seems that the second half of the twentieth century was a time to discuss how climatic change may have influenced history (Manley, 1958; Carpenter, 1966; Lamb, 1968; Claiborn, 1970; Le Roy Ladurie, 1971; Singh, 1971; Chu, 1973; Dansgaard et al., 1975; Bryson, 1978; Suzuki, 1979, 2000; Wigley et al., 1981; Lamb, 1982a; Issar, 1998). Ranging from determinism to probabilism, and possibilism to voluntarism, there can be various viewpoints on climate–civilization relationships (Oliver, 1973). Civilization is effected by economic determinism, political instability, racial invasion, decreasing activity, disaster by disease, population decreases etc., as well as climatic change (Yoshino et al., 1993). However, at the present stage, it can be concluded that even though the Holocene fluctuations are of relatively small magnitude, they have been sufficient to trigger cultural change in marginal situations. As Bryson (1978) wrote, cultural change includes changes in the economic base, such as agriculture, hunter-gathering, and herding. How humans responded to cultural change, i.e. in situational modification of lifestyle, migration, or literal disappearance of the people, must be determined locally.

CLIMATE CHANGE AND GLOBAL WARMING¹

Coal, oil, and natural gas that were formed from the fossilized remains of ancient plants and animals (leading to the term *fossil fuels*) provide 80–85% of the world's energy. This energy contributes to sustaining the world's standard of living and provides much of the power for transportation, generation of electricity, home heating, and food production. Compared to other sources of energy, fossil fuels are relatively inexpensive, transportable, safe, and abundant. At the same time their use contributes to environmental problems such as urban air pollution, acid rain, and elevated levels of mercury (particularly in the Arctic) that arise from trace elements in the fuels, and to long-term climate change that arises because combustion of these fuels releases carbon to the atmosphere that has been geologically sequestered for hundreds of millions of years. The health and environmental problems from the trace element emissions can be reduced by conventional emission control strategies. However, while some carbon can likely be sequestered in the deep ocean or in soils, sharply cutting overall carbon emissions will require substantial reductions in the combustion of fossil fuels for generating energy. The governments of the world began this process by negotiating the UN Framework Convention on Climate Change in 1992 and many of the developed nations are taking the first implementation step by adopting the Kyoto Protocol that was negotiated in 1997.

Concerns about the potential climatic influences of the burning of fossil fuels are not new. During the nineteenth century,

initial interest focused on determining where the carbon went when coal was burned; analyses sought to determine if the atmospheric concentration of carbon dioxide (CO_2) would increase or if new carbonaceous fuels were being formed as rapidly as they were being combusted. In 1897 Swedish scientist Svante Arrhenius suggested that combustion of fossil fuels would cause the atmospheric CO_2 concentration to build up, and he calculated that this would lead to an increase in global temperatures because this gas absorbs and re-radiates infrared radiation. Just before World War II, British scientist G. S. Callendar reported observations indicating both a rising atmospheric CO_2 concentration and rising temperatures over much of the northern hemisphere. However, because analyses of ocean chemistry suggested that the oceans could take up the excess CO_2 , and because northern hemisphere temperatures seemed to be cooling during the late 1940s and early 1950s, Callendar's results were only slowly accepted. In 1957 American scientists Roger Revelle and Hans Suess recognized that, because of ocean chemistry and the slow mixing of surface and deep ocean waters, the oceans would only be able to slowly moderate the excess CO_2 concentration that was being created by the combustion of fossil fuels. They coined the phrase "great geological experiment" to describe what was occurring. To provide the observations needed to confirm their findings, C. David Keeling established a monitoring station atop Mauna Loa in Hawaii to sample the CO_2 concentration in relatively clean and well-mixed air that was expected to represent the average conditions for the northern hemisphere. Over the next several years his observations of the rising CO_2 concentration, along with new calculations with atmospheric radiation models carried out by Syukuro Manabe and his colleagues at the Geophysical Fluid Dynamics Laboratory in Princeton, NJ, led to increasing acceptance of the suggestions of Arrhenius and Callendar. In a 1965 report of the US Government's Council on Environmental Quality, a panel of prominent scientists, led by Roger Revelle, reported to President Lyndon Johnson on the potential for global climate change and consequent impacts.

In the nearly four decades since this first report to government policy makers was submitted, much more information has become available on all aspects of this issue, which has come to be known as human-induced "global warming", even though this term greatly oversimplifies the complexity and diversity of the response of the climate system. Of particular importance have been the international scientific assessments prepared by the Intergovernmental Panel on Climate Change (IPCC), which was established in 1990 under the auspices of the United Nations (see listings of IPCC assessments in the Bibliography; references to the full scientific literature are provided in the technical chapters of these assessments). These assessment reports periodically summarize and evaluate the state of scientific understanding, and the IPCC findings have been unanimously accepted by representatives of the roughly 150 member nations, and endorsed by the leading national academies of science in the world.

Although uncertainties remain about many aspects of the chain of events from emissions to changes in concentration to climatic effects to societal and environmental impacts and options for addressing and responding to the issue, the broad outlines of the global warming situation are quite well established. This article summarizes the state of current understanding about changes in atmospheric composition and climate that are likely to occur as a result of past and future combustion of fossil fuels. An accompanying article provides an overview of the potential impacts of climate change and the challenge of adapting to the

¹This paper is updated from MacCracken, M. C., 2001, Global warming: a science overview, in *Global Warming and Energy Policy*. New York: Kluwer/Plenum, Kluwer, pp. 151–159.

changes, and indicates the level of effort required and underway to limit long-term climate change.

Changes in atmospheric composition

That the composition of the atmosphere is changing is evident from many types of observations. For example, over the past several decades, dozens of observing stations have been established in pristine areas from the South Pole to Point Barrow, Alaska. Observations at all of these stations indicate that the global background concentrations of a number of gases present in the atmosphere at trace levels are increasing. In particular, the atmospheric concentrations of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), and of various halocarbons – including hydrofluorocarbons (HCFC) and, until very recently, chlorofluorocarbons (CFC) – are all increasing. Attention is focused on these gases, which are collectively referred to as “greenhouse” gases, because these gases can exert a warming influence that enhances the Earth’s natural greenhouse effect through their absorption and downward re-emission of the infrared (heat) radiation emitted from the surface and lower atmosphere (see further explanation in next section).

Changes in greenhouse gas concentration

Atmospheric concentrations of greenhouse gases have been measured since 1957 and reconstructed for periods prior to when the instrumental record began. For example, by measuring the composition of air trapped in the bubbles in ice cores drilled through the Antarctic and Greenland ice sheets, the history of the CO_2 concentration now reaches back over 400 000 years. These records indicate that, except for a number of the halocarbons that were created in the early twentieth century for use as refrigerants, these gases were present in the natural (or preindustrial) atmosphere, but at much lower concentrations than at present. By looking at such factors as the history of emissions versus concentrations, analyses of carbon isotopes, tree rings, and other scientific measures, it is clear that human activities have caused the increase from the preindustrial level that has persisted since the end of the last glacial.

Taken together, these results indicate that, as of late 2004, the CO_2 concentration of about 380 parts per million by volume (ppmv) is about 35% above its preindustrial level of about 280 ppmv. In addition, the long record indicates that the present value has not been exceeded back through at least the past few glacial cycles (and likely as far back as several million years or more). The analyses also indicate that the increase in the CO_2 concentration since the mid-nineteenth century has been due primarily to the combustion of fossil fuels and secondarily to the release of carbon occurring in the clearing of forested land and the plowing of soils for agriculture (see Figure C10).

Similarly, the CH_4 concentration is up over 150% compared to its preindustrial value. The analyses indicate that its increase is due primarily to human-induced emissions, including particularly from rice agriculture, ruminant livestock, biomass burning, landfills, and fossil fuel development, transmission, and combustion. Analyses of past concentrations and emissions of halocarbons, however, indicate that many of these compounds were not present in the preindustrial atmosphere and are solely a result of human activities.

By comparing emissions and concentrations it is evident that the persistence (or lifetimes) of the excess contributions of these gases in the atmosphere range from decades (for CH_4) to

centuries (for CO_2 and some halocarbons) to thousands of years (for some perfluorocarbons). For this reason, even in the absence of future emissions, the excesses of their concentrations above natural levels are expected to persist for many centuries. Because of their long lifetimes, the concentrations of these gases tend to be quite uniform around the world, with local variations occurring indicating strong source regions (and for CO_2 , possibly strong seasonal uptake or release by vegetation).

Aerosols

Observations of atmospheric composition also indicate that human activities are contributing to an increase in the atmospheric concentrations of small particles (called aerosols), primarily as a result of emission of sulfur dioxide (SO_2), soot, and various organic compounds. A large fraction of the emissions of these human-induced aerosols results from the combustion of fossil fuels (primarily from coal combustion and diesel and two-stroke engines), with a somewhat smaller fraction resulting from biomass burning. Once in the atmosphere these compounds are transformed and combined in various ways. For example, SO_2 emissions are transformed into sulfate aerosols that create the whitish haze common over and downwind of many industrialized areas. Changes in land cover, especially where this leads to desertification, can also lead to increased lofting of dust particles into the atmosphere.

Of critical importance is that the typical lifetime of aerosols in the atmosphere is less than 10 days. Sulfate and nitrate compounds, for example, are often removed when they first encounter rain systems, causing the acidification of precipitation known popularly as acid rain. Because of their relatively short lifetime in the atmosphere compared to greenhouse gases, the radiative influence of aerosols is most often regional. As a result, large and sustained emissions must occur for aerosols to have a climatic influence that is comparable to the warming influences of the long-lived greenhouse gases.

Because aerosols have direct effects on human health and on visibility, control measures have tended to limit aerosol buildup in most developed nations; however, aerosol concentrations have become quite high in particular regions in many developing nations and in regions where biomass burning is extensive. Recent research is indicating that, in addition to the pollutant effects, the aerosols are causing regional disturbances of the climate. For example, aerosols lofted in southern Asia, primarily from two-stroke engines and inefficient combustion in homes and factories, may be contributing to the diminishment of the monsoon (Lelieveld et al., 2001). In addition, aerosols can have hemispheric effects when they happen to be carried across oceans by the large-scale atmospheric circulation and do not encounter precipitation systems.

Summary

Although natural processes can also affect the atmospheric concentrations of gases and aerosols, observations indicate that natural factors have not been an important cause of significant changes in atmospheric composition over the past 10 000 years. Combined with the evidence of changes in source emissions, this preindustrial stability in atmospheric composition makes it clear that human activities have been the major cause of the dramatic increases in greenhouse gas concentrations since the start of the Industrial Revolution.

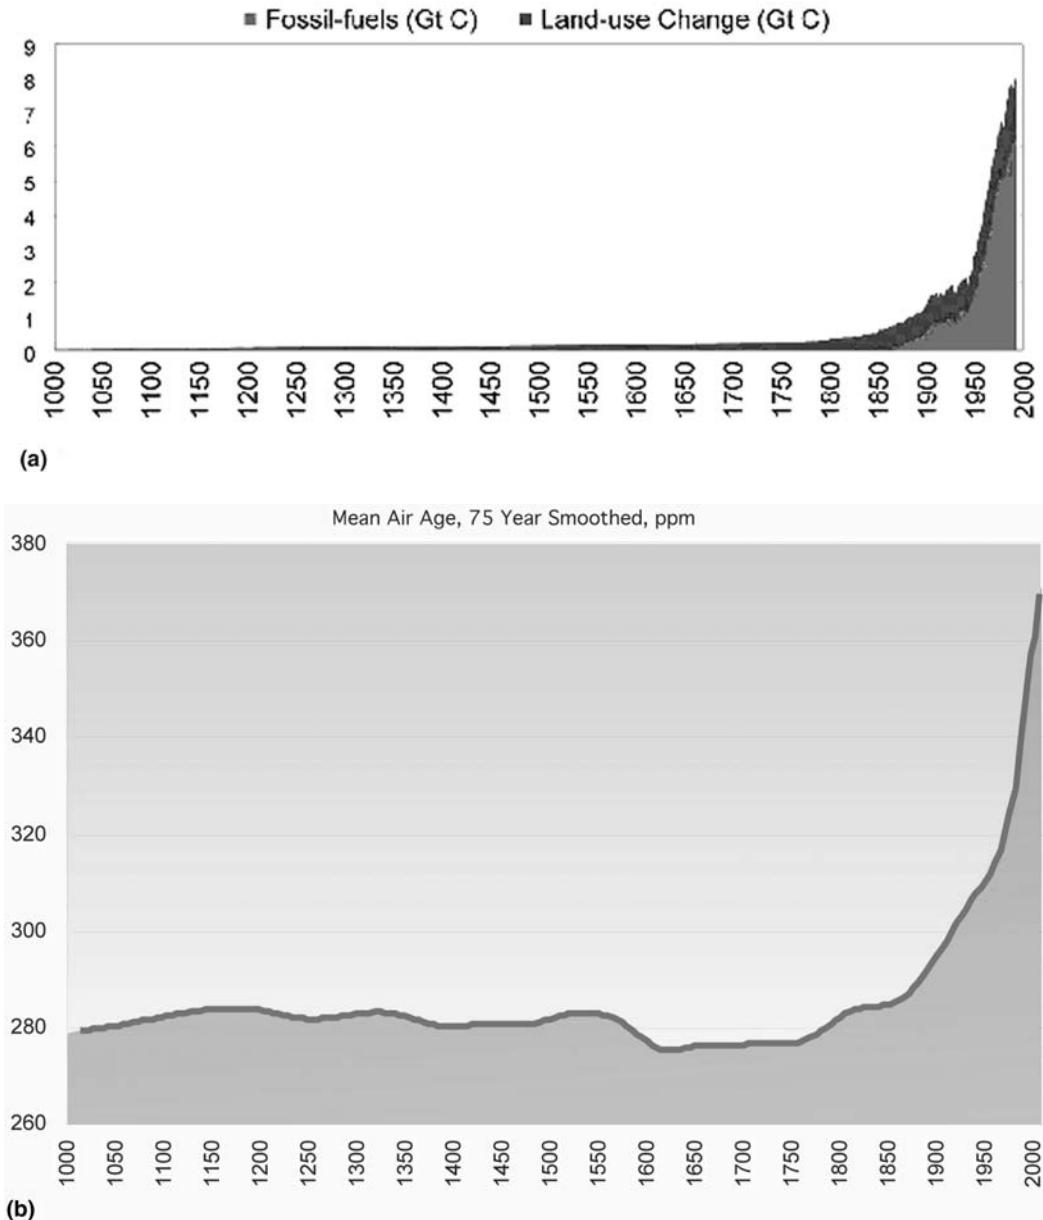

Figure C10 (a) Reconstructions of CO₂ emissions for the last 1000 years. Emissions of CO₂ since 1750 are based on compilations for land clearing and for combustion available from the Carbon Dioxide Information and Analysis Center (CDIAC, <http://cdiac.esd.ornl.gov>). (b) Reconstruction of the CO₂ concentration for the last 1000 years. This record is based on the concentration of CO₂ in ice core bubbles up to the early twentieth century (Etheridge et al., 1998) and instrumental records from Mauna Loa since 1957 (Keeling, 1999).

Intensification of the greenhouse effect

From laboratory experiments, from study of the atmospheres of Mars and Venus, from observations and study of energy fluxes in the atmosphere and from space, and from reconstructions of past climatic changes and their likely causes, it is very clear that the atmospheric concentrations and distributions of radiatively active gases play a very important role in determining the surface temperature of the Earth and other planets. Figure C11 provides a schematic diagram of the energy processes and fluxes that determine the Earth's temperature.

Of the solar radiation reaching the top of the atmosphere, about 30% is reflected back to space by the atmosphere (primarily by clouds) and the surface; about 20% is absorbed in the atmosphere (primarily by water vapor, clouds, and aerosols); and about 50% is absorbed at the surface. For each part of a system to come to a steady-state temperature the energy absorbed in each component of the system must be balanced by the energy lost. For the planet as a whole, the radiation that is emitted away as infrared (or heat) radiation must balance the amount of solar energy absorbed. Were the Earth's

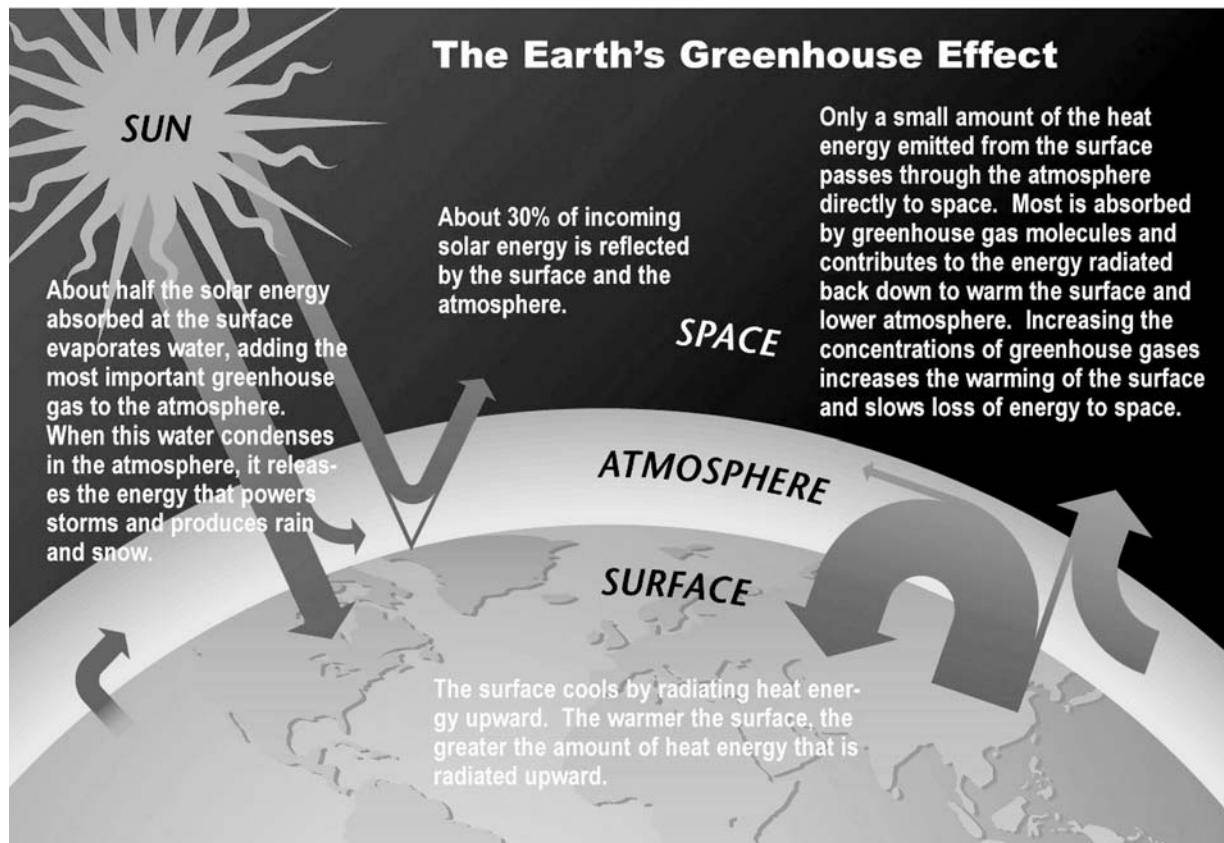

Figure C11 Schematic diagram of the energy fluxes that create the Earth's greenhouse effect. The width of the arrows is proportional to the amount of energy. Total incoming energy from the Sun averages 342 Wm^{-2} (NAST, 2000).

atmosphere transparent, and its surface a simple radiator of energy to space, the Stefan–Boltzmann equation could be used to calculate that the Earth's average surface temperature would equilibrate at close to 0°F (-18°C), given the current reflectivity of the Earth–atmosphere system. Such a temperature would be much too cold to sustain life as we know it.

However, the Earth's atmosphere is not transparent to infrared radiation; instead, a number of gases are able to absorb and emit infrared energy (to be radiatively active, molecules need to have at least three atoms so that various rotational and vibrational bands can be excited by the radiation). As a result of this property of particular atmospheric gases, a warming influence on the climate is created. This warming effect occurs because a large fraction of the infrared radiation emitted by the surface and by the greenhouse gases and low clouds in the atmosphere is absorbed by these radiatively active atmospheric gases before the energy is lost to space. For example, less than 10% of the infrared radiation emitted by the surface is at wavelengths that pass through the atmosphere directly to space without being absorbed. The energy that is absorbed in the atmosphere tends to warm it, in turn causing the radiatively active gases in the atmosphere and the clouds to emit infrared radiation. A significant fraction of this energy is radiated back toward the surface, providing additional energy to warm the surface. This radiation in turn causes the surface to warm, which raises its temperature and causes more radiation to be

emitted upward, where much of it is again absorbed, providing more energy to be radiated back to the surface.

This emission-absorption-re-emission process that recycles energy back to the surface is popularly called the greenhouse effect, even though the processes are radiative and so are different from the limitations on loss of energy by convection and to freely flowing air that keep a greenhouse warm and humid. The Earth's natural greenhouse effect raises the average surface temperature from about -18°C (the temperature at which the Earth would radiate away as much energy as it absorbs from the Sun given its current albedo) to the observed value of about 15°C .

Radiative effects of greenhouse gases

The amount of this greenhouse warming is determined by the concentrations of greenhouse gases in the atmosphere. If the concentrations of greenhouse gases are increased, this causes an intensification of the natural greenhouse effect, inducing some warming. An additional warming influence results because the atmospheric temperature decreases with altitude up to the tropopause (about 10–12 km above the surface) before temperatures start to rise again in the stratosphere, which is warmed primarily as a result of solar absorption by ozone (O_3) molecules. When the concentrations of greenhouse gases are increased and the atmosphere becomes more opaque to infrared radiation, the atmosphere's vertical temperature structure (i.e.

its lapse rate) causes the absorption and reemission of infrared radiation to the surface to occur from lower and warmer layers in the atmosphere. Because the emission of infrared energy is proportional to the fourth power of temperature, this has the effect of increasing the downward-emitted radiation, tending to further enhance the natural greenhouse effect. Similarly, because of the resulting changes in the atmosphere's infrared opacity, increasing the concentrations of greenhouse gases tends to cause the emission of infrared radiation outward to space to occur from higher and colder layers; this leads to less radiation being emitted to space for a given average temperature of the lower atmosphere. With less infrared energy being emitted from the surface-atmosphere system to space, the excess of absorbed energy will cause the system to warm in order to re-establish the planetary energy balance.

The most important radiatively active (or greenhouse) gas is water vapor. Not only does water vapor absorb infrared radiation emitted from the Earth's surface and lower atmosphere, but it also absorbs infrared radiation from the Sun. In addition, under appropriate conditions, water vapor can condense and form clouds that absorb and emit infrared radiation as well as absorbing and scattering solar radiation. The amount of water vapor in the atmosphere is largely determined by the large-scale surface temperature of the Earth, with atmospheric circulation and precipitation processes causing its concentration to be highly variable throughout the atmosphere. Although most of the water vapor is found within about 2 km of the surface, the small amounts at higher levels in the troposphere have very strong influences on the fluxes of infrared radiation. Because of this, changes in atmospheric convection that lead to small changes in the amount of upper tropospheric water vapor could have important climatic effects.

Although human activities loft significant amounts of water vapor into the atmosphere, these additions tend to reduce the surface-atmosphere gradient of water vapor pressure. This tends to reduce the natural rate of evaporation of water vapor, thereby moderating the radiative effects of the injected water vapor. In addition, although there is a lot of water vapor in the atmosphere, the average lifetime of a water vapor molecule in the atmosphere is only about 8 days. This short lifetime makes it very difficult for the direct effects of human activities (e.g. by water vapor injection from cooling towers) to sustain a significant increase in water vapor's natural concentration. The only exception is for the case of water vapor injected by airplane exhausts at altitudes where water vapor molecule lifetimes are relatively long. Present levels of injection in this manner exert a relatively small warming influence that is balanced somewhat by the additional reflection of solar radiation from contrails.

Other than water vapor, the primary radiatively active gases are CO₂, CH₄, N₂O, and a number of HCFCs and CFCs. Because the concentrations of these gases are being directly affected by human activities, these greenhouse gases are usually referred to as the anthropogenic greenhouse gases (strictly speaking, their concentrations are being anthropogenically modified). In addition, the tropospheric and stratospheric concentrations of O₃, which is also a greenhouse gas, are being indirectly affected through chemical reactions caused by the emissions of gases such as non-methane hydrocarbons and nitrogen oxides, many of which are also tied to use of fossil fuels for energy.

Changes in the radiation balance

Changes in the concentrations of aerosols can also affect the radiation balance. Sulfate aerosols tend to be quite bright, and

can exert a cooling influence on the climate by reflecting away a higher fraction of solar radiation than darker ground and ocean surfaces that typically lie below. Dust lofted by the winds also generally has a cooling influence on the climate. Because they are so dark and absorbing, soot aerosols by themselves tend to enhance absorption of solar radiation, thereby creating a warming influence, especially over very light surfaces. The various types of aerosols can also combine to form mixed-composition aerosols that can exert either warming or cooling influences, creating significant uncertainty in the overall effect of changes in aerosol loading.

Changes in land cover can also alter the energy balance of the Earth system. Although changes in vegetation from one year to the next can seem quite small, over time they can become quite extensive. For example, most of the northeastern US was forested in pre-settlement times, then mostly cleared by the early twentieth century due to the demands for farmland, wood for ships and buildings, and charcoal to make steel. This change tended to brighten the surface, exerting a cooling influence. Over the last 100 years, however, as farming shifted to the Great Plains and the Southwest, the forests have regrown and now cover the region, tending to darken it and exert a warming influence. Some studies indicate that such changes can have not only regional effects on the climate but, by altering the atmosphere's heat balance, these changes can also cause shifts in the atmospheric circulation that result in climatic changes elsewhere. With changes of land cover occurring in many regions around the globe (e.g. deforestation in Amazonia and in southern and western Asia), significant regional perturbations in climate are likely to be already occurring along with the growing increment in the global average temperature due to the rising concentration of greenhouse gases.

In addition to changes in the radiation balance occurring due to human activities, changes can result from natural processes. Most noticeable are the influences of volcanic eruptions, which can loft millions of tonnes of SO₂ and dust into the stratosphere, where it can spread out over much of the globe and persist for up to a few years. Major eruptions, such as Mount Pinatubo in the Philippines in 1991, can reduce incoming solar radiation by of order of 1% and cause cooling of order of 0.5°C for a year or more. Major volcanic activity has tended to be infrequent, and no long-term trend in the effects of volcanoes on the radiation budget has been found, although there have been some relatively active and inactive decades.

Variations in the Sun's output are a second natural source of changes in the Earth's radiation balance. Satellite observations have confirmed indications from the surface that the Sun's output varies with the cycle of sunspots, and other indications suggest that there may be multidecadal to multicentury variations. These variations are estimated to amount to perhaps a few tenths of 1% of the solar flux, and may have caused variations in global average temperature of roughly 0.5°C over the last few thousand years.

Over periods of many thousands of years, other natural forcings can also come into play. For example, the Yugoslavian scientist Milutin Milankovitch was the first to calculate the effect on the Earth's radiation balance resulting from its orbit about the Sun being elliptical rather than circular. Over the course of tens of thousands of years, changes in eccentricity (i.e. departure from circularity), tilt of the Earth's axis, and precession of the seasons (time of year of nearest approach to the Sun) cause a redistribution of the incoming solar radiation in latitude and season. That the timing of these orbital changes and the cycling of the glaciers coincide suggests that these

changes have been the drivers of glacial cycling, especially over the last million years. The ice-core records of changes in atmospheric composition suggest that variations in greenhouse gas concentrations are likely one of several additional processes that have contributed to amplifying the climatic response to the orbital changes identified by Milankovitch.

The relative climatic influences of natural forcings and of changes in the atmospheric amounts of gases and aerosols are typically compared by using atmospheric radiation models to

calculate their ability to change the fluxes of solar and terrestrial radiation at the tropopause; that is, to alter the amount of energy entering or leaving the surface–troposphere system. The change in these fluxes as a result of changes in the amounts of gases and aerosols is referred to as the “radiative forcing” that they exert. Based on the latest international assessment report of the IPCC (2001), Table C2 summarizes the best estimates of the changes in abundances of various gases and aerosols and the radiative forcings that are estimated to have resulted since

Table C2 Greenhouse gases and aerosols contributing to changes in climate (based on information in IPCC, 2001)

Greenhouse gas or aerosol or other forcing mechanism	Approximate abundance in 1750	Approximate abundance in 2000	Estimated radiative forcing from 1750–2000 (W m^{-2})	Projected abundance in 2100 based on SRES emissions scenarios (IPCC, 2000)	Projected radiative forcing from 1750–2100 (W m^{-2})
Carbon dioxide (CO_2)	278 ppmv	369 ppmv	1.46 (plus or minus 10 per cent for all well-mixed greenhouse gases)	549–970 ppmv (reference model)	3.64–6.69
Methane (CH_4)	700 ppbv	1745 ppbv	0.48	1574–3413 ppbv	0.42–1.09
Nitrous oxide (N_2O)	270 ppbv	314 ppbv	0.15	354–460 ppbv	0.27–0.57
Perfluoromethane (CF_4)	40 pptv	80 pptv	0.003	208–397 pptv	0.013–0.029
CFC-11 (CFCl_3)	0	268 pptv	0.07	45 pptv per Montreal Protocol	0.01
CFC-12 (CF_2Cl_2)	0	533 pptv	0.17	222 pptv per Montreal Protocol	0.07
Other anthropogenic halocarbons (generally contain C, H, and Cl, Br, or F)	0	Various	~0.1	Various	~0.06–0.33
Tropospheric ozone (O_3)	Increase of ~8 Dobson units		0.35 (0.2–0.5)	–18% to +5%	0.21–1.27
Stratospheric ozone (O_3)	Depletion by several percent since about 1970		–0.15 (–0.05 to –0.25) (1979–1997)	Recovery from halocarbon injections, but some depletion due to stratospheric cooling	Uncertain, but possibly less negative
Sulfate aerosol (SO_4) – direct effect	0.52 TgS		–0.4 (–0.2 to 0.8)	0.15–0.45 TgS	–0.12 to –0.35
Black carbon (BC)	0.26 Tg		0.2 (0.1–0.4)	0.13–0.68 Tg	0.2–1.05
Organic carbon (OC)	1.52 Tg		–0.1 (–0.03 to 0.3)	0.77–4.00 Tg	–0.88 to –1.32
Biomass burning aerosols			–0.2 (–0.07 to 0.6)		
Aerosol – indirect effects due to change in cloud reflectivity			0 to –2.0		Uncertain
Mineral dust			–0.6 to 0.4		
Contrails due to jet aircraft			0.02 (0.00 to 0.07)		
Aviation-induced cirrus			0 to 0.04		
Change in surface vegetation			–0.20 (0 to –0.4)		
Solar irradiance			0.30 (0.1–0.5)		

^a From 1993 to 2002, on assignment from the Lawrence Livermore National Laboratory to the Office of the US Global Change Research Program, serving as Executive Director of the Office from 1993 to 1997 and as Executive Director of the National Assessment Coordination Office from 1997 to 2001. Presently serving as Chief Scientist for Climate Change Programs at the Climate Institute, Washington DC, and president (2003–07) of the International Association of Meteorology and Atmospheric Sciences.

the beginning of the Industrial Revolution in about 1750. Although there is considerable uncertainty in the estimates of the radiative forcing of the various types of aerosols on the radiation balance, the net effect of all of the changes that have occurred is most likely to have been significantly positive, thereby exerting a warming influence on the global climate. Indeed, observations from space-based instruments since the 1970s clearly indicate that the rising concentrations of the anthropogenic greenhouse gases are indeed tending to enhance the natural greenhouse effect.

In addition to the direct effects of changes in greenhouse gas concentrations and aerosol loading on the radiation balance, there are several types of indirect influences on the radiative forcing of a gas or aerosol. For example, changes in the amounts and types of aerosols can affect the amounts and reflectivities of clouds that in turn alter the fluxes of solar and terrestrial radiation. There can also be indirect influences through various effects on atmospheric chemistry. For example, the chemical decomposition of methane in the stratosphere creates water vapor that has a powerful greenhouse effect, and the release of various halocarbons has depleted the stratospheric ozone layer, affecting its role in the infrared radiation balance. Estimates of these indirect influences are also included in Table C2.

Feedback mechanisms

The intensity of the Earth's natural greenhouse effect is also altered through various feedback mechanisms that can amplify or moderate the system's response to the changes in radiative forcing. For example, the warming influence caused by increases in the concentrations of CO₂, CH₄, and other anthropogenic greenhouse gases can be significantly amplified by a positive water-vapor feedback mechanism. This positive feedback occurs because more water vapor can be present in a warmer atmosphere, and an increase in atmospheric water vapor enhances the greenhouse effect and causes a further warming that in turn allows more water vapor to be present in the atmosphere. At the same time, however, changes in the amount of atmospheric water vapor (more specifically, in conditions affecting water vapor removal when the relative humidity exceeds saturation) and in atmospheric circulation can alter the extent and distribution of clouds. These changes in cloud cover and distribution can in turn affect the extent of the absorption and scattering of solar radiation and the absorption and re-emission of infrared radiation, thereby creating both amplifying and moderating feedbacks.

There are many other feedbacks and interactions. For example, warming tends to reduce the amount of snow and sea ice, which in turn reduces the reflectivity of the surface (i.e. the albedo), allowing increased absorption of solar radiation, and reinforces the original warming. Over the longer term, melting of glaciers and ice sheets can similarly enhance the warming influence. Changes in the climate can also affect the type of vegetation and its extent, affecting not only the surface albedo, but also its roughness, the rate of evapotranspiration from the surface, and the lofting of dust. The ocean circulation can also be affected by the climate, with wind changes affecting surface current and changes in ocean temperature and salinity causing global-scale changes in the thermohaline circulation that ventilates the deep ocean. Over thousands of years and longer, glaciological and isostatic processes can affect the height of the land and even the shapes of coastlines, which in turn can affect atmospheric and oceanic conditions. There are thus a great

many processes and feedbacks that can potentially come into play once changes in the climate are initiated.

Climate sensitivity

Estimates of the climate's sensitivity to changes in radiative forcing have been derived from theoretical analysis, from reconstructions of climate changes in the geological past, and from simulations using global climate models. These approaches indicate that, at steady state, each increase in the radiative forcing by 1 W m⁻² seems to be associated with an increase in the global average temperature of about 0.4–1.2°C. This degree of sensitivity is also often expressed in terms of the warming that would result from the change in radiative forcing associated with a doubling of the atmospheric CO₂ concentration. When expressed in this manner, the radiative forcing from the doubling the CO₂ concentration (i.e. almost 4 W m⁻²) would lead to an increase in the global average temperature of 1.5–4.5°C. It is important to emphasize that these estimates are after a new steady-state climate is established, and that, while much of the readjustment would occur over a few decades, the full response would take many centuries because of the time it takes for the deep ocean temperature and feedback mechanisms involving glacial ice and ecological systems to come to a new equilibrium.

Overall, there is broad scientific agreement that increases in the atmospheric concentrations of the anthropogenic greenhouse gases will enhance the Earth's natural greenhouse effect and tend to raise the global average surface temperature by of order of a few degrees Celsius. The remaining uncertainties relate to pinning down by how much and how rapidly warming would occur.

Detecting and attributing past changes in the climate

With the evidence being clear-cut that the concentrations of greenhouse gases have risen significantly since the start of the Industrial Revolution, and that increasing the concentrations of greenhouse gases will induce a warming influence on the Earth's climate, then a key test of scientific understanding of the climatic influence of these changes is to determine if the time history and magnitude of historic changes in the climate match those expected to be occurring as a result of past changes in radiative forcing. Complications in this analysis arise for several reasons. First, there are shortcomings in the climate record, including a near-absence of observations at times before human-induced forcing began to have an influence on the global climate. As a result, *detecting* whether changes have actually occurred requires care to distinguish actual change from changes arising due to limitations in the data (e.g. due to the changing spatial coverage over time) and from the natural variability of the climate caused mainly by varying atmosphere–ocean interactions. Second, there are multiple influences contributing to changes in the radiative forcing; most are not definitively quantified and it is not even clear if all are yet recognized. As a result, *attributing* particular changes in the climate to particular factors requires very careful forensic analysis.

To have the best chance of both detecting and attributing the human influence, it is most useful to look at the longest records of the changing climatic state. Instrumental records of temperature go back only a few hundred years, and a reasonable network of observation stations was only established around the middle of the nineteenth century. Accounting carefully for changes in measurement technique and the local

environment, records of how the monthly and annual average temperatures at each of thousands of locations have changed from their local baseline value can be used to construct a space and time history of such changes. These results can then be used to calculate an area-weighted global average of the change in local near-surface air temperature. This quantity is often referred to simply as the change in the global average temperature, even though this terminology really obscures how its value is determined and unfortunately implies that the global average temperature is actually measured in some direct way by some single instrument.

Detecting changes in climate

Spatially representative estimates of the change in global average temperature go back to about 1860. These records indicate a warming of over 0.6°C , mostly during the early and late twentieth century. Extensive proxy records (e.g. records derived from tree rings, ice cores, coral growth, etc.) have been used to attempt to reconstruct the amount and pattern of changes in surface temperature further back into the past. For the northern hemisphere, proxy records going back about 1000 years indicate that a slow cooling was under way for most of this period. These records also clearly indicate that the twentieth century was much warmer than earlier centuries and that the decade of the 1990s was almost certainly the warmest decade of the last 1000 years. This temporal history is clearly evident in Figure C12, which indicates that a sharp rise in the average temperature began during the late nineteenth century and has continued throughout the

twentieth century. It is also clear that the twentieth-century warming has been much more persistent than earlier fluctuations, which were likely caused by the inherent natural variability of the ocean-atmosphere system (i.e. internally created variability) and natural variations in solar radiation and the occasional eruption of volcanoes (i.e. externally caused variability).

The global warming evident at the surface is also consistent with observations of increasing temperatures measured in boreholes (i.e. dry wells), retreating mountain glaciers, diminishing sea ice in the Arctic, increasing concentrations of atmospheric water vapor, rising sea level due to melting of mountain glaciers and thermal expansion in response to recent warming (augmenting the natural rise due to the long-term melting of parts of Antarctica), and related changes in other variables. As a whole, most records indicate that long-term changes in the climate have been occurring, even though some analyses of some shorter records indicate very little change (e.g. one analysis of changes in tropospheric radiance measured using microwave instruments on a succession of satellites indicates virtually no increase in the implied tropospheric average temperature since 1979, although another analysis and balloon observations of changes in tropopause height do indicate that tropospheric warming has been occurring).

Attributing climate change to human activities

A key question is whether these changes are mainly a natural fluctuation or whether human activities are playing a significant role. The twentieth-century warming is largely being attributed to

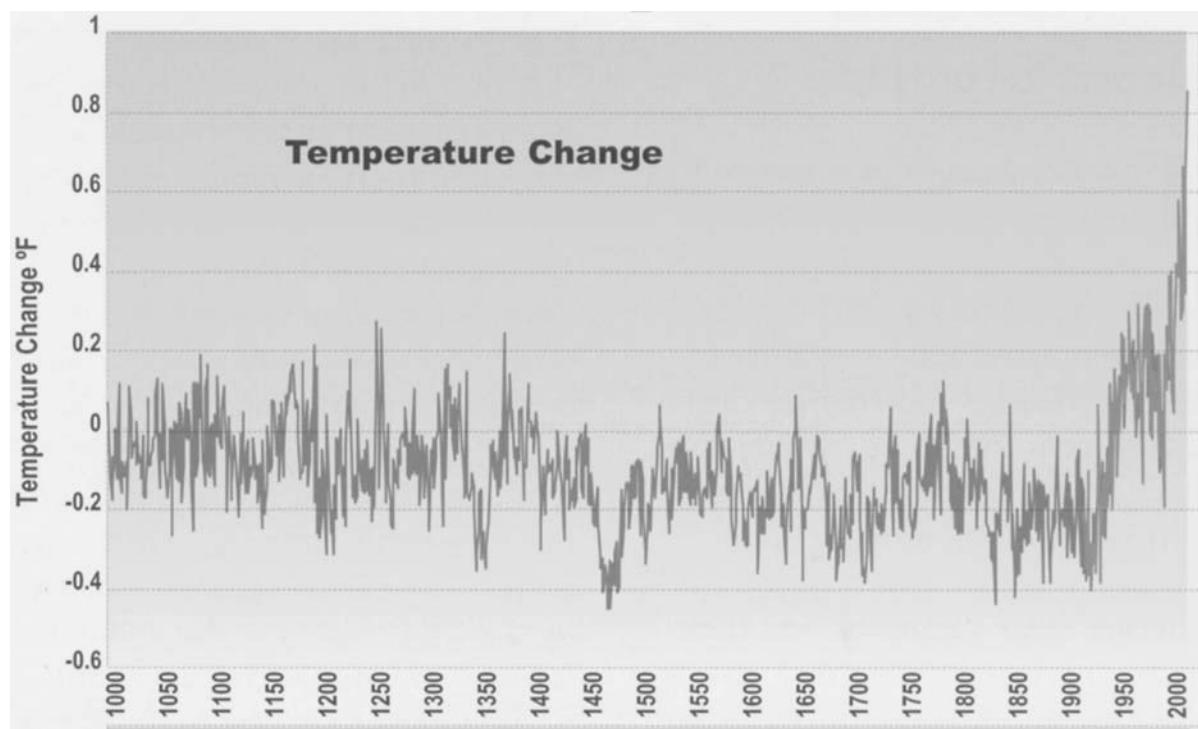

Figure C12 Reconstruction of the northern hemisphere average surface temperature for the last 1000 years. Up to the mid-nineteenth century the record is based on proxy records (e.g. tree rings analyzed by Mann et al., 1999). The estimated uncertainty for an individual year is several tenths of a degree. Since the mid-nineteenth century the record is based on instrumental data, for which the comparable uncertainty is about 0.2°F .

human activities because of the coincidence in timing with the warming influences exerted by the changes in greenhouse gas concentrations, the very large and unusual magnitude of the changes compared to past natural fluctuations, the warming of the lower atmosphere and cooling of the upper atmosphere (a sign of a change due to changes in greenhouse gas concentrations rather than changes in solar radiation), and the global pattern of warming (with larger changes in high than low latitudes). Some uncertainty is introduced because some of the warming occurred before the sharpest rise in greenhouse gas concentrations in the latter half of the twentieth century. For example, some analyses indicate that as much as 20–40% of the warming may be due to a coincidental increase in solar radiation, although other factors, such as changes in land cover or in soot emissions, may also have had an influence. In addition, some uncertainty has been introduced because the rise in tropospheric temperatures over the past two decades may have been a bit slower than the rise in surface temperature. Whether this difference is real or arises from, for example, calibration issues with the satellite instrumentation, natural variations in Earth-surface temperatures, or the confounding influences of ozone depletion, volcanic eruptions, and atmosphere–ocean interactions, is not yet clear.

Taking all of the scientific results into consideration, the IPCC concluded in its Second Assessment Report (IPCC, 1996) that “The balance of evidence suggests a discernible human influence on the global climate”. This conclusion, in essence, is equivalent to the criterion for a civil rather than a criminal conviction in a court of law. The IPCC’s Third Assessment Report (IPCC, 2001) documented even more clearly that the magnitude and timing of the warming during the twentieth century quite closely matches the changes that would be expected from the combined influences of human and known natural influences, concluding that “there is new and stronger evidence that most of the warming over the past 50 years is attributable to human activities”.

Projections of future changes in emissions and atmospheric composition

The continued reliance on fossil fuels for generation of energy and the release of other greenhouse gases are sure to cause further changes in atmospheric composition. Along with the continuing adjustment of the climate system to past changes in atmospheric composition, these changes will far exceed changes in other contributions to radiative forcing, making them the driving influences for future climate change. While it is not possible to provide definitive predictions of how the world will evolve out for decades to centuries into the future, the IPCC (2000) reviewed projections of various trends for the future and, using a number of storylines about how population, energy use and energy technologies, economic development, and international cooperation might evolve, developed a set of plausible scenarios of future emissions of greenhouse gases and some types of aerosols and aerosol precursors. These scenarios indicate, for example, that annual emissions of CO₂ in the year 2100 could range from roughly 5 to over 30 GtC/yr (billions of tonnes of carbon per year) compared to present emissions of about 6 GtC/yr.

A rough indication of what the emissions might be can be derived by simply extending trends from current values. With the global population of 6 billion people and current use of fossil fuels, each person on Earth is presently responsible, on average, for emission of about 1 tC/yr (tonne of carbon per year). Per-capita use, however, varies widely across the world, reaching nearly 6 tC/yr in North America and about 3 tC/yr in

Western Europe, but amounting to only about 0.5–1.0 tC/yr in developing countries such as China and India.

Central projections for the year 2100 foresee a global population of 8–10 billion. With the rising standard of living and the energy required to sustain it, and with continued reliance of fossil fuels for most of the world’s energy, global average per capita emissions of CO₂ seem likely to at least double, with most growth resulting from increased emissions in the highly populated, but currently underdeveloped, emerging economies. If this occurs, total annual emissions could more than triple, reaching roughly 20 GtC/yr or more. IPCC (2000) also considered the potential for variations of various kinds around an estimate such as this, with the possibility that intensified use of coal, which is among the least expensive and most available sources of energy in the developing world, could cause emissions to be even greater, whereas a drop in the rate of population growth and a greatly accelerated switch to non-carbon-based fuels could return emissions in 2100 to about current levels after higher levels through most of the twenty-first century.

If global emissions of CO₂ do gradually increase to about 20 GtC/yr by 2100, models of the Earth’s carbon cycle that are verified against observations of past increases in concentration, project that the atmospheric CO₂ concentration would rise to just over 700 ppmv. This would be almost double its present concentration, and over 250% above its preindustrial value.

For the broader set of emission scenarios that are based on consideration of ranges in global population, energy technologies, economic development, and other factors, projections indicate that the atmospheric CO₂ concentration is likely to reach at least 500 ppmv and may even exceed over 900 ppmv in 2100. The projections also indicate that the CO₂ concentration would continue to increase during the twenty-second century unless global emissions have been reduced to 1–2 GtC/yr by 2100.

Depending on various control measures, the rise in the CO₂ concentration would be expected to be accompanied by increases in the concentrations of CH₄ and N₂O, as well as of sulfate and soot aerosols, although it would take an unrealistically large (and unhealthy) amount of aerosols to affect radiative forcing to an extent that would counterbalance the radiative forcing created by the increases in the concentrations of the anthropogenic greenhouse gases that are projected. Based on IPCC scenarios and analyses (IPCC, 2000, 2001), Table C2 provides estimates of the future abundances of the various gases and aerosols as well as an estimate of the total anthropogenic contribution to radiative forcing expected by the year 2100.

Because the historical temperature record includes natural fluctuations, and because the relative contributions to radiative forcing of the various greenhouse gases and aerosols are changing, extrapolation of historic trends in temperature into the future is not a particularly reliable means for projecting future trends. Similarly, although the geological record provides evidence that both the atmospheric composition and climate have changed in the past, only a rough indication can be provided of how the climate will change over the twenty-first century because the change in atmospheric composition is occurring so rapidly. Because of these limitations, and in order to get a more complete sense of how the many climatic variables would be expected to change, projections of the climatic effects of the various scenarios of changes in greenhouse gas and aerosol emissions must necessarily be based on the use of computer-based climate models.

Global climate models

Global climate models (also known as Earth system models) are assembled by coupling general circulation models of the atmosphere and oceans to land surface and cryospheric models. Each of these component models is constructed by applying the fundamental conservation laws of physics (i.e. for mass, momentum, and energy) and chemistry (i.e. for water and various other species, including chemical transformations) to many thousands of grid cells that are used to cover (or tile) the Earth. Although atmospheric and oceanic models with resolutions of order 10 km in horizontal resolution are starting to become available, developing reliable projections of climatic change requires running multiple simulations for hundreds to thousands of years. As a result of limits imposed by present computer speed and resources, a significantly coarser resolution (e.g. 100–200 km) is being used for most model simulations of climate change. Because this resolution is not adequate to represent the details of, for example, convective cloud development and wind drag caused by variable terrain, the effects of these processes are represented in the models in terms of larger-scale variables using parameterizations that are typically derived from the results of large-scale observations or extensive field investigations of how atmospheric or oceanic processes work. In that these parameterizations are only approximate, and because it is not possible to ensure that all processes have been represented, it is essential to test the models and to carefully evaluate their results.

To develop a sense of confidence in the models a wide range of tests is often performed. The most intensive efforts have been conducted under the auspices of the Program for Climate Model Diagnosis and Intercomparison, which has programs to compare the results of the various model components with observations and with the performance of other models (e.g. Gates et al., 1999). Comparisons of model simulations to the observed behavior of the climate typically cover recent decades, recent centuries, and even geological periods in the past. In general, the models do reasonably well at representing the latitudinal and seasonal distributions of the climate, but are still somewhat limited in their representations of climatic variability on scales from the El Niño/Southern Oscillation to the North Atlantic Oscillation. As indicated above, when driven by both natural and human-induced forcings, the models reasonably represent the changes in global average temperature observed over the twentieth century (see IPCC, 2001, chapter 8).

Projections of changes in climate and sea level

To generate projections of changes in the future climate, the models are typically initiated at conditions that have been reconstructed for the mid-nineteenth century before human activities were contributing substantially to radiative forcing. A control simulation with no change in forcing is then run to establish an estimate of the baseline climate in the absence of human activities. These results are then compared to the results of perturbation simulations that are driven by the scenarios of future emissions and/or changes in atmospheric composition, depending on the model and the type of forcing.

Based on the model simulations, and supported by theoretical analyses and extrapolations of recent trends, the set of IPCC emissions scenarios (IPCC, 2000) for the twenty-first century is projected to cause the global average temperature to increase by about 1.4–5.8°C over the period 1990–2100 (IPCC, 2001). A warming of this amount would be roughly 2–9 times as large as

the warming during the twentieth century. Such a warming would mean that human activities would have increased global average temperature over its preindustrial average by from about 2°C to over 6°C. Model simulations are increasingly providing consistent indications of the warming to be expected in various regions of the Earth, indicating larger changes occurring in higher rather than lower latitudes and over land rather than the ocean (IPCC, 2001, chapter 10). Increases in the average temperatures projected for the end of the twenty-first century, even were they to be at the lower bound, would significantly exceed the temperatures that occurred over the last 1000 years, and most likely since the emergence from the last glacial maximum.

Many types of changes in the weather and climate would result. For example, shifts in storm tracks and an intensification of evaporation and precipitation cycles would be expected to alter the frequency and intensity of floods and droughts. IPCC (2001) also projects that the intensity of various other extreme weather and climate events would increase.

In addition, the projections indicate that the melting of mountain glaciers and thermal expansion of warming seawater would cause the rate of sea level rise to increase from the observed rate of 0.1 to 0.2 m/century during the twentieth century. Because of uncertainties relating to the fates of the Greenland and West Antarctic ice sheets, the estimated rate of rise is quite broad, ranging from about 0.1 to 0.9 m/century during the twenty-first century. The lower estimate of projected sea level rise reflects the possibility that, for perhaps the next century, increased snowfall could cause ice to accumulate over major areas of Greenland and Antarctica more rapidly than it would be lost at the edges. Higher rates of rise could occur during the latter part of the twenty-first century and are projected for the following centuries as the warming over Greenland (and perhaps West Antarctica) initiates a millennium-long melting that could add 0.5–1 m/century to the rate of future sea level rise.

As was the case for the sudden appearance of the Antarctic ozone hole, there is also a real possibility for surprising changes to occur, especially given the potential for thresholds and nonlinearities. One of the possibilities is the disruption of the Gulf Stream and the larger-scale deep ocean circulation of which it is a part. The weakening of the world-girdling thermohaline circulation apparently occurred during the Younger Dryas period about 11 000 years ago, which was an interruption in the recovery from the glacial conditions that had prevailed for the preceding 100 000 years. The weakening of the global ocean circulation, in that case likely caused by a sudden release into the ocean of glacial meltwaters, led to a strong cooling centered over Europe. Were a similar weakening of the thermohaline circulation to occur during the twenty-first century, the cooling temperatures would likely only be regionally significant, even though it might only moderate the influence of global warming. However, because such a change would reduce the rate of cold-water transport into the deep ocean, the rate of sea level rise would tend to increase, creating problems for coastal regions around the world.

An associated item in this volume (Climate Change Impacts) summarizes the expected types of impacts resulting from changes in climate of the magnitude discussed here. That item also indicates the magnitude of the emissions reduction that would be required to stabilize the atmospheric concentrations of greenhouse gases and eventually stabilize the climate, as has been set as an international objective in the Framework Convention on Climate Change that was negotiated in 1992, and has since been agreed to by most of the nations of the world.

CLIMATE CHANGE AND HUMAN HEALTH

Global climate change is one of a larger set of large-scale environmental changes occurring in today's world. These changes reflect, in various ways, the increasing human domination of the ecosphere, as human numbers continue their unprecedented expansion and as human economic activities intensify (Vitousek et al., 1997). All of these changes – climate change, stratospheric ozone depletion, biodiversity loss, worldwide land degradation, freshwater depletion, disruption of the elemental cycles of nitrogen and sulfur, and the global dissemination of persistent

organic pollutants – have great consequences for the sustainability of ecological systems, for food production, for human economic activities and, via those and other pathways, for human population health.

There is a growing realization that the sustainability of human health should be a central consideration in the public debate on sustainable development (McMichael et al., 2000). After all, society's ultimate, if unstated, objective is to maximize the wellbeing, health and survival of its population. The advent of climate change and other global environmental changes, as an indicator that our current developmental trajectory is unsustainable, is obliging us to take a more ecological view of population health. That is, population health is an index of the extent of our success in the longer-term management of social and natural environments.

A change in world climate will influence the structure and functioning of many ecosystems and the biological health of many plants and creatures. Indeed, it has emerged, in recent decades, that many non-human physical and biological systems have undergone alterations that are reasonably attributable to climate change. This includes the retreat of glaciers and sea ice, and the earlier occurrence of bird-nesting and insect migrations (IPCC, 2001; Root et al., 2003). Likewise, there would be various health impacts in human populations. These would differ by location since climate change will induce a range of environmental changes specific to the particular geographical setting. Besides, the vulnerability of each human population will vary as a function of locality, level of material resources, technological assets and type of governance.

Some of the anticipated health impacts would be beneficial. For example, milder winters would reduce the seasonal winter-time peak in deaths that currently occurs in temperate countries, whereas in currently hot regions a further increase in temperatures might reduce the viability of disease-transmitting mosquito populations. Overall, however, scientists assess that most of the health impacts of climate change would be adverse. The health impacts of climate change do not entail novel processes and unfamiliar disease outcomes (in contrast to the recent surprise appearances of HIV/AIDS and human “mad cow disease”). Rather, they entail climate-induced changes in the frequency or severity of familiar health risks – such as floods, storms and fires; the mortality toll of heatwaves; the range and seasonality of infectious diseases; the productivity of local agro-ecosystems; the health consequences of altered freshwater supplies; and the many repercussions of economic dislocation and population displacement.

The human species, via its social organization and cultural practices, is much better – and often intentionally – buffered against environmental stressors than are all other plant and animal species. Hence, *Homo sapiens* is likely to be affected less soon and less sensitively than most other species. Not surprisingly, therefore, at this early stage in the process of global climate change there is little empirical evidence that climate change has already begun to affect human health.

Climate and human health: an ancient struggle

Whoever wishes to investigate medicine properly, should proceed thus: in the first place to consider the seasons of the year, and what effects each of them produces, for they are not all alike, but differ much from themselves in regard to their changes. [Hippocrates, in *Airs, Waters, and Places* (Hippocrates, 1978)]

The idea that states of human health and disease are linked with climatic conditions almost certainly predates written history. The Greek physician Hippocrates, around 400 BC, related epidemics to seasonal weather change. He wrote that physicians should have “due regard to the seasons of the year, and the diseases which they produce, and to the states of the wind peculiar to each country and the qualities of its waters”. He exhorted them to observe “the waters which people use, whether they be marshy and soft, or hard and running from elevated and rocky situations, and then if saltish and unfit for cooking” and to note also “the localities of towns, and of the surrounding country, whether they are low or high, hot or cold, wet or dry...and of the diet and regimen of the inhabitants”.

Two thousand years later, Robert Plot, Secretary to the newly-founded Royal Society in England, collated weather observations in 1683–84 and noted that if the same observations were made “in many foreign and remote parts at the same time” we would “probably in time thereby learn to be forewarned certainly of divers emergencies (such as heats, colds, dearths, plagues, and other epidemical distempers)”.

In those intervening 2000 years many climatic disasters have affected communities and populations around the world, causing starvation, infectious disease, social collapse and, sometimes, the disappearance of whole populations. One such example is the mysterious demise of the two Viking settlements in Greenland in the fourteenth and fifteenth centuries, as temperatures in and around Europe began to fall (Pringle, 1997). These culturally conservative livestock-dependent settlements were established during the tenth century ad early in the Medieval Warm Period. They could not cope, however, with the progressive deterioration in climate that ensued from the late Middle Ages. Food production declined and food importation became more difficult as sea ice persisted. The Viking settlements eventually died out or were abandoned.

There are numerous historical accounts of acute famines occurring in response to climatic fluctuations (Bryson and Murray, 1977). Throughout pre-industrial Europe, food supplies were marginal, and the mass of people survived on monotonous diets of vegetables, grain gruel and bread. A particularly dramatic example in Europe was the great medieval famine of 1315–17. Climatic conditions were deteriorating, and the cold and soggy conditions led to widespread crop failures, food price rises, hunger and death. Social unrest increased, robberies multiplied, and bands of desperate peasants swarmed over the countryside. Animal diseases proliferated, contributing to the die-off of over half the sheep and oxen in Europe. This tumultuous event, and the Black Death that followed 30 years later, may have contributed to the weakening and dissolution of feudalism in Europe.

Over these and the ensuing centuries, average daily food intakes were less than 2000 calories, falling to around 1800 calories in the poorer regions of Europe. This caused widespread malnutrition, susceptibility to infectious disease, and low life expectancy. Recurrent famines culled the populations, often drastically. In Tuscany, for example, there were over 100 years of recorded famine between the fourteenth and eighteenth centuries. Meanwhile in China, where the rural diet of vegetables and rice accounted for an estimated 98% of caloric intake, in the 2000 years between around 100 BC and AD 1900 there were famines that involved at least one province in over 90% of years (Bryson and Murray, 1977).

The health impacts of climate change

It is important to stress, again, that there is yet little direct empirical evidence of climate change affecting human health over recent decades. In part this is because epidemiologists have had little interest in studying the relationship of climatic variations to human health. The low premium accorded to this topic has presumably reflected a general assumption that there are few opportunities for direct intervention to reduce adverse health impacts from climatic influences. Nevertheless, the position has changed markedly in recent years in the wake of newly recognized “anthropogenic” global climate change.

This upsurge in research activity falls into three categories: (a) studies seeking to broaden the empirical information base by examining how recent variations or trends in climatic conditions have related to changes in health outcomes, (b) studies seeking evidence of early impacts of global climate change on human health, and (c) studies that use existing empirical and theoretical knowledge to model the future impacts of given scenarios of climate change.

It is usual to distinguish several generic categories of health impacts due to climate change – first, those that arise from relatively direct impacts of alterations in temperature, precipitation and extreme weather events; second, those that occur in response to climate-induced changes in ecological processes and systems; and, third, those that result from the economic and demographic dislocation of human communities.

Direct effects

The more direct and immediate impacts include those due to changes in exposure to very cold and very hot weather extremes and those due to increases in extreme weather events (floods, tropical cyclones, storm-surges and droughts). Climate change would also directly increase the production of certain air pollutants, such as tropospheric ozone (the formation of which is affected by both temperature and level of sunlight), and various aeroallergens (spores and molds) involved in the causation of asthma, hay fever and other allergic disorders.

Populations display a characteristic pattern of daily deaths (and hospitalizations) in relation to daily temperature (Wilkinson et al., 2002). Typically, death rates increase both with greater heat and greater cold. In cool temperate countries, climate change would result in a decrease in winter mortality because of less severe winters, and this may offset the increases in summer heat-related mortality (Langford and Bentham, 1995; Rooney et al., 1998), at least initially. In warm temperate and tropical countries the overall number of temperature-related deaths is likely to increase. The net balance of future changes in hot and cold effects remains contentious and, anyway, varies substantially between different geographic regions, states of economic development, and between urban and rural populations.

The extent to which the regional frequency of extreme weather events will alter because of climate change remains somewhat uncertain. Climatologists, however, are becoming increasingly confident of their modeled regional predictions, as the downscaling of their climate models improves. Further, extreme weather events appear to have increased in tempo during the 1990s (e.g. McMichael et al., 2003; Milly et al., 2002), with commensurate risks to human life and limb. Nevertheless, despite the potentially great impact of such events on deaths, injuries and consequent diseases (infections, malnutrition and mental health disorders), estimating the future profile of health impacts is at best an indicative exercise. Hurricane Mitch, centered in Honduras in 1998,

had a death toll of over 11 000 people, and was followed by tens of thousands of new cases of malaria, cholera and dengue fever.

Indirect effects (especially infectious diseases and food yields)

The indirect, second, category of health impact refers particularly to changes in the transmission patterns of infectious diseases and changes in regional food-producing systems. These impacts are, in essence, a result of ecologically mediated mechanisms. In the longer term it is probable that these indirect impacts on human health would have greater magnitude than the more direct impacts (McMichael et al., 1996, 2003).

For vector-borne infectious diseases the geographic range and abundance of vector organisms (and, in some cases, their intermediate hosts) are affected by various meteorological factors (temperature, precipitation, humidity, surface water and wind), biotic factors (vegetation, host species, predators, competitors, and parasites) and human interventions. The rate of maturation of the pathogen within the vector is typically sensitive to temperature, in a curvilinear fashion. This means, for example, that an increase of 1°C across different parts of the temperature range would yield very different increases in transmissibility.

There is some evidence that tick-borne encephalitis, a viral disease of humans, has increased its geographic range within Sweden over the past two decades, as winter temperatures have increased (Lindgren and Gustafson, 2001). Other studies have found some evidence that malaria has extended its range in parts of highland Eastern Africa in association with local warming (Patz et al., 2002) and that, in northeastern Australia, Ross River virus disease has increased its geographic distribution since 1990 (Tong et al., 2001).

Considerable recent effort has sought to develop better mathematical models for making scenario-based health impact projections (McMichael et al., 2003; Epstein, 1999; Martens, 1998). The models in current use have well-recognized limitations. For example, the transmission cycles of some vector-borne diseases are highly complex, involving multiple vector and host species. This can have the effect of limiting the geographical scale of predictive modeling (from the global to, say, the subnational level), as well as increasing the range of uncertainty around estimates of climate change impact on disease transmission (Woodruff et al., 2002). Nonetheless, mathematical modeling studies have provided useful indicative forecasts of the likely direction and magnitude of impacts, and are an important stimulus to further research.

Mathematical models have forecast that an increase in worldwide average temperature and associated changes in precipitation patterns would cause a net increase in the geographic range of malaria-transmitting mosquito species (Martens et al., 1999) – although some localized decreases may also occur in regions that become too hot or dry, such as in the Sahel region of Sub-Saharan Africa (McMichael et al., 1996; Martens, 1998). Further, temperature-related changes in the life-cycle dynamics of both the vector species and the pathogens (protozoa, bacteria and viruses) would increase the potential transmission of many vector-borne infectious diseases such as malaria (mosquito), dengue fever (another of the world's great vector-borne viral infectious diseases, transmitted by mosquito) and leishmaniasis (sand-fly) (Patz et al., 1996; Martens, 1998). Models indicate that dengue fever would extend its range and seasonality (Hales et al., 2002). In Australia, a combination of heavy rainfall and high temperatures have been used to predict

epidemics of Ross River virus disease (transmitted by mosquitoes) with a likely increase in future transmission expected in some regions (Woodruff et al., 2002).

Climate change would also affect the transmission of water-borne infectious diseases via several mechanisms (McMichael et al., 2003), including intensification of rainfall episodes, leading to flooding that causes contamination of drinking water supplies. Bacterial water-borne illnesses such as gastroenteritis due to coliform bacteria, giardiasis, and cholera may thus be affected; so too would various protozoal water-borne infectious diseases such as cryptosporidiosis. Similarly, warmer temperatures would tend to increase the summer seasonal peaks of food-borne bacterial enteric infections, such as those due to *Salmonella* and *Campylobacter*. In low-income countries, with poor hygiene and resources, rates of serious child diarrhoeal disease would rise. The sensitivity of child diarrhea to variations in climatic conditions has been well demonstrated in studies in Lima, Peru and in Fiji (Singh et al., 2001; Checkley et al., 2000).

Another fundamental potential impact on human health would arise from any downturn in food availability. Climate change is likely to affect crop yields, livestock health and resultant food products, and fisheries. However, the processes are generally complex – and often entail seemingly stochastic events (e.g. the occurrence of new infectious diseases in plants and animals). Cereal grains account for around 70% of world food energy – both via direct consumption and via the feeding of grains to livestock for meat production. Various modeling studies have made estimates of the impact of climate change upon cereal grain yields – allowing for the expected “fertilization” effect of increasing concentration of atmospheric carbon dioxide. Globally, a slight downturn in grain production appears likely, especially in the latter half of the twenty-first century (Parry and Carter, 1998; McMichael et al., 2003). This downturn would be greater in the already food-insecure regions in South Asia, parts of Africa and Central America. Such downturns would increase the number of malnourished people in the world (currently an estimated 830 million) by at least several percent overall – with higher percentage decreases in Sub-Saharan Africa and South Asia. World cereal grain yields have become a little more unstable during the 1990s, displaying increased inter-annual variability: could this be (partly) due to changing climatic conditions?

Effects of economic, social and demographic disruption

The third category of health impact is somewhat speculative and difficult to model quantitatively. The situation of several small island states in the Pacific region typifies issues that are likely to be experienced, at some level, in other parts of the world. These islands are registering growing concern about sea-level rise and disturbance of natural and managed food systems, due to the depletion of freshwater stocks, arable land, and damage to coastal industries. The economic downturns, unemployment, and civil strife typically associated with such large-scale changes, and the resulting population displacement, are also conducive of a range of risks to health. Refugee populations typically experience mental health problems, malnutrition, infectious diseases, and the physical hazards of new and improvised living environments.

The anticipated health consequences of economic and social disruptions due to climate change may not become evident for several decades. A usual difficulty for researchers is in deciding

whether an event, such as climate change, has caused such outcomes, given the many, often interrelated, causal influences involved. It will therefore be difficult to detect early climate impact "signals" against the considerable background "noise".

Population vulnerability, and adaptive responses

The magnitude of the impact of climate change upon health depends both on the extent of that change and on characteristics of the target population. Although changing climate conditions may make the environment more favorable for disease transmission and other negative health impacts, this does not necessarily mean these will occur, as long as there is the capacity to adapt to the changed conditions. For example, warmer temperatures are predicted to extend the distribution of many disease-carrying vectors into new areas. This increased risk does not have to mean a large increase in cases of disease, provided there is a continuing expansion of the public health response to the disease, additional quarantine efforts, etc.

A population's "vulnerability" is a function both of the sensitivity of the exposure-response function in that population and of the population's adaptive (i.e. impact-lessening) capacity (Parry and Carter, 1998). That adaptive capacity depends on factors such as population density, level of economic development, food availability, local environmental conditions, pre-existing health status, and the quality and availability of public health care. It also depends on various structural and politically determined characteristics, including social-cultural rigidity, international connectedness and political flexibility (Woodward et al., 2000). The level of risk to the population's health is therefore a function of that vulnerability and the amount of exposure to climatic or associated environmental factors.

The reduction of socioeconomic vulnerability remains a high priority. Poor populations will be at greatest health risk because of their lack of access to material and information resources and because of their typically lower average levels of health and resilience (nutritional and otherwise). The long-term improvement in the health of impoverished populations will require income redistribution, improved employment opportunities, better housing and stronger public health infrastructure – including primary health care, disease control, sanitation and disaster preparedness and relief.

Adaptation will be either reactive, in response to climate impacts, or anticipatory, in order to reduce vulnerability. These adaptive actions can be categorized as: (a) administrative or legislative, (b) engineering, or (c) personal (behavioral) (Patz, 1996). Legislative or regulatory action can be taken by government, requiring compliance by all (or by designated classes of) people. Alternatively, voluntary adaptive action may be encouraged via advocacy, education or economic incentives. The former type of action would normally be taken at a supranational, national or community level; the latter would range from supranational to individual levels. Adaptation can be undertaken at the international/national level, the community level and the individual level.

It would be shortsighted to expect that adaptation will provide a complete antidote to the problems of climate change. Reduction of greenhouse gas emissions remains a primary preventive health strategy, with appreciable 'collateral' health benefits in the short term. Transport policies to reduce dependence on the motorcar could lead, for example, to improved air quality and increased physical activity (linked to a reduction in obesity, diabetes and heart disease at the population level). Even so, we are already committed to some degree of global climate change over coming

decades despite any mitigation actions we might take now. It is important to begin assessing, for any particular population, both its vulnerability and its adaptation options.

Conclusion

Although it is now generally agreed that human-induced climate change is under way, and will continue to occur, the magnitude and rate of change remain uncertain. Future levels of greenhouse gas emissions will be affected by population and economic growth, as well as by technological change, energy preferences, and social behavior. Our ability to explain the chaotic variations within the climate system is improving, but there will always be inaccuracies involved in modeling natural systems.

In addition to climatic change and increased variability, numerous other factors (i.e. social, behavioral, environmental) influence the risk of the diseases discussed in this item. Teasing out the climatic contribution is a major challenge to health researchers. Given the unavoidable uncertainties pertaining to the projected health impacts of climate change, social policy should be developed within the framework of the "precautionary principle" – that is, the principle of proceeding on the basis of the incomplete evidence that is available in relation to future processes that are never fully knowable in advance (McMichael et al., 2003).

CLIMATE CHANGE IMPACTS: POTENTIAL ENVIRONMENTAL AND SOCIETAL CONSEQUENCES¹

With some changes in climate having already occurred, with the climate continuing to adjust to past changes in atmospheric composition, and with continuing greenhouse gas emissions certain to cause further climate change, there is no doubt that the world will be undergoing relatively large changes in climate that will be ongoing for centuries. Such changes will inevitably cause consequences for society and the environment.

¹This item is updated from MacCracken, M.C., 2001, Global warming: a science overview, pp. 151–159 in *Global Warming and Energy Policy*. New York: Kluwer Plenum.

In developing estimates for these consequences, it is important to consider not only the impacts that would be expected were the projected changes in climate to affect systems as they exist at present, but also to carry out the analyses in the context of how these systems are changing (naturally and due to other human-induced stresses) and in recognition of the possible adaptation of strategies for responding and adapting to the projected combination of stresses. Because vulnerability is really the difference between the sensitivity to the impact and the ability to adapt, all considered in the context of other stresses on society and the environment and resources available to help respond, the vulnerability of each nation will depend particularly on its own situation and the local ability and commitment to respond.

The Second and Third Assessment Reports of the IPCC summarize present understanding of the types of consequences for continental-scale regions around the world (IPCC, 1996a,b, 2001b). Figure C13, taken from IPCC (2001b), provides a summary diagram of how the relative importance of the potential impacts is likely to increase as the amount of warming increases. This figure also makes clear that, because climate change will occur with differing intensities at different latitudes, and because different emissions scenarios will lead to different overall rates of change, different countries are likely to be in very different situations.

Recognizing this, many nations have begun to analyze the potential consequences that they anticipate having to deal with. Information for many nations on potential impacts and adaptive measures can be found in their national assessment reports (e.g. for the US, see NAST, 2000 and 2001; for Canada, see Environment Canada, 1998). Many of the nations of the world summarize their findings in reports called for by the United Nations Framework Convention on Climate Change (UNFCCC); for example, for the US, see Department of State (2002) and for other nations see “National Communications” section at <http://unfccc.int/>). Generally, it has been found that the impacts are likely to be relatively more important for developing than developed nations because developing nations must devote their more limited resources to more immediate challenges and so do not have the flexibility and resources to adapt that developed nation economies may have available. Because it is impossible to be comprehensive in a brief review, both the IPCC and the national assessment reports should be consulted to gain a fuller understanding.

The regional and temporal variations in projected consequences create significant difficulties for negotiators in determining criteria for meeting the central objective of the UNFCCC that was negotiated and internationally accepted in 1992. This objective is to achieve “stabilization of the greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system” while at the same time doing this in a way that would “allow ecosystems to adapt naturally to climate change, . . . ensure that food production is not threatened, and . . . enable economic development to proceed in a sustainable manner”.

In thinking about the importance of potential impacts it is also important to remember that fossil fuels provide wide-ranging benefits to society, providing roughly 80% of the world’s energy and so sustaining the world’s economy and enabling the present standard-of-living of peoples around the world. Recognizing this, some argue that, if the use of the energy source that supports the global economy is to be sharply reduced, such impacts will have to be relatively certain and substantial. In contrast, others point out that we have only one “spaceship Earth”, so

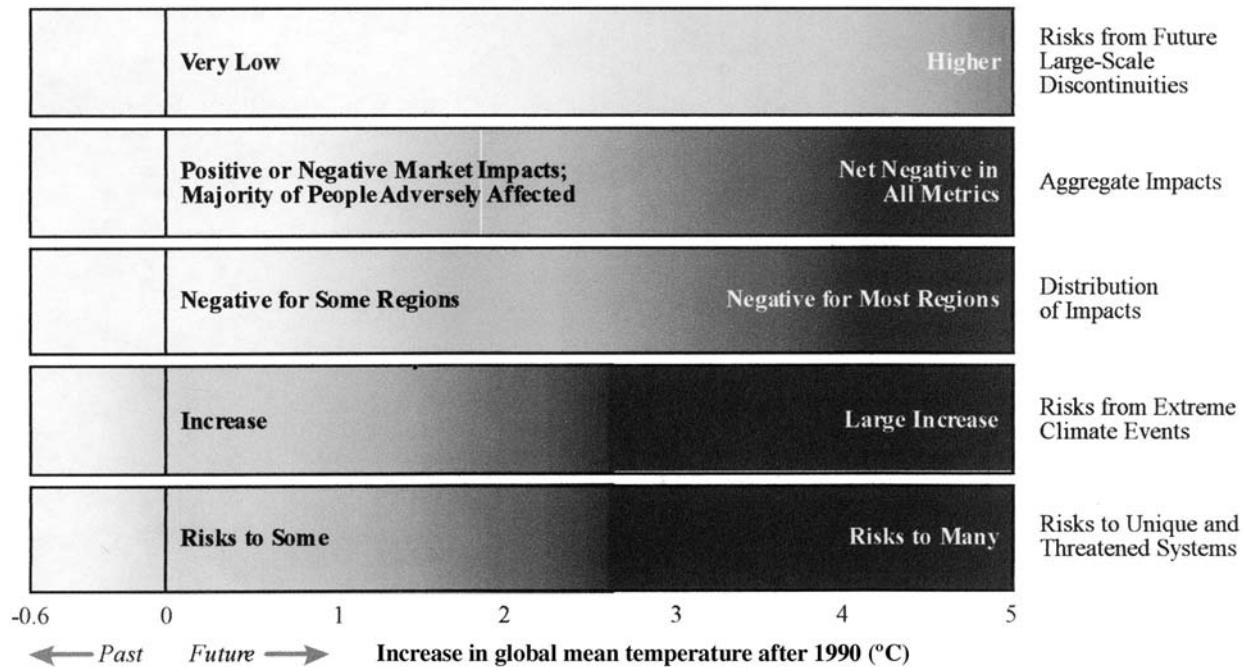

Figure C13 Estimated level of risk as a function of the change in global mean temperature from its value 1990 (in °C), with the areas to the left of the vertical line referring to the risk created by warming prior to 1990. Each horizontal bar refers to a different reason for being concerned. The more intense the shading, the greater the risk. Figure developed as part of IPCC's Third Assessment (IPCC, 2001b).

precaution suggests that the chance of significant or irreversible changes should be avoided. This article provides an overview of some of the important categories of potential impacts that have been identified, providing a sense of the types of impacts (for further details, see the various IPCC assessments).

Human health

Given the large number of people that could be affected, even a modest health impact could create very significant societal and economic consequences. For many regions, significant increases in summertime temperature (and in the absolute humidity that is often associated with such high temperatures) could lead to much more frequent and intense occurrence of dangerously high heat index conditions. While more extensive availability of air-conditioning and warning of dangerous events could limit an increase in heat-related mortality in developed nations, the threat for developing nations where such remedies might not be available could be quite significant.

With the poleward movement of wintertime frosts, mosquitoes and other disease vectors are likely to spread poleward; this has the potential to increase the incidence of infectious diseases if these influences cannot be offset by more attention to appropriate public health measures, enhanced building and community design, and new medicines. Again, those in developed nations are likely to be much better off than those in developing nations; for example, the 17-year total of cases of dengue fever, which is mosquito-borne, is about a thousand times as high in northeastern Mexico as in Texas, mainly due to the relative level of development. The increased intensity of extreme events such as hurricanes and typhoons is also likely to injure or kill more people (and disrupt communities) unless

steps are taken to enhance risk-averse planning and construction and to provide better warning and recovery capabilities, and again, developing countries are much more vulnerable.

Food production

The UNFCCC objective specifically mentions the need to ensure that food production is not threatened, for if there is not enough food to survive into the future, the amount of climate change will not really matter. Fortunately, laboratory and field studies indicate that CO₂ concentrations are very likely to enhance the growth of many types of crops and to improve their water use efficiency. If this happens widely (i.e. if other constraints on agriculture do not arise), changes in climate would be expected to contribute to an increase in agricultural productivity (i.e. yield per hectare), thus working in the same positive direction as improvements in agricultural practices, seed strains, and technology. If these positive influences exceed the negative influences caused by deteriorating soil fertility and altered climatic conditions, the potential exists for increasing overall agricultural production while using less land for agriculture. Such an outcome would have the potential for reducing food costs for the public, and there are some studies indicating that the past increase in the CO₂ concentration has contributed to overall food production.

Given the varying soil, climatic, and agricultural capabilities around the world, however, the benefits and impacts are unlikely to be evenly spread. For example, the altered climatic conditions facing farmers in some low-latitude developing nations might well exceed the tolerances for present crops, or, for farmers used to growing only a few types of crops, could at least require a disruptive change in what is grown. For farmers

in developed nations, many are facing economic hardships now because of the low prices that result, at least in part, from overproduction. This overproduction presently causes many governments to have to provide subsidies or to impose trade barriers of various kinds. Thus, if changes in climate lead to increases in productivity that cause additional downward pressure on commodity prices or to an increase in costs of production (e.g. to pay for additional irrigation), income for farmers in marginal growing areas is likely to decrease. Even though these farmers might benefit from some gain in overall crop productivity, it is likely to be less than the increase for farmers in the most productive areas, meaning that those in marginal areas are unlikely to remain competitive. This could cause economic and environmental problems in nearby rural communities unless other profitable crops are identified and farmers have the incentive and resources to tend and conserve the land resources.

Ecosystems and ecosystem services

As is clearly evident from a hike up a mountain or a vacation excursion across a continent, the prevailing vegetation is closely tied to the climate that a location experiences. Although the world's vegetation shifted dramatically as the climate warmed at the end of the last glacial maximum, the shifts took place over many millennia and were possible in part because the world's wildlife and plant species had been squeezed equatorward and so had a base from which to spread. For the future, the amount and rate of climatic change are projected to be much, much greater than has been experienced over the past 20 000 years. In addition, the ultimate climatic conditions are projected to reach levels that are well beyond existing conditions, thereby rapidly recreating climatic conditions that have not been experienced in the world for many millions, even tens of millions, of years. In that the ecosystems that make up our landscape provide such a range of services, including water and air purification, supply of food and fiber products, and recreational and esthetic enjoyment, the likelihood of significant changes in ecosystems prompted the provision in the UNFCCC objective that necessitates understanding how ecosystems are likely to change and adapt.

Ecosystem simulation models, which are calibrated based on past and present climate–vegetation relationships, project that changes are likely to be quite extensive. In general, temperature changes are likely to increase with latitude and to be larger over land areas than over ocean areas. Precipitation in low and high latitudes is expected to increase, but with an expanded subtropics where increased evaporation likely further reduces soil moisture. Wintertime precipitation in middle- and high latitudes is projected to increase (proportionately) more than summertime precipitation. Evaporation rates are likely to increase, especially in summer, causing reductions in soil moisture that could affect pest and fire disturbance frequencies for forests and grasslands. As the seasonal patterns of temperature and soil moisture change, the competition among various species will be changed, leading to changes in prevailing tree and grass types and then in the types, abundance, and migration of birds and other wildlife. Some, but not all, of these effects may be offset by the increased CO₂ concentration, which is expected to help many types of plants grow better if other factors, such as nutrients, are not limiting. To the extent that regions accumulate carbon in vegetation and dry out during persistent warm episodes, fire risk is likely to increase even though plant growth may overall be more vigorous. At the same time, increased

precipitation over deserts caused by shifting atmospheric circulation patterns, even though perhaps seasonally concentrated, could lead to more vegetation in some regions.

Climatic changes will also lead to significant impacts on freshwater and marine ecosystems. Already, bleaching of coral reef ecosystems is being attributed, at least in part, to the warming oceanic conditions. The increasing CO₂ concentration also affects ocean chemistry, and for coral reefs the impact is to dramatically shrink the regions of the world where temperatures and ocean chemistry are conducive to generation of strong reef structures. Fish populations are also very sensitive to the temperatures of streams and ocean waters, and significant shifts are projected as the climate changes. Changes in ocean productivity also cause effects all the way up the food chain, ultimately affecting the resources, and so the populations, of species as varied as whales, seals, and penguins.

What is most important to understand is that the notion of ecosystem migration is a misconception – as climate changes, the dominant species in particular locations will change, and so the local ecosystem will change as species now dominant become, if they can, dominant elsewhere. However, because each species is distinct, this process is likely to lead to the deterioration of existing ecosystems and the creation of new ones. During this century the changes are likely to be relatively rapid, and the complexity and resilience of current systems is likely to be disrupted because there will not be sufficient time for adjustment and evolution to take place. As a result, the ecological services that society depends on seem likely to be diminished.

Water supplies

Water is absolutely vital to society, and water resource limitations are currently affecting many nations. By affecting the hydrological cycle in a variety of ways, climate change is likely to exacerbate the availability of water for peoples around the world. Changes in the location and timing of storms will alter the timing and amount of precipitation, soil moisture, and runoff. For example, the intensity of convective rainfall is projected to increase, creating the potential for enhanced flooding in watersheds that experience frequent rainfall. Conversely, increased summertime evaporation will reduce soil moisture and may also reduce groundwater recharge in areas such as the Great Plains, and cause lower levels in the lake and river systems, reducing water supplies for communities and agriculture as well as opportunities for shipping and recreation.

Warmer conditions are also likely to increase the rate of evaporation and to change precipitation in cold regions from snow to rain. These and other types of changes will thus affect the overall amounts and availability of water resources, as well as potentially intensifying both floods and droughts. Adapting to such changes will require changes in how river and reservoir systems are managed in order to satisfy the demands of water for communities, industry, hydroelectric power, irrigation, water levels, groundwater recharge, and preservation of fish migrations and aquatic ecosystems. The challenges will be especially severe in mountainous regions where the snowpack (and even mountain glaciers) presently serve as virtual water reservoirs, typically providing water during the spring and summer. Because wintertime precipitation is projected, on a relative basis, to increase the most, avoiding floods is likely to require an even greater lowering of reservoir levels in winter, even though this would reduce water availability in summer when demand is likely to be highest. In addition, because water

resources are under increasing stress due to many non-climatic factors, the impacts of climate change are likely to be a significant exacerbation of these other influences.

Coastal endangerment

After the rapid rise of sea level at the end of the last interglacial, reconstructions of beach height, taking into account isostatic adjustments of the deformed land surface, suggest that sea level was relatively constant through most of the Holocene. Indications are that global sea level started rising during the nineteenth century, rose by about 0.1–0.2 m during the twentieth century, and will rise more rapidly in the future. If the rate of sea level rise triples (using mid-range estimates from IPCC, 2001a), this would put many coastal regions at significant risk of inundation. For regions currently experiencing subsidence of their coastlines (e.g. river deltas as sediments compact and are not renewed, regions just equatorward of ice sheet edges), there could be an even more significant acceleration in the rate of rise. Because there are few resources to protect sensitive natural areas such as wetlands and fish- and bird-breeding grounds, accelerating loss is very likely. The rate of loss will be greatest during coastal storms when storm surges (and therefore wind-whipped waves) will reach further inland and further up rivers and estuaries.

There are also many cities and significant infrastructure along coastlines. For highly developed areas, retreat would be very costly, and so strengthening of coastal protection is essential, not just to protect against sea-level rise, but also to reduce current vulnerability to the storm surge from coastal storms and hurricanes. For smaller communities and residential structures, protective structures such as levees are likely to be too expensive and so retreat will be required, or forced by events. Already, some coastal villages in Arctic regions are at risk because the wintertime retreat of sea ice is increasingly exposing these communities to high waves whipped up by winter storms.

With the likelihood that the rate of sea-level rise will continue at significant levels for many centuries, determining when near-term protective measures are best replaced by long-term relocation will be very difficult for many nations, especially with the increasing desire of affluent populations to live near the coastline and enjoy its scenic and recreational opportunities. However, it is essential that such analyses be done as the choice is important in determining how best to deal with rising sea level and its impacts over time (e.g. if the coastline is to be preserved, roads need to be parallel to the coast; if retreat is to occur, roads need to be perpendicular to the coast to allow phased movement).

Societal infrastructure

Although societal infrastructure is generally designed to withstand a wide variety of weather extremes, the changing climate is projected to create changes in the intensity and frequency of extreme events. For example, the climate model of the Canadian Climate Centre projects that the return period of 100-year storms could decrease by half or more over the next 100 years. Given the economic costs and psychological impacts of recovering from such intense and damaging storms and conditions, a phased response that leads to infrastructure designs that provide more resilience has the potential of limiting potential consequences. Although the incremental cost of providing more resilience is not likely to be high for any single project in

developed nations, there is an extensive amount of infrastructure in these nations and so total costs could be quite significant, although mostly hidden within large budgets. For developing countries the cost of designing resilient infrastructure is likely to be a greater increment, but, in that old infrastructure is not having to be replaced, may be feasible. What is most important is that such precautionary investments (e.g. elevating new sewer plants to withstand projected changes in sea level) be made, starting as early as possible, rather than further investing in facilities that will soon have to be reconstructed.

Transportation systems represent a very large societal investment. Present intensities of severe weather and floods typically cause disruptive economic impacts and inconvenience that can become quite important for particular regions during particular extreme events. While information is only starting to emerge about how climate change might lead to changes in weather extremes, a range of possible types of impacts seem possible, including some that are location-dependent and some that are event-specific. Location-dependent consequences could include: lower levels in rivers and lakes used for transportation and as sources of water for communities and industry, relocation of coastal channels as a result of shifting sediments and barrier islands, and opening of Arctic shipping routes as sea ice melts back. Event-specific consequences could include: more frequent occurrence of heavy and extreme rains (a trend already evident during the twentieth century); reduced or shifted occurrence of winter snow cover that might reduce winter trucking and air traffic delays; altered frequency, location, or intensity of hurricanes and typhoons accompanied by an increase in flooding rains; and warmer summertime temperatures that raise the heat index and may increase the need for air pollution controls. By reducing the density of the air, warmer temperatures will also cause reductions in combustion efficiency, which would both increase costs and require longer runways or a lower load for aircraft, just as now occurs for airports in mountainous regions. Starting to consider climate variability and change now in the design of various types of infrastructure could well be a very cost-effective means of enhancing the short- and long-term resilience of society to weather extremes and climate change.

Air quality

Warmer temperatures generally tend to accelerate the formation of photochemical smog. The rising temperature and rising absolute (although perhaps not relative) humidity will raise the urban heat index significantly, potentially contributing to greater air pollution. Meeting air quality standards in the future is therefore likely to require reductions in pollutant emissions beyond those currently in force (although, of course, a move away from the combustion engine might make this change much easier). Increasing amounts of photochemical pollution could also increase impacts on stressed ecosystems, although the increasing concentration of CO₂ may help to alleviate some types of impacts by causing the leaf's stomata to close somewhat. In some regions, summertime dryness would be expected to exacerbate the potential for fire, creating the potential for increased amounts of smoke, whereas in other regions the climatic changes may make dust more of a problem.

International interactions

While it is natural to look most intently at consequences within a particular nation, each nation is intimately coupled to the

world in many ways. For example, economic markets and investments are now coupled internationally and a nation's foods come from both within and outside its borders. Because of international travel for business and pleasure, health-related impacts are also international. Many resources, from water- and hydropower-derived electricity to fisheries and migrating species, are shared across borders, or move and are transferred internationally. Finally, people continue to relocate from one nation to another, becoming citizens of one area while tied by family and history to other areas, especially when disasters strike. Increasingly, all countries are connected to what happens outside their borders, and those in one country will be affected by the repercussions of the societal and environmental consequences experienced by others.

Summary of impacts

Given the variety of potential impacts and the varying capabilities and resources for responding to them, international assessments (e.g., IPCC, 1996b, 2001c) provide primarily a qualitative indication of the potential consequences. In addition to the scientific challenges of developing the estimates, issues of equity and cultural values introduce many more complications. For example, IPCC (1996b) struggled with the issue of whether the imputed value of a human life should be considered the same in a developed and a developing nation even though the lifetime earnings and economic evaluations of a life lost are quite different across the world.

Present assessments indicate that there are very likely to be important consequences, some negative and some positive, and that impacts are likely to be greater for developing than for developed nations. However, most analyses currently treat rather large regions and so average out the most costly and most beneficial outcomes, thereby perhaps obscuring what could be rather large implications for localized groups.

The mitigating effects of emissions reductions

In recognition of the potential for significant climatic and environmental change and consequent impacts, the nations of the world in 1992 agreed to the United Nations Framework Convention on Climate Change (UNFCCC). As indicated in the preceding section, this agreement set as its objective the "stabilization of the greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system". Because of difficulties in deciding upon what might be considered dangerous, and because uncertainties in understanding of the climate system create only a loose coupling to the changes in atmospheric emissions and composition and consequences that might occur, discussions about potential stabilization levels have so far been based mainly on a sense of the level of change in atmospheric composition that seems likely to have significant consequences, considered generally in the context of what might be technologically and economically possible. For example, considerable attention has been given to attempting to stabilize the atmospheric CO₂ concentration at double its preindustrial level (i.e. at about 550 ppmv). Although not discussed below, similar limitations would need to be imposed on the other greenhouse gases and aerosols if atmospheric composition is to be stabilized.

Based on current scientific understanding of the carbon cycle, limiting the atmospheric CO₂ concentration to 550 ppmv would require *the world as a whole* to remain, on average, at

the present per-capita CO₂ emission level of about 1 ton of carbon (tC) per year throughout the twenty-first century. This contrasts with the expectation that per-capita emissions are likely to double over this period in the absence of agreements to control emissions. As context for considering the challenge that this would impose, the typical American is now responsible for emission of 5–6 tC/year and the typical European is responsible for emission of about 3 tC/year, ignoring any imputed contribution that might arise from considering the energy used to create imported products on which they depend. Maintaining the CO₂ concentration at 550 ppmv beyond the twenty-first century would require, for example, that global emissions for the twenty-second century drop to more than a factor of 2 below current global emissions levels (i.e. to less than half of the 6 billion tonnes of carbon now emitted each year). Such an emissions level would require that global per-capita emissions of carbon be about one-third of the emission level of developing countries today, or one-twentieth of the current per-capita level in North America. Such low levels would not mean that per-capita *energy* use would need to be reduced by this amount, only that net per-capita use of fossil fuels (so emissions minus sequestration) would need to be this low. The IPCC (2001c) suggests that the necessary transition in sources of energy could be accomplished by meeting most of the world's energy needs using renewables and nuclear, if there is significant effort to improve the efficiency of energy end uses, although this is controversial (Hoffert et al., 2002).

As perhaps a start toward this objective, the Kyoto Protocol has been negotiated. Even though its goal is relatively modest in a scientific sense (i.e. by 2008–2012, developed nation emissions of a set of greenhouse gases would be reduced on average to several percent below their 1990 emissions level), it is proving to be a political challenge to get approved and implemented. Even if the US were to participate in its implementation, the emissions limitation would only begin to limit the rate of increase in the global CO₂ concentration because emissions from developing nations would not be similarly controlled and are, not surprisingly, projected to increase significantly along with their economic growth, even though many of these countries are making voluntary efforts to limit growth in emissions. With full implementation of the Kyoto Protocol through the twenty-first century, the CO₂ concentration would be expected to rise to about 660 ppmv as compared to an expectation of a rise to 710 ppmv in the absence of emissions controls. Such analyses make it clear that reducing CO₂ emissions to achieve stabilization at 550 ppmv would thus require significant further steps, and these would need to involve all nations. Accomplishing such an emissions reduction would require much more extensive introduction of non-fossil energy technologies, improvement in energy generation and end-use efficiencies, and switching away from coal to natural gas (unless extensive carbon sequestration of carbon in forests, oceans, or underground can be accomplished).

Absent such efforts on a global basis, the CO₂ concentration is projected to rise to about 800–1100 ppmv (about 3–4 times the preindustrial level) during the twenty-second century. Were this to occur, climate simulations indicate that the resulting warming would be likely to induce such potentially dangerous long-term, global-scale impacts as the initiation of the eventual melting of the Greenland and the West Antarctic ice sheets (each capable of inducing a sea-level rise of up to about 5–7 m over the next several centuries), the loss of coral reef ecosystems due to warming and rapid sea-level rise, the disruption of the global oceanic circulation (which would disrupt the nutrient

cycle sustaining ocean ecosystems), and extensive loss or displacement of critical terrestrial ecosystems on which societies depend for many ecological services (e.g. see O'Neill and Oppenheimer, 2002).

What seems most clear from present-day energy analyses is that there is no “silver bullet” that could easily accomplish the major emissions reduction that is needed to achieve the UNFCCC objective of stabilization of atmospheric composition, even in the face of significant potential impacts. Rather, moving toward the objective will require a multifaceted international approach involving a much more aggressive (although not unprecedented) rate of improvement in energy efficiency, broad-based use of non-fossil technologies (often selecting energy sources based on local resources and climatic conditions), and an accelerated rate of technology development and implementation.

Conclusion

A major reason for controversy about dealing with the climate change issue results from differing perspectives among and within nations about how to weight a wide range of influential factors. These factors include, among other aspects:

1. the need for scientific certainty versus making decisions in the face of uncertainty;
2. the flexibility and adaptability of the energy system that provides for the national and global standard of living;
3. the potential for improving efficiency and developing new technologies;
4. the potential risk to “Spaceship Earth” that is being imposed by this inadvertent and virtually irreversible geophysical experiment;
5. the economic and environmental costs and benefits of taking early actions to reduce emissions (including what factors to consider in the analysis and how to weight the relative importance of long-term potential impacts versus better defined near-term costs); and
6. the weight to give matters of equity involving relative impacts for rich versus poor within a nation, for developed versus developing nations, and for current generations versus future generations.

Moving toward an international consensus on these issues sufficient to negotiate international agreements will require that the publics and governmental officials of all nations become better informed about the science of climate change, about potential impacts and their implications, and about potential options for and costs of reducing emissions. Moving toward collective action will require finding approaches that tend to balance and reconcile these (and additional) diverse, yet simultaneously legitimate, concerns about how best to proceed.

CLIMATE CLASSIFICATION

The philosophical base of climate classification follows the same logic as all classifications and can be dealt with accordingly. Classification is variously defined but is well described as the systematic grouping of objects or events into classes on the basis of properties or relationships they have in common. The function of classification is also given different interpretations but essentially concerns the needs:

- (a) to bring structure, order and simplicity to a complex system,
- (b) to provide an intellectual shorthand,
- (c) to identify spatial limits and boundaries, and
- (d) to provide practical as well as theoretical uses.

Each of these cited functional goals must be considered in the formulation of a useful climate classification scheme. However, the identification of spatial limits and boundaries has proved of special interest to climatologists. Much of the literature dealing with climatic classification deals with limits of a climate group rather than the climate itself.

Of the many ways in which to classify components of the world's climate, the simplest is through classification using a single variable. Each distributional map of any climatic variable is, by definition, a classification scheme. The long history of climatic classification has its roots in the orderly presentation of the distribution of a single variable.

Single-variable classification

The earliest writings providing a consideration of the different climatic environments over the Earth can be traced to the contributions of thinkers in the sixth century BC and to such scholars as Aristotle and Plutarch. The ancient Greeks had postulated a spherical Earth and, through knowledge of the travel of the sun, identified the five-zone system – a torrid zone, two temperate zones and two frigid zones – still identified today. Aristotle provided the first quantitative boundaries of the system by identifying the Tropics, a division based upon astronomy and geography. Following the earlier Greeks, Ptolemy (AD 90–168) used day length as the classification variable and identified seven climates based upon duration of the longest day.

The ideas of Greek and Egyptian scholars passed to the Arab schools and such writers as Ibn Hauqual (ninth century), al Biruni (tenth century) and Idrisi (twelfth century) reproduced and expanded upon the work of the ancients. This work carried over to the geographical writings of the Renaissance and, in 1650, Varenius presented a table, the *climata*, giving the day lengths at the solstices for zones of the Earth. From the findings of these early theorists it is apparent that day length zones rather than temperature zones provided the quantitative expression of climate.

Distributions other than those based upon day-length appeared soon after thermometric data were assembled in the early nineteenth century. In 1817 von Humboldt produced the first isothermal map; while in 1846 Dove prepared monthly temperature distributions and went on to compute mean temperature of latitudes and hence the concept of temperature anomalies. Thereafter contributions became more numerous. Supan (1879) developed the first map of climatic belts based upon mean annual temperature and temperature of the warmest month. Later, in 1884, he produced a system in which zones were identified by regional names.

Single-variable classifications also used precipitation data and it was here that Koppen, the best known of climatic classifiers, made his first major climatological contribution. Both Schimper (1898) and Herbertson (1905) drew upon Koppen's work to produce regionalized world precipitation maps. As more data became available, world maps and regions were constructed for most climatic variables, and classification passed to the use of multiple variables.

Vegetation distribution and climatic classification

The early development of climatic classification is related closely to vegetation studies. Of significance in these early studies of vegetation was the approach used. Systematic botanists arranged plants of the world into classes, genera, etc.

using what might be termed a floristic approach; plant geographers used a physiognomy of vegetation in which plant communities expressed in such terms as forests, meadows, moors, etc., were identified. Table C3 provides an example showing the relationship between climate and vegetation.

In 1874, De Candolle proposed a classification that was designed for tracing the development of plants through geologic time. Six subdivisions were initially used but one, the megatherms (mean annual temperature above 30°C), while prevalent in earlier geologic times, are found today only in the vicinity of hot springs. The remaining five, megatherms, mesotherms, microtherms, hekistotherms and xerophiles, were designated with letters A through E, with B referring to the xerophiles. Given that De Candolle was identifying groups as parallel zones, the insertion of moisture-based unit (B) in a temperature-based grouping is not really illogical. It has led, however, to many misunderstandings in its transfer to the Köppen system.

The Köppen system

From the pioneer work on vegetation classification came climate organizational schemes based upon vegetation distribution. This realm of classification is dominated by the work of Wladimir Köppen, who published his first paper in 1868 and continued to be a productive scholar up to his death

Table C3 Correspondence between climatic and vegetation types

Climate	Vegetation type name	Vegetation
Rainy tropical	Malayan	Evergreen rain forest
Subhumid tropical	Nicaraguan	Deciduous or monsoon forest
	Timoran	Savanna forest or woodland
	Visayan	Tropic grassland
Warm semiarid	Tampicoan	Thorn forest, thorn scrub
	Tamaulipan	Desert savanna, wetter parts
Warm arid	Tamaulipan	Desert savanna, drier parts
	Sonoran	Subtropic desert
	Tripolian	Short grass; desert grass
Hyperarid	Atacaman	"Barren" desert
Rainy subtropical	Kyushun	Warm temperate rain forest
	Argentinean	Prairie
Summer-dry subtropical	Mediterranean	Sclerophyll woodland and scrub
Rainy marine	Tasman	Subantarctic forest
Wet-winter temperate	Oregonian	Conifer forest
Rainy temperate	Virginian	Mixed deciduous and conifer forest
Cool semiarid	Patagonian	Cold desert, wetter parts
Cool arid	Patagonian	Cold desert, drier parts
Subpolar	Alaskan	Taiga forest
Polar	Aleutian	Tundra and polar barrens

After Putnam et al. (1960).

in 1940. Köppen's work in classification may be viewed as a climatic determinism of vegetation types, while his greatest contribution was to stress the fundamental unity of pattern in the location of climatic regions throughout the world.

Table C4 provides the outline of Köppen's 1900 classification. It is seen that the idea of providing letters (A – E) is introduced but not emphasized. Instead, Köppen retained the nineteenth-century approach of using plant and animal names for identified regions. Some of these, for example the Penguin Climates, are certainly interestingly informative. The classification also contained some quantitative boundaries, but the well-known characteristics of the classification known to us did not appear until 1918.

The 1918 Köppen classification provides the basis for that used today (Table C5, Figure C14). Each climatic type is given a

distinctive upper- or lower-case letter, each of which has a specific meaning. Local regional and biological names are dropped. Over time, changes to the initial system have been both suggested and implemented. The main changes introduced

Table C4 Climatic regions identified in Köppen's (1900) classification

A. Megathermal or tropical Lowland climates; coldest months $>18^{\circ}\text{C}$

1. Liana
2. Baobab

B. Xerophytic climates – arid and semiarid. Continuous scarcity of precipitation

- I. Coastal deserts of low latitudes
3. Garua (Fog)

II. Lowland desert and steppe experiencing great summer heat

4. Date palm
5. Mesquite
6. Tragacanth
7. East Patagonian

III. Lowland desert and steppe with cold winters and short hot summers

8. Buran
9. Prairie

C. Mesothermal or temperate climates. Coldest month below 18°C , warmest month over 22°C

I. Subtropical climates with moist, hot summers

10. Camellia
11. Hickory
12. Maize

II. Subtropical climates with mild, wet winters and dry summers

13. Olive
14. Heather

III. Tropical mountain climates and maritime climates of middle latitudes

15. Fuchsia
16. Upland savanna

D. Microthermal or cool climates. Warmest month between 10°C and 22°C

17. Oak
18. Spruce
19. Southern beech

E. Hekistotherm or cold climates. Warmest month between 0°C and 10°C

20. Tundra
21. Penguin or Antarctic
22. Yak (Pamir)
23. Rhododendron
24. Ice cap

Quantitative values were given for each identified type.

Table C5 The Köppen classification of climate

A. Temperature of the coolest month above 18°C (64.4°F)

- f: rainfall of driest month at least 6 cm
- m: rainfall of driest month $>(10 - \text{annual rainfall}/25)$ but $< 6 \text{ cm}$
- w: rainfall of driest month, 6 cm and dry in low-sun season (but does not meet m criteria)
- s: rainfall in driest month, 6 cm and dry in high-sun season (but does not meet m criteria)

Also recognized:

- w': maximum rainfall in summer
- w': two rainfall maxima
- i: annual temperature range $< 5^{\circ}\text{C}$
- g: warmest month precedes summer solstice

B. Evaporation exceeds precipitation for the year

BW (desert) and BS (steppe) determined as follows:
Substitute r (annual precipitation in cm) and t (annual average temperature $^{\circ}\text{C}$) in

$$\begin{aligned} r &= 2(t + 14) \text{ when } 70\% \text{ rain is in summer 6 months} \\ r &= 2t \text{ when } 70\% \text{ rain is in winter 6 months} \\ r &= 2(t + 7) \text{ when evenly distributed or neither of above} \\ \text{If } r &> \text{right-hand side of equation then climate is not a desert} \\ \text{If } r &< \text{right-hand side of equation then climate is a desert (BS or BW)} \\ \text{If right-hand side of equation is } < r/2 &\text{ then BW, else it is BS} \\ h: &\text{ average annual temperature } > 18^{\circ}\text{C} \\ k: &\text{ average annual temperature } < 18^{\circ}\text{C} \end{aligned}$$

Also recognized:

- k': average temperature of warmest month $< 18^{\circ}\text{C}$
- n: high frequency of fog
- s: 70% of rainfall in winter 6 months (summer dry)
- w: 70% of rainfall in summer 6 months (winter dry)

C. Coolest month average temperature $< 18^{\circ}\text{C}$ and above -3°C ; warmest month average temperature $> 10^{\circ}\text{C}$

- f: at least 3 cm precipitation each month
- w: at least 3 times as much precipitation in a summer month as in driest winter month
- s: at least 3 times as much precipitation in a winter month as in the driest summer month, with 1 month $< 3 \text{ cm}$
- a: warmest month $> 22^{\circ}\text{C}$
- b: warmest month $< 22^{\circ}\text{C}$ but at least 4 months $> 10^{\circ}\text{C}$
- c: only 1–3 months $> 10^{\circ}\text{C}$

Also recognized:

- x: rainfall maximum in late spring or early summer: dry late summer
- n: high frequency of fog
- i: annual temperature range $< 5^{\circ}\text{C}$
- g: warmest month occurs before summer solstice
- t': warmest month occurs in fall
- s': maximum rainfall in fall

D. Coolest month average temperature $< -3^{\circ}\text{C}$; Warmest month $> 10^{\circ}\text{C}$

- d: coldest month $< -38^{\circ}\text{C}$
Other categories same as C climates

E. Warmest month average temperature $< 10^{\circ}\text{C}$

- ET: average temperature of warmest month between 0°C and 10°C
- EF: average temperature of warmest month $< 0^{\circ}\text{C}$

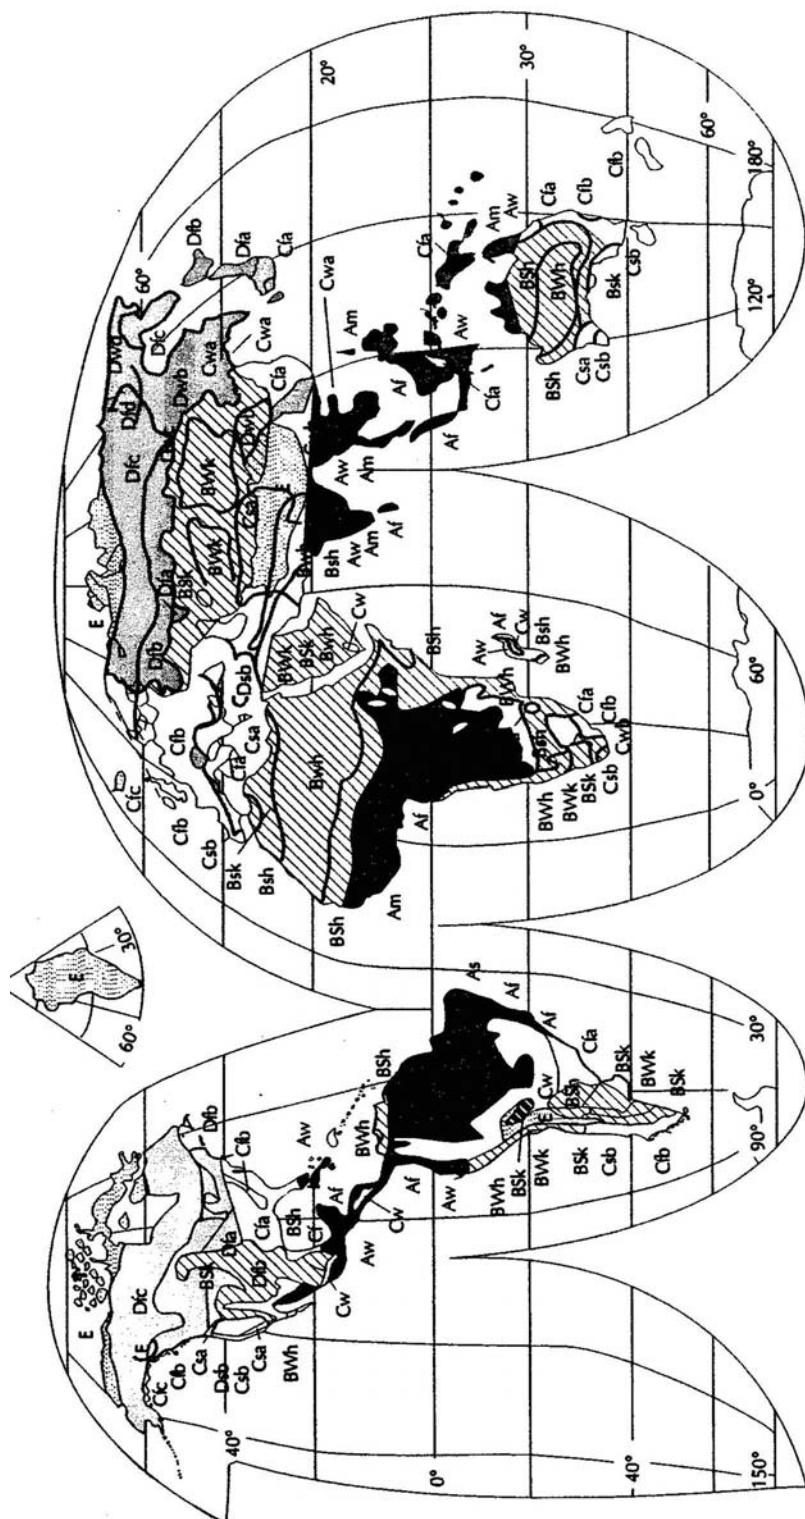

Figure C14 The Köppen classification of world climates.

by Köppen himself largely concerned the definition of the B climates. It remained for others to expound upon the work, and of these there were many. In a survey completed in 1952, Knoch and Schultz identify 70 works concerning the use of the Köppen system. Excellent reviews of the Köppen systems have been given by Thornthwaite (1943) and Wilcock (1968).

So dominant was the Köppen system that many fine alternate vegetation-based systems did not gain the widespread recognition. A system proposed by Vahl (1919), for example, overcomes the reliance upon average annual temperatures of the Köppen approach. Vahl based his classification upon four zonal climates that are subdivided by temperature limits that use both the warmest and coldest months. Another interesting approach was given by Troll (1958) who, by noting that "The life of plants, animals and humans . . . is subject to rhythm of climatic phenomena" produced a classification of the sea-

sonal climates of the Earth. Graphical representation also plays an important role in the classification introduced by Peguy (1961).

A classification of considerable interest was proposed by Holdridge (1947), who explained its formulation. "While attempting to understand relationships between the mountain vegetation of an area of Haiti and other vegetation units of the island and surrounding regions, the literature was searched unsuccessfully for a comprehensive system which presented formation or vegetation units on a relatively equal or comparable basis." To meet this end he produced what is now called the Holdridge Model, which related temperature and precipitation to produce a series of nested hexagons. The ecological value of the system was ably demonstrated by Tosi (1964).

Table C6 Some empirical approaches to climate classification

Author(s)	Purpose	Base of System
Bagnous and Gaussen (1957)	Biological climates	Duration of the dry season based upon the derived xerothermal index (X). Twelve major regions identified according to X values, temperature of coldest month, and frost/snow data.
Blair (1942)	An orderly description of world climates	Five main zonal climates distinguished: tropical (T), subtropical (ST), intermediate (I), subpolar (SP), and polar (P). Fourteen types and six subtypes distinguished using letter notation. Based upon precipitation and temperature data and related to vegetation types.
Brazol (1954)	Human comfort zones	Use of wet and dry bulb temperatures to establish comfort months. Twelve ranked classes ranked from no. 12 – lethal heat – to No. 1 – glacial cold.
Budyko (1958)	Distribution of energy in relation to water budget	Use of rational index of dryness to relate ratio of net radiation to energy required for vaporizing moisture. Moisture regions form basic unit.
Carter and Mather (1966)	Environmental biology	A modification of the 1948 Thornthwaite system.
Creutzberg (1950)	Climate–vegetation relationships	The annual rhythm of climate based on identification of <i>Isohygromen</i> (lines of equal duration of humid months) and <i>Tag-Isochione</i> (lines of equal daily snow cover duration). Four major zones differentiated, subdivided by monthly moisture values.
de Martonne (1909 and following years)	World regional (land-form) studies	Nine first-order divisions based upon temperature and precipitation criteria. Numerous subdivisions named for local areas in Europe. Considerable attention given to desert limits, but most boundaries derived nonquantitatively.
Emberger (1955)	Biologic (ecologic)–climate relationships	Two main climates differentiated: deserts and non-deserts. Differentiated and subdivided in terms of annual range of temperature and duration of light periods.
Fedorov	The "complex" method, utilization of day-to-day weather observations	An incomplete system that relies upon codification of daily weather events. For example, the first letter indicates character of prevailing wind; second letter character of temperature; third letter character of precipitation, cloudiness, humidity; fourth letter character various phenomena of atmosphere and state-of-ground surface.
Gorcynski (1945)	The decimal system	Ten "decimal" types associated with five main zonal climates. Emphasis on continental versus marine climates and definition of aridity.
Geiger-Pohl (1953)	World map of climate types	Modification of the Köppen system.
Köppen (1918 and following years)	See description in text	
Malmstrom (1969)	Precipitation effectiveness as a teaching scheme	Retention of the basic concepts of the Thornthwaite (1948) system but with arbitrary threshold values to express water needs of plants. Warmth index ($N - 38m/100$) also used.
Miller (1931 and following years)	Temperature and precipitation used as main variables	A basic system for location of general world patterns.

Table C6 (Continued)

Author(s)	Purpose	Base of System
Papadakis (1996)	Agricultural potential of climatic regions	Use of "crop-ecologic" characteristics of a climate based upon empirically derived threshold values. Ten main climate groups recognized, each divided into subgroups which are themselves divided.
Passarge (1924)	Climate–vegetation relationships	Recognition of five climatic zones and their subdivision into 10 regions emphasizing vegetation distribution.
Penck (1910)	World climates in relation to studies in physical geography and physiography	Recognition of three main types of climates significant in determining weathering and erosion. Humid, Arid, and Nival. Each subdivided into two.
Peguy (1961)	See description in text	
Philippson (1933)	Climatic regionalization on the world, continental and regional levels	Based on temperature of warmest and coldest months and upon precipitation characteristics. Five climatic zones with 21 climatic types and 63 climatic provinces.
Putnam et al. (1960)	Coastal environments of the world, climate–vegetation characteristics	Fourteen types recognized. Climatic characteristics expressed as those occurring between the 25th and 75th percentile of the frequency distribution appropriate to each climatic type. Variables include mean maximum and minimum temperatures, mean annual precipitation and monthly precipitation frequency.
Terjung (1966)	Bioclimatic, based on humans	Use of comfort index and wind effect to identify physiological climates.
Thornthwaite (1948)	See description in text	
Trewartha (1954)	An orderly description of world climates	Modification of the Köppen system.
Vahl (1919)	World climates related to vegetation	Five zones appraised by temperature limits which are a function of the data for warmest and coldest months. Subdivision by precipitation expressed as a percentage of number of wet days in a given humid month.
von Wissman (1948)	World distribution of climate related to vegetation	Related to the Köppen approach. Five temperature zones subdivided by precipitation distribution and temperature regimes.

Table C6 provide a listing of some of empiric approaches to the classification of climate.

Applied empiric classifications

While the vegetation-based classifications, typified by the Köppen system, received most attention, many other authors proposed empiric schemes that might be classed as special-purpose. These applied empiric classifications were as diverse as the things upon which climate has an impact, but their nature can be demonstrated using selected examples.

In early published works using the applied empiric approach, climate was considered a component of the proposed classification rather than the base of the system itself. In the De Martonne (1909) classification the principal goal was to provide a basis for physiographic studies. This was accomplished by identifying nine main regions grouped upon a variety of parameters ranging from temperature thresholds, annual temperature range and annual average precipitation. De Martonne refined his approach in successive published books, many of which were translated into English (De Martonne, 1927). Another physiographer, A. Penck (1910), used an already-existing formula (rainfall/evaporation ratio) to suggest that humid, dry and transitional climates could form the basis of a world classification of utility in physical geographic studies.

The more recent applied empiric systems relate climate to a wide range of applied areas. Terjung (1968) formulated a

bioclimatic classification, while in his text *World Climates*, Rudloff (1981) applies a bioclimatic aspect to the Köppen system. Of systems relating climate to crops, the classification outlined by Papadakis (1966) is of interest. In some ways such an approach is an extension of the crop analog studies completed by Nuttenson (1947).

The moisture balance

In a paper published in 1931, C. W. Thornthwaite proposed a climatic classification that appeared as a marked departure from preexisting systems. Unlike most classifications available at the time Thornthwaite based his system on the concept of precipitation and thermal efficiency. Of more significance at present, having superseded the earlier system, is Thornthwaite's 1948 classification (Figure C15). This shows a radical departure from the 1931 system because it makes use of the important concept of evapotranspiration. While the earlier system had been concerned with the loss of moisture through evaporation, the new approach considers loss through the combined process of evaporation and transpiration. Plants are considered as physical mechanisms by which moisture is returned to the air. The combined loss is termed evapotranspiration, and when the amount of moisture available is non-limiting, the term potential evapotranspiration is used. As with any widely used system, the 1948 classification has been subject to criticism. Many of the criticisms relate to the empiric formula used to express evapotranspiration, and to the

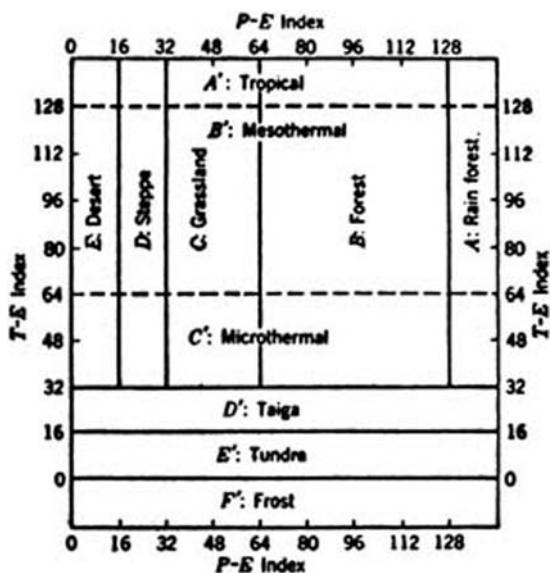

Figure C15 Temperature and humidity provinces of the Thornthwaite classification.

way in which the water budget of a station is manipulated. Its present status is well described by Muller and Oberlander (1984), who note that because its computations are time-consuming, the Thornthwaite system is not often used to define climatic regions on a global continental scale. At the same time it is an invaluable tool in water budget analyses.

Airmass and synoptic climatology

Just as climates may be classified according to the effect of climate upon environmental systems, so may they be grouped according to factors that contribute toward their cause. These causative effects relate to the origin (or genesis) of the climates concerned and resulting systems may be termed the genetic classifications. The development of synoptic meteorology and the concept of airmasses led to enormous improvements in comprehending weather. It seemed that a similar methodology could provide a suitable base for the study of genetic climatology for, as Thornthwaite (1943) suggested "Climatic types are to climate what airmasses are to weather". Subsequent to the basic delineation of airmass types, a number of significant climatological studies based upon airmasses were published. Willett (1933) described the properties of airmasses of the United States, while Showalter (1939) produced airmass identification tables. Despite these advances no comprehensive climatic classification based upon airmasses was formulated and, even at present, such systems are still only first approximations of the climatic complex of the Earth. Valuable maps of seasonal airmasses were presented by Berry and Bollay (1945), while Oliver (1970) used an airmass identification chart to classify world climates using set theory. But of the airmass groupings available perhaps the most utilitarian is that given by Strahler (1951 and following years) in his popular text *Physical Geography* (Figures C16 and C17). Essentially, three main groups of climates are differentiated:

1. Group I. Climates dominated by equatorial and tropical airmasses all the year.
2. Group II. Climates that occur between groups I and III and that are influenced by the interaction between tropical air-masses (group I) and polar airmasses (group III).
3. Group III. Climates controlled by polar airmasses.

Dynamic/synoptic classification

Today, some of the most significant classification schemes are developed as part of dynamic/synoptic climatology. The forerunners to the most recent systems are those that were based upon identified physical determinants. One of the earliest workable systems of classifying climate by cause was introduced by Hettner (1930), with that by Flohn (1950) exemplifying a later approach. The nature of more recent work in synoptic classification, and the concepts of grosswetterlagen (large-scale weather patterns) is well described by Barry and Perry (1973). These authors note the various approaches that can be used in synoptic classification, and differentiate the static pattern (the features of circulation including pressure patterns) and the kinematic, in which streamline analysis is of importance. Of note, however, is that many of the studies using such approaches are purpose-oriented classifications and differ in objective and character from the classic world schemes. Barry (in Oliver et al., 1989) has described the significant advances in classification procedures in synoptic climatology made in recent years. He cites the progress in evaluating existing objective procedures (e.g. Yarnal and White, 1984), and the value of clustering techniques. Many of the techniques used are an integral part of the methods used in numerical classification.

Numerical classification

Of singular importance in the developmental history of climatic classification is the introduction of numerical classification or numerical taxonomy. Classifications may be derived either by the logical subdivision of a population or by agglomeration of similar individuals within that population. Most of the classification systems described thus far use logical subdivision as the methodological choice. By contrast, the use of any one of the discriminatory techniques now available, permit classification by agglomeration. The advances in electronic computing permit univariate and multivariate systems of climate to be generated from enormous databases and sophisticated techniques have been incorporated in existing classification methodologies. In reality the numerical taxonomic method supplies a rational mathematical approach to the basic needs of a classification. Willmott (1977) points out that decision making in deriving any classification must concern (a) the number of regions to be identified, (b) the identification of boundary criteria, (c) the variables selected to represent the climate, and (d) the methods in which the selected variables may be summarized. Prior to the utilization of taxonomic theory, the availability of extensive databases and electronic computing devices, decisions concerning these were highly arbitrary. Using the newer methodology the decisions obviate arbitrary choices. McBoyle (1971), following Steiner (1965), produced one of the earliest numerical classifications of climate, and his methodology illustrates the nature of the approach. Using 20 variables for 26 stations in Australia, McBoyle completed a factor analysis to produce three factors that together accounted

for almost 90% of the total variance. Then, through linkage analysis, he showed how a grouping of Australian climates could produce a number of regions most applicable to the needs for which the classification was completed. This latter point is of considerable importance for, ultimately, classification rests with the goals of the user. This example is but one of many numerical classifications now available. In reviewing available grouping methods, Balling (1984) provides a most useful inventory of both the techniques and appropriate examples of their use. Table C7 outlines the approaches he identifies.

The introduction of numerical taxonomy has opened new vistas for the regionalization of climate, and perhaps it is this realm that represents the future of climatic classification. In effect, it seems that, for general pedagogic purposes, users appear satisfied with world climatic systems that are available. It is possible that other general-purpose world classification systems may be proposed, but given the history of non-use of some excellent classifications, the likelihood of widespread use and acceptance is minimal. In contrast, the increasing significance of climate impact studies, applied climatic research and scenario analysis suggests that special-purpose classifications will be used, and that these will largely be based upon numerical classification.

CLIMATE COMFORT INDICES

Climate has profound influence on human comfort and health. Weather elements can act singly or in combination to bring about effects on human bodies. Assessment of the influence of atmospheric environment on human comfort becomes an area of great concern in the context of human health and diseases, recreation, migration, tourism, heating and ventilating industry and architecture.

To obtain relative comfort the human body has to achieve a thermal equilibrium with the surrounding environment. The basis of human thermal response is the energy balance equation, which is expressed by

$$M \pm R \pm C - E = \pm S \quad (1)$$

where M is metabolic rate, R and C are heat exchange through radiation and convection, E is heat loss through evaporation, and S is heat storage in the body. Positive S indicates an energy gain for the body whereas negative S shows an energy loss. Physiologically, least thermal stress is experienced when S equals zero. To maintain a constant core body temperature near 37°C, the human body acts as an energy exchange surface and a balance is conserved through heat exchange with the environment and heat gain from metabolism.

Human thermal comfort is the result of the combined effect of several atmospheric variables. To quantify comfort or discomfort it is necessary to devise biometeorological indices to predict the human responses to weather stress and to assess the physiological strain. These indices incorporate a combination of atmospheric parameters depending upon their applications. Also, the terms in the energy balance equation given earlier may have to be simplified or detailed. In cold environments, evaporative-expired air energy loss is assumed to be constant, and it is presumed that metabolic rates need to increase to make up the losses in the energy balance. On the contrary, in warm

environments, sweating, that leads to elevated metabolic rate and inefficiency of cooling due to sweat covering the body surface, makes calculation extremely complicated.

Empirical indices

Table C8 presents representative comfort indices, largely from Driscoll (1985), Beshir and Ramsey (1988), Auliciems (1997) and Pepi (1999). The listing is not inclusive.

The Effective Temperature (ET) combines temperature and humidity into a single index; and is defined as the temperature of still-saturated air that produced the same thermal sensation as the actual atmosphere. ET is criticized for overestimation of the effect of humidity at low air temperature and underestimation at higher air temperature. ET can be modified to include air movement. Its derivative corrected effective temperature (CET) is simple and easy to use, and is considered as a useful index for engineers. Gagge et al. (1971) introduced the new effective temperature (ET*). This revised ET* employs reference conditions of 50% relative humidity and 0.6 clo of clothing insulation instead of 100% humidity and 1.0 clo. ET* can be applied in environments in high altitudes and underground mines.

The Discomfort Index (DI) was developed by the US Weather Bureau (now the National Weather Service). It gives the equivalent temperature at 100% humidity. It was renamed the Temperature–Humidity Index (THI). The index does not include radiation and wind speed.

The major criticism of the THI is the use of 100% saturation in the computation. A new index called the Summer Simmer Index (SSI), which is calculated as the THI in the usual manner, but 10% humidity is employed, was developed. Ten percent humidity is selected because it is a value experienced at typical temperature extremes in dry climates of the United States. So the SSI is an index expressing how hot one feels relative to a dry climate. A new SSI was proposed in 1999 using dewpoint of 2°C (35°F) as the dry equivalent base. This new index is confirmed by subjects testing at Kansas State University.

Humiture (H) incorporates temperature and vapor pressure to characterize warm and hot environment. The Atmospheric Environment Service of Canada modified and changed the units in the index from degree Fahrenheit to degree Celsius and named the new index Humidex (Masterton and Richardson, 1979), that is used to inform the public as to the heat stress.

The Wet-bulb Globe Temperature Index (WBGT) is an index of heat stress and incorporates air temperature, wet bulb temperature and black globe temperature. The WBGT is a better index than the old ET as it shows a good correlation with sweat rate. The index is commonly used by the US Marine Corps to control drill activity outdoors, and by industries to estimate heat stress potential in industrial environments.

The Relative Strain Index (RSI) includes temperature, humidity, air movement, the insulating effect of clothing and net radiation of heat of the body. It assumes that a person, dressed in a light business suit, walking at a moderate pace in a very light air motion, has a metabolic rate of 3.2 km/h.

The Predicted 4-hourly Sweat Rate Index (P₄SR) adds the rate of heat produced from physical work to the WBGT. The index assumes to assess the amount of sweat perspired by a physically fit young man in the conditions under review for a period of 4 hours. It is commonly utilized in hot climates to estimate sweat loss and the required water intake.

The Belding–Hatch Heat Index also involves the heat rate produced by physical work. It compares the amount of sweat

Table C8 Representative comfort indices

Name of index	Description or comment
Effective Temperature (ET)	Physiological principles are not considered. Overestimates the effect of humidity at low temperature.
Corrected Effective Temperature (CET)	A modification of ET. Combines temperature, humidity, air velocity and radiation. Underestimates the effect of humidity and low air movement. Used in the British armed forces.
New Effective Temperature (ET*)	Used by ASHRAE for indoor comfort. Good indicator of physiological strain and warmth discomfort. Difficult to apply and complicated instruments are needed.
Temperature–Humidity Index (THI); formerly called the Discomfort Index (DI)	Gives the equivalent temperature at 100% humidity.
Summer Simmer Index (SSI)	Same as THI but 10% humidity is used. To indicate how hot one feels to a dry climate. New SSI proposed in 1999, also related to a dry environment and a dewpoint base of 2°C (35°F) is used.
Humiture (H)	Incorporates air temperature and vapor pressure. The Atmospheric Environment Service of Canada modified the index and named it the Humidex, that is more sensitive to humidity change.
Wet-Bulb Globe Temperature Index (WBGT)	Good correlation with sweat rate. Practical for industrial purposes. Estimation gets poorer under low humidity conditions. Metabolic workload is not considered.
Relative Strain Index (RSI)	Includes temperature, humidity, air movement, clothing and radiation of heat of the body. Applicable to assess heat stress of manual workers under shelter at various metabolic rates.
Predicted 4-hourly Sweat Rate Index (P_4 SR)	Same as WBGT with addition of heat rate produced by physical work. Estimates sweat loss and required water intake.
Belding–Hatch Heat Index	Same as WBGT with addition of heat rate produced by physical work. Evaluates hot working environment. Underestimates the adverse effect of low wind speed and hot humid environment.
Apparent Temperature (AT)	To quantify sultriness.
Heat Index (HI)	A multiple regression model converted from AT. Used by the US NWS to alert the public of heat stress.
Wind Chill	Most widely used cold stress index. A new formula was implemented by the US NWS on 1 November 2001.

needed to maintain thermal equilibrium to the maximum amount of sweat that can be evaporated. It incorporates air temperature, globe temperature and the wet bulb temperature.

Steadman (1979a,b) studied sultriness that led to the development of the Apparent Temperature (AT). AT was an attempt to quantify sultriness. The index incorporated temperature, humidity, clothing and human physiology. The algorithms were simplified and regression equations were provided for indoor, shaded and sunny conditions (Steadman, 1984). The US National Weather Service (NWS) converted AT into a multiple regression model called Heat Index (HI), which is used to alert the public to heat stress. Table C9 presents the apparent temperatures of HI, and the heat stress categories and their associated symptoms based on the severity of impact on humans.

Wind Chill (WCT), a measure of the combined effects of low temperature and wind, was devised by Siple and Passel (1945) on the basis of experiments examining the freezing rate of water in a cylinder at various temperatures and wind speeds in

Antarctica. The index and derived wind chill equivalent temperature are widely used, especially among the media; meanwhile they have also received criticisms over the past five decades. The recent reviews of wind chill are given by Dixon and Prior (1987) and Brauner and Shacham (1995). Steadman (1971) introduced a new wind chill formula that included the effect of clothing and all forms of heat loss. The model was justified in human conditions. However, it is less popular due to its complex equation. Because of the dissatisfaction of the WCT, the Office of the Federal Coordinator for Meteorological Services and Supporting Research (OFCM) formed a special group called the Joint Action Group for Temperature Indices (JAG/TI), that included the Meteorological Services of Canada (MSC), the US NWS and several members of the academic community, to develop a new WCT formula. Besides mathematical modeling, human experiments were also involved. Volunteers, with temperature sensors on their faces, were exposed to various thermal conditions in a wind tunnel. The

47	40	44	51								
48	41	45	53								
49	42	47									
50	42	48									

The US National Weather Service has guidelines for the following ranges of heat index:

32–40°C Heatstroke, heat cramps, or heat exhaustion are possible with prolonged exposure and/or physical activity.

41–53°C Heat cramps or heat exhaustion are likely, and heatstroke possible with continued exposure.

≥54°C Heatstroke is highly likely with continued exposure.

NWS implemented the new WCT on 1 November 2001. The new formula is shown in equation (2).

$$\text{WCT} = 13.13 + 0.62T - 13.95V^{0.16} + 0.486TV^{0.16} \quad (2)$$

where T is the air temperature (°C) and V is wind speed (m/s). Using the new WCT formula, frostbite may occur in 30 min or less according to Table C10.

Energy balance models

A large variety of models have been developed to include all energy exchange processes and outdoor environments. These models are extremely complex. The major models are presented in Table C11.

Fanger (1970) devised a model that comprises all forms of heat exchange. The model was based on the results of laboratory experiments involving nearly 1400 subjects wearing light clothing, and the relationship between the computed energy exchange and the predicted mean vote (PMV) of comfort sensation was derived. The PMV of comfort sensation is rated on a seven-point scale ranging from +3 (hot) to -3 (cold). The PMV equation represents the human physiological responses to particular environments. The model was designed for indoor conditions and has been modified to incorporate the complex

outdoor radiation conditions, being known as the Klima Michel model (Jendritzky et al., 1979).

Höppe (1984) proposed the MEMI model (Munich Energy-balance Model for Individuals) that took into account the basic thermoregulatory processes, such as constriction or dilation of peripheral blood vessels and sweat rate. The MEMI consists of three equations. They are the energy balance equation of the total body, the equation of heat flux from the body core to the skin, and the equation of heat flux from the skin through clothing layers to the surface of the clothing. The model is the basis for the calculation of the physiological equivalent temperature (PET), that is equivalent to the air temperature at which, in a typical room indoors, the heat budget of the human body is balanced with the same core and skin temperatures as under the outdoor conditions being assessed.

Blazejczyk (1994) proposed the MENEX model (Man-environment Heat Exchange Model), that is the evolution of the model proposed by Budyko (1974). The model also takes into account human thermo-physiological considerations. Its applications include forecasting human thermal conditions outdoors, and evaluations of bioclimates and heat load at work.

De Freitas (1985) developed the STEBIDEX (Skin Temperature Energy Balance Index) and the HEBIDEX (Heat

Table C10 The new Wind Chill Temperature (WCT) chart

V_{10}	T_{air}

Approximate thresholds:

Risk of frostbite in prolonged exposure: wind chill below

-25

Frostbite possible in 10 minutes at

-35

Warm skin, suddenly exposed. Shorter time if skin is cool at the start.

Frostbite possible in less than 2 minutes at

-60

Warm skin, suddenly exposed. Shorter time if skin is cool at the start.

T_{air} = air temperature in °C and V_{10} = observed wind speed at 10 m elevation, in km/h; courtesy of the Meteorological Service of Canada.

Table C11 Major energy balance models

Name of model	Description or comment
Predicted Mean Vote (PMV)	First model including all forms of heat exchange. Mean skin temperature and sweat rate are quantified as comfort values, being only dependent on activities.
MEMI	Thermo-physiological heat balance model. Basis for the calculation of PET.
MENEX	Thermo-physiological heat balance model.
Klima Michel Model	Modification of Fanger's PMV to incorporate complex outdoor radiation.
HEBIDEX and STEBIDEX	To identify the relationship between the environmental stress being experienced and the condition of mind, being expressed in thermal sensation.
STOEC	Based on the fall of body core temperature. Applied in cold environment.

Budget Index). The adequacy of both indices was tested by empirical study of human thermal response outdoors on the beach. The results indicated that the STEBIDEX model could provide a more reliable estimate of thermal sensation.

De Freitas and Symon (1987) developed the STOEC (Survival Time Outdoors in Extreme Cold). The STOEC incorporates temperature, wind, solar radiation, clothing and the human energy budget, which is based on the rate of fall of core temperature from 37°C to 27°C. It provides the calculations for the shortest, longest, mean and indefinite survival times. It is useful in estimating the duration of research and rescue operations.

Conclusion

The trends in the development of comfort indices reflect the move from the conventional static approach to environmental

assessment. This change has been toward the use of dynamic energy exchange models, that synthesize the interaction between the human thermo-physiological processes and the atmospheric environments. However, it is important for an index to provide realistic meaning and simple interpretation of abstract index value to the lay public.

CLIMATE DATA CENTERS

With recent advances in computer storage capability, and the proliferation of the Internet, climate data for virtually every country in the world are becoming easily obtainable for researchers and the general public alike. Many countries have set up, within the organizational structure of the various departments of meteorology and climatology, systems for gathering, editing and archiving the volumes of climate information that are available. While the following is not a comprehensive list of the climate centers around the world, it represents places of

international renown that service the research and public domain communities by providing raw, edited, or aggregated datasets and have important links to modeling and research centers.

Japan

Tokyo Climate Center

The Tokyo Climate Center (TCC) was established in April 2002 to provide climate data and services to the Asian-Pacific environment and to assist in the mission of the Japan Meteorological Agency and the National Meteorological and Hydrological Service of Japan. The activities of the center include monthly reporting of climate events of a global nature and investigations in the climate systems that may affect the weather of the Asian-Pacific realm, including, and especially reporting on, the El Niño phenomenon and to produce ensemble monthly forecast models and verification of them.

The TCC is involved in assisting with the technical expertise needed to design the delivery of climate services throughout the Asia-Pacific region and to provide climatology data to the region. It also works in concert with other organizations in nations within the region to help facilitate the delivery of climate data, services and forecasts by the meteorological and climatological agencies in other Asia-Pacific nations.

United Kingdom

British Atmospheric Data Center (BADC)

The BADC is the main archive for atmospheric data in the UK. It is one of seven data centers designated by the National Environmental Research Center and is housed within the Space Science and Technology Department of the Rutherford Appleton Laboratory in Oxfordshire. The BADC produces datasets derived from NERC-funded projects, and serves as an efficient link to data provided by such services as the European Center for Medium-Range Weather Forecasting Office (the ECMWF) and the UK Meteorology Office.

The BADC was established in 1994 building upon the work of the former Geophysical Data Facility (GDF). The BADC presently holds up to 70 datasets of a variety of atmospheric variables and is the archive for the ECMWF reanalysis dataset. In addition, research work by BADC staff includes projects delegated to three main groups: atmospheric dynamics, cloud physics and data assimilation. BADC staff are also engaged in research efforts with the RAL SSTD Atmospheric Modeling and Data Interpretation Group (AMDI).

United States

Carbon Dioxide Information Analysis Center, CDIAC, Oak Ridge, Tennessee

The CDIAC, operating out of the Oak Ridge Laboratory, compile data and information related to greenhouse gases, their rates of emission, and the cycle of these gases between the oceans, the biosphere and the atmosphere. They also have surface climate data, edited for selected stations that are part of the United States Historical Climate Network and historic mid-tropospheric height data. The CDIAC also houses surface data for the People's Republic of China. The World Data Center for Atmospheric Trace Gases is housed in the CDIAC.

The Climate Diagnostics Center (NOAA – CIRES, CDC), Boulder, Colorado

The CDC is a research and archival unit designed to analyze climate events. It archives the National Center for Environmental Protection's Re-Analysis Dataset, as well as time series of sea-surface temperatures, various El Niño and Southern Oscillation indices, as well as the northern hemisphere teleconnection indices.

US National Snow and Ice Data Center (NSIDC), Boulder, Colorado

The NSIDC, under a joint agreement with the University of Colorado, operates houses the World Data Center for Glaciology.

The center compiles, archives and maintains data related to snow cover, snow depth, snow pack, sea-ice extent and depth, freshwater ice and glacier extent.

US National Climate Data Center (NCDC), Asheville, North Carolina

The NCDC has the largest climate and meteorology database in the world. It also houses the World Data Center for Meteorology. Designed originally to house weather records obtained by National Weather Service offices and cooperative stations, it now archives 99% of the data obtained by departments of the National Oceanic and Atmospheric Administration (NOAA). The center also maintains and archives radar data, satellite imagery from 1960, radiosonde,

Table C12 Selected members of the World Data Center network directly related to research in climatology

World Data Centers	Affiliation and location	Data emphasis
Atmospheric Trace Gases	Carbon Dioxide Information Center, Oak Ridge National Laboratory, Oak Ridge, Tennessee	Data related to atmospheric trace gases that affect and contribute to the Earth's energy budget.
Glaciology – USA	National Snow and Ice Data Center, Boulder, Colorado	Snow cover, snow pack, sea-ice extent, sea-ice thickness, images and pictures of historic glacial extent.
Glaciology – Geocryology, China	Lanzhou Institute of Glaciology and Geocryology, Chinese Academy of Sciences, Lanzhou, China	Glacial atlas of China, snow cover, glacial extent and variation, periglacial data and hydrologic data.
Glaciology, UK	The Royal Society and the Scott Polar Research Institute, University of Cambridge	Data related to glaciers, periglacial processes, satellite imagery, snow and ice chemistry.
Airglow – Japan	National Astronomical Observatory, Tokyo, Japan	Airglow data, solar radiation data.
Meteorology – China	Climate Data and Applications Office, Beijing, China	Real-time synoptic data, historical surface climate data, dendrochronology data, glacial data and atmospheric chemistry data.
Meteorology – Russia	Federal Service of Russia for Hydrometeorology and Monitoring of the Environment, Obninsk, Russia	Both surface observations and gridded surface and upper air meteorology data, marine ship observation data, and aerology data.
Meteorology – USA	National Climate Data Center, Asheville, North Carolina	Archives of data from many national and international research projects and experiments including data from the IGY 1957–1958 and International Quiet Sun Year, 1964–1965, among many others.
Paleo-climatology – USA	National Geophysical Data Center (NGDC), Boulder, Colorado	Dendrochronology data, ice-core data, sea-floor sediment cores, Coral data, proxy data on climatic forcing, including volcanic aerosol data, ice volume, atmospheric composition, etc. Numerical model simulation experiments data, climate reconstructions and maps.

rawinsonde, rocketsonde and other advanced technology sources. The center also houses weather data from diaries, notes and other sources. The center also services a network of regional and state climatology data centers designed to deliver climate data of regional and local interest.

International Organizations

The Intergovernmental Panel on Climate Change Data Distribution Center (DCC)

The DCC acts as a gateway to many datasets used to assess changes in the global climate. The DDC acts in concert with the Deutsches Klimareschenzentrum (DKRZ) in Germany and the Climate Research Unit (CRU) in the United Kingdom to archive and distribute much of the data that the IPCC provides. The DDC maintains links to locations that have data in the public domain. Output from Global Circulation Model (GCM) runs are available at the DKRZ distribution site. The DDC also archives the CRU Global Climate Dataset that has monthly surface variables from 1905 to 1995 and is arranged on a 0.5° by 0.5° latitude–longitude grid. This includes all land grid cells except for Antarctica. The DDC also maintains another dataset arranged by country and containing both averages (1961–1990) and month-by-month variations (1901–1995).

World Climate Data Centers

The World Climate Data Center system is a network of data centers that was originally designed to archive the data derived during the International Geophysical Year (IGY) but has subsequently expanded to include climatological, meteorological, astronomical, oceanographical as well as geophysical datasets. The centers are usually housed within other organizations. Each of the following regions, United States, Europe, Australia, China, Russia, Japan and India, have several centers specializing in one of the areas of geophysical data and research. Table C12 lists those centers that have data directly related to research in climatology in particular.

CLIMATE HAZARDS

This review of climate hazards outlines the great variety of such events and their impacts. It illustrates some of the present concerns of and future challenges for the climatologist.

Nature and variety of the threats

Potentially hazardous atmospheric phenomena include tropical cyclones, thunderstorms, tornadoes, drought, rain, hail, snow, lightning, fog, wind, temperature extremes, air pollution, and climatic change. Hazards may arise from single-element extremes, such as excessively high temperatures causing physiological heat stress; or from various combinations of elements, such as tropical cyclones with high wind, torrential rain and storm surge, all posing threats to people and their property. Estimates of annual global economic losses due to meteorological disasters showed a fourfold increase from the 1960s to the early 1990s to nearly \$90 billion, and insured losses increased about tenfold to over \$50 billion (Bruce, 1994).

Hazards producing disasters with economic, political, and social repercussions have always been newsworthy. The public view of climatic hazards has been nurtured by frequent media reports of events such as the tropical cyclone that killed about 300 000 people in the former East Pakistan in 1970; the severe frost damage to coffee crops in Brazil in 1975, followed by huge increases in world coffee prices; the storm that devastated the Fastnet yacht race in 1980; the exceptional storm in 1988 which left the most severe damage for many generations in southern England; another tropical cyclone in Bangladesh in 1991 which killed about 139 000 people; Yangtze floods which destroyed over four million dwellings in 1991; Hurricane Andrew which produced damage estimated at over \$25 billion in Florida and Louisiana in 1992; ice and snow storms in eastern North America in 1993, 1994 and 1998, with total damages of several billions of dollars; the heatwave in the Midwest and eastern USA in 1995; El Niño-related weather events in 1997–1998 around the world; Hurricane Mitch in Central America in 1998; and in 2002 Typhoon Rusa, the deadliest storm in South Korea in over 40 years, as well as widespread flooding in Europe.

Perhaps Leonardo da Vinci was the first to recognize the downburst associated with severe thunderstorms (Gedzelman, 1990), but there is little evidence of research on climatic hazards

before the nineteenth century, with early emphasis mainly on the cataloguing of events, such as tropical cyclones in a particular area (e.g. Knipping, 1893). The work of Barrows (1923) on human structuring of, and adjustment to, environment provided an identifiable start for a more balanced research tradition, the development of which may be traced through studies such as those by Visher (1925) on tropical cyclones in the Pacific Ocean and by Foley (1957) on drought in Australia. Interest and emphasis have shifted to a much greater concern with the nature and alleviation of impacts, as reflected in the wide range of natural, physical, and behavioral scientists, and economists working on frequencies, magnitudes, causes, behavior, and impacts of climatic hazards, as well as with studies of perception, preparedness, planning, mitigation and control. This diversity of interests, and the directions in which research has been heading, is exemplified in works such as those by White (1974), Heathcote and Thom (1979), Hewitt (1983, 1997), Burton et al. (1993) and Smith (2001).

Identification of hazardous events is not always easy, although certain criteria are usually present. They include property damage; economic loss, such as loss of income or a halt in production; major disruption of social services, communications and transportation; excessive strain on essential services such as police, fire, hospitals, and public utilities; and psychological stress, injuries, and fatalities (e.g. Changnon, 1989, 1999; Barker and Miller, 1990; Morison and Butterfield, 1990; Hoque et al., 1993; Brugge, 1994a, b; Kalkstein, 1995; Fink et al., 1996; Curran et al., 2000; Dupigny-Giroux, 2000; Palecki et al., 2001; Ulbrich et al., 2001; Pielke and Carbone, 2002).

It can be difficult to distinguish between the atmospheric and nonatmospheric factors producing climatic hazards. Hot, dry winds may promote fire disasters but do not cause them. An avalanche depends on the quality and quantity of snow and on the timing of a thaw, but it is unlikely to happen without certain slope characteristics. Increasing losses over time point to the significance of socioeconomic factors in exacerbating the vulnerability of communities to hazard events. More than half of the world's population lives within 60 km of the ocean. Known flood plains, hurricane- and drought-prone regions have experienced development pressures and increased volumes and values of property at risk (e.g. Riebsame et al., 1986; Pielke and Pielke, 1997; Kunkel et al., 1999; Changnon et al., 2000; Easterling et al., 2000). Climate change is also seen by some as creating potential new threats (e.g. Obasi, 1994; Woodhouse and Overpeck, 1998; Yarnal et al., 1999; Parry et al., 2001). There are already very large disparities in the nature and magnitude of hazard losses in different parts of the world; differences mainly attributable to socioeconomic factors (Degg, 1992).

Atmospheric, and socioeconomic, factors fulfill a variety of roles in the development of a hazardous situation. A broad distinction can be made between phenomena such as tropical cyclones or severe local storms, and their associated weather extremes, which involve the sudden impact of very large amounts of energy discharged over relatively short periods; and those features that become hazards only if they exceed tolerable magnitudes within or beyond certain limits (Gentilli, 1979). In the latter category can be included heat waves; cold spells; flood-producing rains; frosts; fogs; droughts; high winds, snow and ice associated with extratropical low-pressure systems; and the effects of climatic change. Some climatic hazards result from human activity. Under the broad umbrella of air pollution, these include hazards to human health, the possible dangers of

inadvertent modification of climatic patterns, and the effects of acid rain on natural ecosystems.

The treatment of climatic hazards that follows is not exhaustive, nor is it the only approach possible, but it illustrates various types of threats and their impacts. Examples of alternative approaches include Changnon and Changnon (1992), who group 11 causes of storms into four classes; and Smith (1997, 2001), who classifies climatic hazards into four groups: single-element extremes from common and less common hazards, and compound-element events from primary or secondary hazards.

Sudden-impact hazards

Tropical cyclones

Tropical cyclones can be the most dangerous and deadly storms on Earth. They are usually very mobile and relatively unpredictable. The main dangers to people and property arise from three distinct hazards: violent winds, storm waves and surges, and torrential rain. Winds in Hurricane Gilbert in the Caribbean in 1988 gusted to over 320 km/h (Eden, 1988), and in Hurricane Linda in the East Pacific in 1997 reached about 350 km/h (Brugge, 1998). Sustained winds approaching 280 km/h were reported for Hurricane Gilbert, but most tropical cyclones do not reach such intensity. Death and injury may result from structural collapse or from the impact of flying objects. Rainfall associated with tropical cyclones may total over 1000 mm in 24 h. Cyclone Hyacinthe dumped 6433 mm of rain on Reunion in 14 days in January 1980, with more than 1000 mm falling on each of two successive days (Smithson, 1993). During Hurricane Mitch in October 1998 parts of Honduras received 698 mm in 41 h, leading to widespread flooding and landslides (Hellin and Haigh, 1999). Flooding can be severe when such heavy rain falls in restricted catchments, or when run-off combines with storm wave and storm surge effects. The northern Bay of Bengal suffers a particularly serious storm surge problem because of a combination of large astronomical tides, a funneling coastal configuration, low and flat terrain, and frequent severe tropical storms. The November 1970 storm in this region may have been the deadliest ever to devastate a coastal area in recent times, with a storm surge of over 6 m and about 300 000 people killed (Frank and Husain, 1971), although tropical cyclones in the same region in 1737 and 1876 may have rivaled this (Sensarma, 1994).

Most of the 80–100 tropical cyclones each year form between latitudes 5° and 25°, 60–70% in the northern hemisphere. Tropical cyclone tracks sometimes reach beyond 40° latitude. The area immediately affected by the full force of a storm is typically about 1° by 1° latitude, corresponding to approximately 100 km of coastline. On this basis there are about 800 separate prime target areas around the globe, each with peculiar local conditions, especially with respect to storm surges.

Tropical cyclones are responsible for an annual average of about 20 000 deaths and over \$6 billion in damage globally (Obasi, 1994). In some cases, like the 1991 Bangladesh storm which destroyed over 500 000 dwellings, millions of residents can be directly affected (Haque and Blair, 1993). Three types of most vulnerable areas can be identified: densely populated, fertile coastal plains and deltas (e.g. the Ganges); island groups dependent on agricultural economies (e.g. Oceania, the Caribbean, the Philippines); and highly populated coastal regions developed as residential resorts (e.g. Florida, the

Queensland Gold Coast) or for industry (e.g. the Texas Gulf Coast, Japan) (Stevens, 1991).

Regional variation in the socioeconomic impact of tropical cyclones is related to factors such as the geographic vulnerability of communities, their experience with severe storms, population density, coastal and inland topography, land use, social organization, property and infrastructure at risk, and warning and response capabilities. Extensive delta regions in developing countries present the greatest potential for loss of life.

Evacuation is one form of emergency response in developed countries. However, as population densities increase, evacuation plans may prove inadequate, so that evacuation times may exceed what is feasible given the number of people to be moved and likely lead times from existing forecast capabilities (American Meteorological Society, 1993, 2000b). Costs of evacuation, estimated at about \$0.6 million per kilometer of coastline (Pielke and Carbone, 2002), could in some cases at least match those resulting from storm damage. Research after cyclone Tracy hit Darwin has suggested that mass evacuation may pose more problems than it solves, and that greater use of the victims' resources might speed up reconstruction and reduce psychological stress (Western and Milne, 1979). Research on the impact of tropical cyclones in such areas, however, cannot adequately represent impacts in countries with labor-intensive rural economies. Hurricane Gilbert produced damage in Jamaica estimated at \$800–1000 million, and estimates of reinsurance inflows were \$650 million; even the lower value exceeded the country's annual foreign exchange earnings from exports (Barker and Miller, 1990). Shortfalls in domestic food production had to be met by imports, virtually the whole banana crop and most of the coffee crop were wiped out. In Bangladesh in 1991 an estimated 51 000 ha of crops were completely destroyed and over 150 000 ha were partially damaged (Haque and Blair, 1993).

An industrialized society may plan for a low rate of building failures. This requires a high degree of engineering attention to housing design and construction, together with stringent building regulations. However, a developing country may elect to accept a higher level of building failures, adopting a strategy of temporary housing during and after a tropical cyclone. A variety of public buildings would then be strengthened and designed as refugee or reception centers. These contrasting approaches are exemplified by the decisions made by authorities in Darwin after cyclone Tracy in 1974 and by those in Sri Lanka after a rare tropical cyclone in 1978.

Most building damage is caused by the effects of wind on buildings that are not properly engineered, such as domestic houses and small, low-rise industrial and commercial structures. The effects of extreme winds on buildings are well understood, and wind engineering technology in theory can be applied anywhere. The impact of tropical cyclones is greatest when the population is rendered homeless, so housing design in vulnerable areas should include consideration of the effects of wind and water. Areas of infrequent tropical cyclone occurrence (e.g. the Queensland Gold Coast, the Atlantic Coast of the United States north of Cape Hatteras, parts of Mexico, India, and Japan) tend to have greater building vulnerability; whereas communities in areas battered relatively frequently by tropical cyclones have learned to cope with the hazard and tend to be less visible as disaster areas (e.g. Mauritius, Reunion Island, Guam, Northwest Australia, some South Pacific islands).

Improvements in warnings and in community preparedness have decreased the death toll from tropical cyclones, but the average annual inflation-adjusted hurricane losses in the United

States have grown from about \$5 billion in the 1940s to more than \$40 billion in the 1990s (Easterling et al., 2000). In developing countries, where some of the expected increase in world population will be in regions subject to tropical cyclone impact, a growing death toll and damage may be unavoidable, partly due to limitations on national resources to apply effective mitigation measures and partly due to a lack of understanding of the vulnerability of certain areas to the effects of tropical cyclones. In all parts of the world there is a continuing need for better community education about the potentially damaging hazards and about long-term mitigation planning (American Meteorological Society, 2000b).

The warning system is a primary feature of organization for disaster preparedness. Key elements in a warning system, apart from early detection and accurate forecasting, are the efficiency of the dissemination process and the reaction of the community. Education is vital to ensure that warnings are understood and that people are aware of the necessity to heed such warnings. Hazard warning involves a sensitive balance between over-warning, resulting in unnecessary and sometimes expensive preparations and leading ultimately to complacency and apathy, and underwarning, which gives insufficient time for adequate protective measures to be taken. The benefits of improvements in tropical cyclone detection technology and in behavior prediction are lost without corresponding progress in ability to utilize the information in planning, organizing, and acting for protection and convenience (Jagger et al., 2002). McAdie and Lawrence (2000) note that tropical cyclone track forecasts for the Atlantic basin improved from 1970 to 1998, but Powell and Aberson (2001) suggest that no statistically significant change is apparent for landfall position forecasts during the last 25 years. In most other parts of the world the situation is no better. In Taiwan, for example, hit by an average of nearly four typhoons per year, forecasting, and hence warning, is difficult because of lack of data over the North Pacific (Wu and Kuo, 1999). Despite some recent possible reductions in track forecast errors there has been little improvement in forecasts of storm intensity or structure, including overall size; and, while there have been advances in basic understanding, accurate predictions of tropical cyclone genesis are still some way off (American Meteorological Society, 2000b).

There were many false warnings in East Pakistan prior to the storm of November 1970, mainly because of lack of facilities to distinguish between killer and nonkiller cyclones. An estimated 90+% of the people in the disaster area knew about the storm, yet less than 1% sought refuge in substantial buildings. Most residents had never experienced a storm surge like that predicted, and thus felt no urgency to leave their homes. In addition, few had the means to move, or anywhere to go in the time available. A comparable situation occurred in Darwin with cyclone Tracy when the potential benefits of technically good predictions were not realized. Records show several near-misses for Darwin, including cyclone Selma only 3 weeks before Tracy, and at least six tropical cyclones which had seriously affected the community. However, the last severe event had been in 1937 and was remembered by few residents in 1974; Christmas Eve as Tracy approached, and Christmas Day when it struck, were not ideal times to muster enthusiasm for effective action.

Severe local storms

Severe local storm hazards are widespread, relatively unpredictable, seemingly impossible to prevent, and often costly in

lives and property damage (Atlas, 1976). At any instant there may be about 2000 active thunderstorms around the world (Dudhia, 1996). As separate cells, or as organized line squalls, thunderstorms develop cold downdraughts with high velocities that are capable of causing severe localized damage. The squall of a thunderstorm can gust to 185 km/h, and its effects are often compounded by intense rainfall, large hail, or lightning. Individual storms usually affect only small areas, but there may be many such storms at any one time in a particular region. Their association with flash floods, downbursts, strong winds, tornadoes and lightning makes accurate forecasting vital.

High-intensity, localized thunderstorms may produce flash floods. A storm in August 1988 at Khartoum, with daily rainfall of about 200 mm being more than twice the previous fall on record, left tens of thousands of homes destroyed and vast areas around the city inundated (Hulme and Trilsbach, 1989). An estimated 1.5 million were made homeless, and there were over 100 deaths and hundreds of injuries. Most of the homeless had nowhere to go; even areas which had not suffered damage were under water and there were few areas dry enough for temporary camps to be erected. A flash flood, produced by rainfall approaching a 500-year return period event, at Fort Collins in Colorado in July 1997, caused five deaths, 62 injuries and more than \$250 million in property damage (Weaver et al., 2000). Lessons from that event, with a systematic effort to improve awareness, communication and warning, meant that another flash flood in April 1999 caused significantly less damage.

Hailstones are usually less than 10 mm in diameter and cause little damage, but they are occasionally 100 mm or more in diameter and can cause serious damage to crops, buildings, and motor vehicles. About 20000 severe thunderstorms occur annually in the USA, with damage to property and agriculture of up to \$3 billion (Bentley et al., 2002). Hailstones up to softball size were reported in a storm causing about \$350 million damage in Denver in June 1984 (Blanchard and Howard, 1986), and there have been at least two reports from South Africa of coconut-sized stones (Perry, 1995). In the period 1982–1989, 250 people were reported killed by hail in India (Nizamuddin, 1993). Giant hailstones weighing 2–3 kg were reported in February 1988 in parts of Orissa state.

Thunderstorms are the most common cause of air traffic delays and play a major role in weather-related aircraft accidents (Bromley, 1977). Turbulence, hail, and wind shear within storm clouds have damaged many aircraft, with wind shear recognized as a major aviation hazard, particularly in the airport environment. The gust front ahead of the cold outflow from thunderstorm downdraughts is particularly hazardous because of associated large surface wind shears and because of its very localized nature. The strongest downdraughts, those most likely to be hazardous to aircraft during takeoff and landing, are called downbursts or microbursts (Fujita and Caracena, 1977; McCarthy and Serafin, 1984; Dudhia, 1997). Very high-resolution modeling of a developing thunderstorm has confirmed reports from aircraft of relatively narrow regions of turbulence in layers more than 1 km deep above the cloud (Lane et al., 2002). Thunderstorm downdraughts may also be a critical factor in driving some bushfire fronts; sometimes the fires themselves having been started by lightning strikes.

Lightning is one of the major causes of fatalities in the USA and is a significant hazard to outdoor activity during the summer months (Watson and Holle, 1996; Holle et al., 1999; Curran et al., 2000). It is probable that lightning deaths and injuries are considerably underestimated (Lopez et al., 1993),

with most people displaying inappropriate behavior during thunderstorms and not realizing the range of possible medical implications from a lightning strike, including paralysis, external burns, severe headaches, hearing and memory loss, and many others (Shearman and Ojala, 1999).

Some thunderstorms and the peripheral circulation of some tropical cyclones are accompanied by tornadoes, which are among the smallest but most destructive features of atmospheric circulation. Tornado wind speeds can exceed 350 km/h. The Tri-State tornado in March 1925 traveled about 350 km from Missouri to Indiana at speeds of 91 km/h to 109 km/h. About 80 km² of land were totally devastated, 689 people were killed, nearly 2000 people were injured, and over 11 000 people were left homeless (Flora, 1953). Over 2 days in April 1974 an outbreak of 148 tornadoes in the Midwest and southeast USA left 350 dead (Brugge, 1994c). On a single day in November 1981 an outbreak of 102 tornadoes struck parts of England and Wales (Rowe and Meaden, 1985). Just one tornado in May 1996 is reported to have killed at least 400 people in Bangladesh (Snow and Wyatt, 1997).

The global distribution of tornadoes is difficult to determine accurately (Perry and Reynolds, 1993). Most reports of tornadoes come from the United States, but they occur in many parts of the world including most of Europe, northern India and Bangladesh, Australia and New Zealand, Japan, Uruguay, and southern Africa (Fujita, 1973). Frequency data for tornadoes are unreliable for most parts of the world. During the 1950s about 200 tornadoes were reported annually in the United States, but by the late 1990s around 1200 were noted each year (American Meteorological Society, 2000a). Most of the increase may be accounted for by more frequent reports of weak tornadoes, probably because of growing public awareness, rather than any meteorological factors. Numbers of tornadoes reported from other parts of the world are substantially less, perhaps related to lack of awareness and sparse weather-observing networks. A study of tornadoes on the Indian sub-continent identified only 51 events between 1835 and 1977, but the path lengths and widths were larger than those characteristic of the United States, so many smaller tornadoes may have passed unreported (Peterson and Mehta, 1981). Elsewhere, for example, 191 tornadoes were reported in Argentina from 1930 to 1979; 42 in Taiwan from 1951 to 1978; 87 in Japan in 5 years from 1968; and 273 in France from 1680 to 1998 (Snow and Wyatt, 1997; Paul, 1999).

Tornadoes exhibit a considerable range of intensity, size, and duration. Typical New Zealand tornadoes have been reported to have damage paths only 10–15 m wide. The typical or median path of tornadoes in the United States has been given as 3.2 km long by just under 50 m wide (National Severe Storm Forecast Center Staff, 1980), but there have also been reports of tornadoes with paths ranging from less than 50 m to over 400 km. Damage associated with tornadoes is very localized, including severe structural damage to buildings (roofs lifted, walls and windows collapsed) and mobile homes, and tops screwed or snapped off trees, which may also be uprooted.

Tornado-generated missiles, ranging from gravel to semi-trailer trucks, present engineers with major design problems. In tornado-prone areas of the United States, where protection of people in buildings is important, the tornado missile can be the controlling design factor. Buildings such as hospitals, fire stations, and emergency operating centers, where critical functions must be maintained, are particularly susceptible to missile damage (McDonald, 1976). Small outdoor equipment

and larger objects such as utility poles can become tornado missiles. A tornado at Lubbock, Texas, in 1970 was responsible for moving a cylindrical tank (3.35×12.5 m) weighing over 11 tonnes about 1.21 km; and three 40-passenger school buses apparently became airborne in a tornado at McComb, Mississippi, in 1974.

Increasing public awareness, emphasis on tornado preparedness, improved warning systems, better understanding of tornado formation, the use of tornado drills, spotter groups and other measures at local and state levels have contributed to the decreasing death toll from tornadoes in the United States. However, a single tornado in Bangladesh may kill several hundred people because none of these conditions or measures exists, and because of the very dense population.

The broad environmental conditions leading to the development of severe thunderstorms and tornadoes are reasonably well recognized and can be forecast with some skill, but there is still no reliable method for predicting the development of a specific severe storm (Hoium et al., 1997; Snow and Wyatt, 1998). Technological advances such as Doppler radar, high-resolution satellite imagery, and acoustic sounders have improved prospects for forecasting severe local weather. In the USA there have been marked improvements in the remote detection of severe local storms and flash floods, accompanied by better warnings of such events (Polger et al., 1994; Vasiloff, 2001); but in most regions of the world the observing network and the available technology are inadequate for detection and measurement of most small-scale events.

Some local storms occur in areas where warnings, if they are given, will not help very much. A severe dust storm followed by heavy rain, for example, hit Karachi in May 1986 causing extensive property damage and dislocation of services (Middleton and Chaudhary, 1988). Thousands of bamboo huts and improvised houses with tin or asbestos roofs were blown away; telephone and electricity wires were snapped, giant trees uprooted and vehicles overturned; and more than half the city was plunged into darkness. There is no doubt that improved short-term forecasts can greatly diminish the impact of some local storms, in areas where such forecasts are available and can be readily disseminated. Warnings during the May 1999 tornado outbreak in Oklahoma and Kansas are credited with saving hundreds of lives, and Doppler radar provided significant warning lead time during the tornado outbreak in Georgia in February 2000 (Vasiloff, 2001).

Cumulative hazards

Many atmospheric disasters result from an accumulation of events, that singly would not be hazardous. One dry day or even one dry year does not necessarily constitute a drought, but a succession of abnormally dry years can have disastrous effects on the environment and its inhabitants. Similarly, hot days are common in many parts of the world, but a succession of many very hot days can prove lethal, especially in areas not normally accustomed to heat waves combined with high humidities.

Drought

In the period from 1967 to 1991 droughts were estimated to have affected 50% of the 2.8 billion people who suffered from weather-related disasters (Kogan, 1997). It is difficult to find a generally accepted definition of drought. Drought clearly involves a shortage of water, but realistically can be defined

only in terms of a particular need (Linsley, 1982). Drought is not just a physical phenomenon; it results from interplay between a natural event and demands placed on water supply by human use systems (American Meteorological Society, 1997). The absence of a precise definition adds to confusion about whether or not a drought exists and, if it does, its severity. The effects of a drought accumulate slowly over long periods and may linger for years after termination of the event. The reporting of drought occurrence may be overestimated or underestimated, because the material well-being of the reporter may be affected (Heathcote, 1979).

Four types of drought are usually recognized: meteorological or climatological, agricultural, hydrological and socioeconomic. Droughts impact both surface and groundwater resources. They can lead to reductions in water supply, diminished water quality, crop failure, reduced power generation, disturbed riparian habitats, suspended or curtailed recreation activities and a variety of other associated economic and social activities (Riebsame et al., 1991; Woodhouse and Overpeck, 1998). Long-term impacts on plant and animal life have received relatively little attention, and many questions are unanswered concerning the role of drought in ecosystems.

The impact of drought on human activities is usually described in terms of reduced water supplies and economic losses throughout the community. The evaluation of such impacts is complicated, with many factors needing to be taken into consideration. Several uncertainties can be involved, such as shortfalls in expected yields tending to inflate the value of actual yields on which the value of lost production is calculated, yet there being no guarantee that lost production could have been sold anyway.

Frequent droughts around the world, and interest in their possible links with phenomena such as El Niño, keep the hazard in evidence even for the casual observer. The 1975–1976 drought in Western Europe had widespread effects on agriculture, domestic and industrial water supplies, and on river and canal traffic. The drought in Britain, particularly southern England, was the worst for about 250 years. In some parts of the country, water supplies to domestic consumers were cut for up to 17 hours per day, and production of root and vegetable crops was down by as much as 40%. Droughts of the early to mid-1980s in Africa affected more than 40 million people. The Canadian Prairie Provinces are particularly sensitive to rainfall shortages and associated soil losses due to wind erosion (Wheaton and Chakravarti, 1990). In 1984 conditions rivaled those of the “Dust Bowl” years of 1936–1937, with farmers losing up to half of their grain crop to the value of about \$2.5 billion (Sweeney, 1985). The 1988 drought in the USA was rated as one of the worst in 100 years, with an estimated impact on the economy of \$40 billion (Kogan, 1997). An unexpected impact in this instance was on barge traffic on the lower Mississippi river, the industry suffering an income loss of about 20% (Changnon, 1989). The El Niño event of 1997–1998 was linked to drought in Central America and southeast Asia, with major impacts on vegetable quantity and quality in the former and on coffee and palm oil in the latter, both leading to reduced exports and increased prices on global markets (Changnon, 1999). It has been suggested that worldwide disasters triggered by droughts are twice as frequent during year two of ENSO warm events as during other years, particularly in southern Africa and southeast Asia (Dilley and Heyman, 1995).

Several factors may be implicated as potential causes of drought: ENSO, abnormal sea surface temperature patterns in

areas other than the equatorial eastern Pacific, soil moisture desiccation, and nonlinear behavior of the climate system (Orville, 1990). It is tempting also to suggest that climate is changing and that droughts are becoming more frequent and/or more severe. However, there have always been droughts, and records show that events such as those mentioned are within the realm of statistical expectations (Landsberg, 1982). Examination of the paleoclimatic record for the Great Plains suggests that the droughts of the 1930s, 1950s and 1980s were eclipsed several times by droughts within the last 2000 years, and that more severe droughts could occur in the future (Woodhouse and Overpeck, 1998).

The massive Australian drought of 1895–1903, which followed rapid growth of rural enterprises in the 1870s and 1880s, and the great American drought of the 1930s, are good examples of lack of understanding of the environment leading to unwise land use. Farmers in southeastern Australia before 1893 believed that the climate was on their side, and in South Australia, the leading wheat producer, there was a belief that rain followed the plow. Notions that plowing and tree planting could bring rain were widespread, enticing farmers into marginal areas. The number of sheep in Australia fell from an estimated 106 million in 1891 to 54 million in 1902, cattle numbers were almost halved to about 7 million, and dust storms were common as a result of the vast expansion of land plowed for wheat. In areas such as the Sahel, where nomadism and intermittent grazing have been prevalent and more or less in balance with environmental conditions, more intensive exploitation has had disastrous results for social systems and ecosystems when drought has struck.

Drought is a common feature in many countries but is often regarded as an unfortunate and irregular abnormality of the environment. It would be more appropriate to consider drought as part of the normal sequence of events. Society must be prepared to cope with the effects of drought at any time. Impacts in the past have been exacerbated by absence of coping mechanisms, with too little preparation during non-drought periods.

Heat and cold

Excessive heat possibly contributes to more illness and mortality than any other direct, weather-related cause, certainly in regions better equipped to cope with the more violent hazards (Kalkstein, 1995). Most heat-related deaths occur in midlatitude cities, in northern India and China, eastern and Midwestern USA and Western Europe, with infrequent but extreme heat waves. Subtropical and tropical cities with higher mean summer temperatures seem less vulnerable, partly due to acclimatization of residents and perhaps due to more efficient cooling of houses. Heat-related deaths, averaging about 1000 per year, appear to be on the increase in the USA, exceeding those caused by other hazardous weather conditions (Changnon et al., 1996). Heat waves may also be associated with increases in the incidence of rioting, violence and homicide.

Heat-related death rates are usually higher in urban areas than in rural areas. This is almost certainly the result of climatic modification and heat retention due to urbanization, the heat island effect, plus the pollution trapping and concentrating effects of stagnant atmospheric conditions of heat waves, adding to those of heat stress. Death rates are also higher among the aged, especially as a result of aggravating effects on pre-existing conditions such as heart disease or cancer.

An exceptionally severe heat wave in parts of the southwestern USA in June 1994 produced the highest temperatures ever recorded in four states (Brugge, 1995). At the same time authorities in southern Ontario advised residents with heart or respiratory problems to rest, and also requested people to avoid driving, and avoid the use of aerosols that could worsen ground-level ozone. A short but intense heat wave in mid-July 1995 caused over 800 deaths in the USA, over 500 in Chicago alone (Kunkel et al., 1996; Karl and Knight, 1997). About 70 daily maximum temperature records were set during this heat wave at locations from the central and northern Great Plains to the Atlantic coast (Livezey and Tinker, 1996).

Many places in England and Wales experienced record high temperatures during a heat wave in August 1990. Apart from the usual impacts upon those unaccustomed to temperatures over 37°C, tar on roads melted, leading to closures, one runway at Heathrow airport was closed when newly laid tar failed to set, the entire stock of a Liverpool chocolate factory melted, a life-sized waxwork knight at a castle in Essex melted into a puddle, and there was a spate of drownings as people tried to keep cool by swimming (Brugge, 1991).

Increased demands for air-conditioning and refrigeration can produce overloading of power supply systems during heat waves, leading to power restrictions and breakdowns, tending to aggravate the heat-stress situation. Assessment of the causes of death in the 1995 Chicago heat wave included factors such as inadequate warning systems, insufficient time to acclimatize, the heat island effect, an aging population, an inadequate ambulance service, and the inability of many residents to properly ventilate homes due to fear of crime or lack of resources for fans or air-conditioning (Changnon et al., 1996). During a subsequent heat wave in Chicago in July 1999 the death toll was much lower, because lessons had been learned from the previous event. Heat wave plans included timely warnings, activation of cooling shelters, frequent broadcasting of information and the ready availability of help-lines (Palecki et al., 2001). In any such event, indeed in almost any hazard event, there are winners. In this case air-conditioner sales increased, sales of ice creams and ice set records, private ambulance operators were busier than normal, utilities not experiencing major equipment failures made record profits, people went to shopping malls and movie theaters to escape the heat in air-conditioned facilities, and merchants at lakeside outlets benefited from record attendances at the height of the heat wave. ‘Properly spaced green areas are the most effective and aesthetically pleasing means of controlling urban temperature excess by improving ventilation and circulation and reducing heat storage capacity. Building materials with lower heat conductivity and storage properties, and water bodies within or close to cities help to keep maximum temperatures down and encourage mixing and ventilation resulting from enhanced temperature differentials. Adequate surveillance systems are needed, to alert the public and authorities that potentially dangerous weather is imminent. A promising approach is based on the identification of high risk air masses historically associated with increased mortality (Kalkstein, 1995; Kalkstein et al., 1996). A similar approach, using a weather type classification scheme developed for North America, has been used in several heat stress warning systems worldwide. It has been incorporated in systems developed for Rome, Shanghai, Toronto, Phoenix, New Orleans and Cincinnati (Sheridan, 2002).’

Excessive cold directly causes death through the effects of exposure and is indirectly responsible for deaths from causes such as fatal heart attacks while clearing snow and asphyxiation in stranded vehicles. The annual average mortality rate

attributable to winter storms and cold in the USA up to the mid-1990s was between 130 and 200 (Changnon et al., 1996). The number of cold-related fatalities may be increasing, perhaps because an aging population becomes more sensitive to the effects of cold. Over 600 people died from cold-related accidents in each of the North American winters of 1977–1978 and 1978–1979, with temperatures averaging 6°C below normal from December 1978 to February 1979.

The impact of a severe winter extends beyond increased fatalities. Production losses in industry, crop losses, transportation losses in revenue and damage to roads and bridges, losses in retail sales, and losses resulting from increased energy consumption in the winter of 1976–1977 in the United States were at least \$40 billion. Unemployment rose by 2 million, the consumer price index had its largest 2-month jump in 3 years, the inflation rate rose, the number of business failures increased, and the balance of payments dropped by \$1.4 billion (Hughes, 1982). Record low temperatures were registered in January 1994 across central and eastern USA and eastern Canada, down to –31°C at Akron, Ohio, –30°C at Pittsburgh, –36°C in parts of Minnesota, –41°C in New York State and below –45°C in parts of Ontario (Brugge, 1994b). A wind-chill figure of –70°C was reported from the Midwest. Impacts of the severe cold included school closures; interrupted train services; closed airports; closed public services; record power consumption and electricity blackouts; water mains frozen for up to a week; ice-making machines frozen; canceled garbage collections because of frozen equipment; many weather-related injuries, including a man who set himself on fire trying to light a fire; a halt to brewery production in Milwaukee; and a crack in a gasoline pipeline leaking over 450 000 L, much into the Mississippi. To impacts like these should be added elements such as personal inconvenience, worry and stress, extra work, injuries, higher taxes to cover costs of repairs, and decreased tax income through lost work-days.

Frost presents a hazard to crops around the world. Freezing temperatures in southern Brazil, in 1979 and 1985 at around 20°S, damaged coffee trees and severely reduced coffee production. Severe frost, although infrequent, is also a major climatic hazard in the near equatorial latitudes of the highlands of Papua New Guinea (Brown and Powell, 1974). Risk of ground frost in Papua New Guinea starts at about 1 500 m, increasing with elevation and in valleys and basins. The worst frost in memory occurred in the early 1940s, accompanied by a prolonged drought. Gardens as low as 2000 m were wiped out by weeks of frosts, with sleet and snow at higher levels destroying gardens, food-bearing trees, domestic pigs, and wild animals. Food shortages forced extensive migrations to lower areas, leading to severe social conflict and occasional fighting. In March–April 1990 much of the UK was affected by unusually severe ground frosts and prolonged air frosts, leading to widespread damage to tree fruit crops in flower at the time and to young nursery stock (Morison and Butterfield, 1990). There were also reports of substantial damage to winter-sown cereal crops, with from 10% to 90% of ears in barley and wheat crops being killed. The damage was exacerbated because of previously mild conditions throughout the preceding winter and the corresponding advanced development of many of the plants.

There is growing recognition of the potential value of meteorological information in decision making. Deciduous fruit trees are very susceptible to frost damage in spring, with loss of fruit yield and even permanent tree damage. Several protective devices are available, such as wind machines, sprinklers, and heaters, but these are expensive. Accurate minimum temperature

forecasts can help the grower in making decisions whether or not to protect on a particular occasion, and so may help to save money (Katz et al., 1982).

Snow and ice

Snow hardly worries an alpine village; indeed it may be welcomed as improving prospects for the tourism industry, but the same depth of snow may bring panic and total disruption to a lowland city unaccustomed to it. The nature of the snow hazard is influenced by other weather conditions, particularly wind, by topography and by road surface materials. On crowded roads even a shallow snow cover of 20 mm may be sufficient to halt or hinder traffic flow, leading to increased costs in work losses, late delivery of goods, losses of consumer sales and receipt losses by public transportation, apart from increasing accident and casualty rates (Perry, 1981). Snow has widespread impacts on construction, merchandising, manufacturing, agriculture, power supply, communications, recreation, and public health and safety services and can induce heavy financial losses either in terms of direct damage and disruption or in costs of mitigation (Rooney, 1967). However, snow can be beneficial if it covers crops or vegetation and protects them from air frost.

There are numerous examples of the impacts of major snow storms on large urban areas (e.g. Speakman, 1994; Brugge, 1944a; Wild et al., 1996). The severe winter storm of March 1993 along the east coast of North America illustrates the possible impacts of snow on communities. Property damage was estimated at \$1 billion; snow clearance costs were estimated at \$100 million; and total damage was put at about \$4 billion. Structural damage was widespread from Florida to Canada; hundreds of roofs collapsed under snow loads; and over 3 million customers were without electrical power due to fallen trees and high winds, which reached 210 km/h on Cape Breton Island. Over 200 people died from weather-related causes and 48 were lost at sea. Many deaths were attributed to heart attacks clearing snow, others died in fires, drowned or suffered carbon monoxide poisoning when trapped in cars or buildings (Brugge, 1994a).

A record early snow storm which hit parts of the High Plains and Midwest of the USA in October 1997 and an extremely severe ice storm in the northeast and in eastern Canada in January 1998 were both attributed to the El Niño event of 1997–1998, as were many other climatic hazards at that time (Changnon, 1999).

Ice storms can cause major economic and social disruption (Assel et al., 1996). Aircraft icing, through the accretion of super-cooled water, has been identified as a cause of many aircraft accidents during winter storms (Rasmussen et al., 1992). The 1998 ice storm was remarkable for its spatial extent and duration, as well as in terms of the severity of its impacts on the region (DeGaetano, 2000; Dupigny-Giroux, 2000). Total storm damages in the USA and Canada exceeded \$2 billion, over \$800 million to the hydroelectric installations in Quebec alone, where well over 1 million people were at times without power. In Montreal the entire commercial sector was closed down for a week. Deaths occurred from falling ice, house fires, hypothermia and carbon monoxide poisoning. Thousands of farmers in the dairy industry were particularly hard hit, with losses of cattle and milk production; and the long-term consequences of milk shortages affected ice-cream makers, cheese suppliers and all relying on dairy products. The livelihoods of maple syrup producers were placed in jeopardy because of extensive ice damage to trees.

Telecommunications and electrical services were tested beyond design limits by ice accumulations, radio and television stations were put off the air, airports were closed and rail services suspended. Damage to hiking and snowmobile trails had impacts on the leisure industry, and it was estimated that most Christmas trees intended for the 1998 season were damaged beyond salvage.

Fog

Fog is a hazard to land, sea, and air transportation. Many multiple-vehicle accidents occur when visibility is severely restricted on highways. In 1974 fog was estimated to have cost over £12 million on roads in the United Kingdom (Perry, 1981). The worst aviation accident on record occurred in March of 1977 in the Canary Islands when two wide-bodied jets collided on a runway in heavy fog, killing 583 people. Possibly the worst fog disaster occurred in May of 1914 when the *Empress of Ireland* sank after a collision in the St Lawrence estuary with the loss of 1078 lives (Whittow, 1980). The collision between the *Stockholm* and *Andrea Doria*, and subsequent sinking of the latter, in sea-fog off Massachusetts in July 1956, is another example of a dramatic impact of what can appear as an innocuous phenomenon.

The aviation industry loses millions of dollars each year when fog causes aircraft diversions and delays, inconveniencing thousands of passengers and incurring increased operating costs. Costly adjustments, such as automatic aids for aircraft, are possible and many fog dispersal techniques have been tried. Supercooled fog can be modified but accounts for only a small proportion of fogs. Warm fog can also be modified using thermal energy, but high costs of installation and operation of dispersal systems and the problem of pollution have discouraged their use (Kunkel, 1980).

Visibility is one of the most difficult of meteorological phenomena to forecast. Several objective fog forecasting techniques have been tried, but there is still no entirely reliable method. Publicity of the hazards and driver education remain the surest ways of reducing the dangers of fog on highways.

Air pollution

Many studies have pointed to an association between air pollution and ill-health, particularly for diseases such as bronchitis and lung cancer, and less so for cardiovascular ailments and nonrespiratory tract cancers (e.g. Lave and Seskin, 1970).

The first noticeable effect of photochemical pollution is a stinging of the eyes due to peroxyacetyl nitrate gas. Ozone, also formed in photochemical reactions, damages lung tissue, increases death rates as a result of swellings in lung passages, and reduces athletic performance. Sulfur dioxide can lead to infections of the lower respiratory tract, especially among the elderly, the very young, and those already weakened by illness. Carbon monoxide may cause drowsiness in low concentrations, extending to severe headaches, nausea, and collapse in high concentrations. Large cities such as Beijing, Bombay, Cairo, Jakarta and Mexico City are now the most susceptible to hazards arising from air pollution.

Air pollution impact can be reduced, chiefly by not locating pollution sources in badly ventilated areas known to experience frequent low-level temperature inversions. A common approach to air pollution from motor vehicles is emission control, either through the fuel or through exhaust abstraction systems, although the efficiency of these is debatable and their public acceptance often poor. Design of buildings and layout of city streets can help

promote greater turbulence and better diffusion of pollutants. Good traffic flow promotes better urban air quality, but traffic engineering and air pollution control aims are frequently at variance. Implementation of fuel conservation policies, use of alternative fuels, and pollutant-emission regulations are steps toward minimization of total pollution emissions and thus of the pollution hazard. On the other hand, it may be better and cheaper to achieve clean air from the outset through sensible planning rather than through remedial steps later. Transport of air pollution by atmospheric circulation means that the problem is one for legislators at the national or continental level.

Acid deposition from the atmosphere is a major worldwide environmental concern, particularly in parts of northern and western Europe, North America and China (Mason, 1990). It originates from the release of sulfur and nitrogen oxides by industry and transport. Oxidation and hydrolysis of the oxides produce sulfuric and nitric acids or related sulfates and nitrates, which are transported in and eventually removed from the atmosphere in rain, snow, dew, frost, fog, gases, or particles. There is evidence that acid rain may be responsible for long-term adverse effects on the environment. These effects may include acidification of rivers, lakes, and groundwater, with damage to all components of the aquatic ecosystems; acidification and demineralization of soils; changes in agricultural and forest productivity; corrosion damage to buildings, monuments and water supply systems; degradation of water supplies; and reductions in biodiversity, with acid-tolerant species flourishing in severely stressed ecosystems (Bridgman, 1997).

Biomass burning for forest clearing, fossil fuel burning and "slash-and-burn" agricultural practices in the tropics of south-east Asia, the Amazon Basin and central Africa create a wide range of pollutants, including smoke components and dust. Such emissions can be transported long distances downwind. The Asian brown haze, largely composed of particulates and sulfate aerosols from south, southeast and east Asia, significantly reduces solar radiation and has possible impacts including a reduction in rainfall, reduction of light available for photosynthesis and adverse health effects (Anon, 2002). Cooling of the land surface; a stronger and more frequent thermal inversion trapping more pollutants; and an overall reduction in evaporation and precipitation, with implications for water quality and availability, are possible indirect effects of the brown haze.

Climatic changes

The importance of climatic changes to the world's future and of human dependence on a stable climate to maintain present patterns of agriculture has been highlighted by many authors (e.g. Schneider, 1976; Bryson and Murray, 1977; Roberts and Lansford, 1979; Lamb, 1982).

Climatic inputs provide the essential resource base for agriculture; even with present technology the world is not immune to the effects of climatic variation. In 1972, when the global climate was particularly unfavorable for food production, millions starved. The increasing demands of a growing population mean that there may be more frequent imbalances between food supply and need, especially in regions of increasing pressure for cultivation of climatically marginal land. The results could be depletion of grain reserves, malnutrition, starvation, and political unrest. Parry et al. (2001) have examined the possible impacts of climate change in some key areas of risk: hunger, water shortage, exposure to malaria transmission, and coastal flooding. They concluded that millions more people will become at risk and that it will be necessary to find

a blend of mitigation, to buy time, and adaptation, which in turn can raise thresholds of tolerance.

There has been much speculation about what might happen to frequencies, intensities and distribution of climatic hazards in the future, although not all changes in risk would necessarily be attributable to climate change; societal shifts such as population growth, demographic moves to more at-risk locations, and the growth of wealth have all made for greater vulnerability (Changnon et al., 2000). Some projections suggest an increase in the risk from droughts, floods, heat waves, tropical cyclones and storms (e.g. Changnon and Changnon, 1992; Bruce, 1994; Yarnal et al., 1999). There is evidence that diseases such as malaria and dengue fever, carried by mosquitoes, are undergoing resurgence and redistribution, possibly in response to global warming (Epstein et al., 1998). Mosquito-borne diseases are being reported at higher elevations and higher latitudes, consistent with a spread of warmer, wetter conditions. The distribution of agricultural pests could also shift, with implications for food security and pointing to the need for the public and policy makers to be aware of the possible biological consequences of climate change (Harrington and Wooldridge, 1995).

There is still considerable uncertainty about the nature of climatic trends, much depending upon the rate at which greenhouse gas concentrations increase and on the particular models and scenarios used to predict future climate. It has been suggested, for example, that there is no clear evidence of long-term trends in global tropical cyclone activity, with indications that the broad geographic regions of cyclogenesis and of regions affected by tropical cyclones will not change significantly (Henderson-Sellers et al., 1998). Increasing trends in weather-related losses in recent decades have led to a popular view, nurtured by greater media coverage, that hazard frequency and intensity are increasing, but societal changes may be the primary cause (Kunkel et al., 1999). The lack of high-quality long-term data makes it difficult to determine changes in extremes, and observations of the impact of global warming are based on very short records for analysis (Easterling et al., 2000).

Climatologists can assist in many ways to plan for severe weather, now and in the future (Hunt, 1990): for example, with advice at design and planning stages of projects to reduce possibilities of weather-related disasters; with advice on land-use planning and design of structures to minimize risks from climatic hazards; and with improving forecast and warning capabilities and awareness and coping strategies. Whatever changes may occur in the future, and whatever adjustments they may necessitate, there is a need for greater recognition by the public, policy makers and planners that change is possible and preparation is necessary (e.g. Glantz, 1979; Wilson, 1981; Robinson and Hill, 1987; Changnon et al., 1995).

CLIMATE MODELING AND RESEARCH CENTERS

The following provides an overview of the main world centers where climate research and climate modeling are carried out.

Australia

Bureau of Meteorology Research Centre, Melbourne (BMRC) – Department of the Environment and Heritage, Commonwealth of Australia

The BMRC has six research groups focusing on different aspects of climatic and meteorological modeling, including model development, model evaluation, data assimilation, weather and climate forecasting and marine and ocean forecasting. Attention is given to the Australasian region in the

development of numerical models, long-range forecasting, tropical meteorology and meteorological observation systems.

The research objectives of the center are generally designed to support the operations of the Bureau of Meteorology as well as to produce research that would be of interest to the scientific community. The center maintains close ties to the World Meteorological Organization (WMO), the Commonwealth Scientific and Industrial Research Organization (CSIRO) and is involved with the Cooperative Research Centre program of the Commonwealth Government.

Commonwealth Scientific and Industrial Research Organization (CSIRO), Melbourne – Atmospheric Research

The CSIRO is the major science research institution in Australia. It has several divisions that produce research in all aspects of the environment, of which the Atmospheric Research Division (ARD) is but one. The ARD operates three laboratories, located in Canberra, Victoria and Aspendale, and is grouped into three major programs: Earth systems modeling program; pollution program; and measurements, processes and remote sensing programs. Most of the research conducted within this organization is applied and covers topics that are specific to Australia's interests. The CSIRO collaborates with the BMRC, as well as participating in such programs as the International Geosphere–Biosphere program and the World Climate Research Program.

Canada

Canadian Centre for Climate Modelling and Analysis (CCCma), Victoria

The CCCma is a division of the Climate Research Branch of the Meteorological Services of Canada and is located on the campus of the University of Victoria. This center specializes in modeling coupled sea-ice and atmospheric modeling, climate variability, climate predictability and the carbon cycle, among other areas. They developed the Atmospheric General Circulation Model (AGCM2), which models equilibrium climate change simulations using variations of sulfur aerosols. This model has been used in paleoclimate studies, tracer studies, and predictability studies. The model has also been used to produce operational seasonal forecasts for the Canadian Meteorological Centre and by other collaborators. A newer model (AGCM3) has been developed and became operational as of January 2003.

The CCCma is involved with many international projects such as the Program for Climate Model Diagnosis and Intercomparison Project (PCMDI), hosted by the Lawrence Livermore Laboratory in the United States. CCCma has contributed to the Intergovernmental Panel on Climate Change (IPCC) reports of 1990, 1995 and 2001 and presently participates in the Climate Variability Predictability Program (CLIVAR) and the Scholarly Publishing and Academic Resources Coalition (SPARC).

France

Institut Pierre-Simon Laplace des sciences de l'environnement (IPSL) (Campus du Jussieu)

The IPSL is composed of several laboratories that model different aspects of the environment and have working relation-

ships with other institutions within France, throughout Europe and the rest of the world. Under the auspices and collaborative efforts of all of the laboratories in their institute, they have developed their own ocean-climate models (e.g. the IPSL model, the LMD and LMDZ, OPA-ICE). All of the IPSL laboratories are associated with the National Center for Research in the Sciences (CNRS) of France. Below is a survey of three laboratories related directly to climate modeling. All of them are affiliated with the IPSL.

1. Laboratoire de Meteorologie Dynamique du CNRS, Paris. The Laboratoire de Meteorologie Dynamique du CNRS (LMD) is part of the IPSL. It encompasses three sites: l'École Polytechnique in Palaiseau, l'École Normale Supérieure, in Paris and l'Université Pierre et Marie Curie, also in Paris. The LMD has four areas of research: climate modeling, remote sensing, experimental data measurements, and theoretical activities. The research is divided into several different teams located at the three university sites. They have developed the LMD and the LMDZ models of the general circulation of the atmosphere and presently collaborate with numerous laboratories, research centers and universities to develop linkages to study a wide variety of climate issues.
2. Laboratoire d'Optique Atmosphérique (LOA) Lille. This laboratory, housed at the University of Lille, is involved with modeling the radiative properties of the atmosphere, especially as relating to its optical properties and its role in the global energy budget. The LOA focuses on the interaction of solar and terrestrial radiation with the atmosphere in the context of the global climate and climate change. It initially began as a research project on solar ultraviolet irradiance and radiative transfer theory, then shortly thereafter concentrated on air-sea interactions and on the remote sensing of the oceans. In the 1970s the laboratory focused its research on the radiation budgets of Venus and Mars. In the 1980s it applied its modeling efforts to the radiative forcing of the Earth-climate system, particularly to the development of radiative models involving the oceans, cloud cover and other aerosols, and the greenhouse gases.
3. Laboratoire d' Océanographie Dynamique et de Climatologie (LODYC). Housed in the University of Pierre et Marie Curie, the LODYC works to foster understanding of the Earth-climate system and the oceans' contribution to it. They have developed the OPA-ICE model that simulates oceanic circulation that can be coupled with other models (like the LMDZ) through the research at IPSL. They are also interested in modeling marine ecosystems in order to understand the role of the oceans in the exchange of carbon between the ocean and the atmosphere.

European Center for Research and Advanced Training in Scientific Computation (CERFACS), Toulouse, France

CERFACS has a set of research teams devoted to various aspects of scientific modeling, including climate modeling and global change, and modeling in fluid dynamics. They developed the OASIS model that is used as the coupler between general circulation models of the atmosphere and ocean circulation models in the research done by the laboratories of IPSL.

Germany

Alfred Wegener Institute for Polar and Marine Research (AWI – Bremerhaven, Germany)

The AWI is an institute devoted to modeling the Arctic and Antarctic environments and for using and developing general circulation models for polar and marine research. They also devote some attention to modeling for research in middle-latitude regions. The AWI has four main units, one of which is devoted to the climate system. In the climate unit, they have sections focusing on research in large scale and regional circulations, and on the physical and chemical processes of the atmosphere.

Deutsches Klimarechenzentrum (DKRZ) – German Climate Research Center, Hamburg

The DKRZ is a limited corporation funded in part by the Federal Ministry for Research and Technology, and is a service center for those participating in climate research in Germany. It was founded in 1987 at the University of Hamburg and is responsible for maintaining the infrastructure necessary for basic and applied research in climatology. It also cooperates with the European Climate Computer Network to allow for climate research to be pursued in both the larger and smaller nations of Europe.

Max Planck Institute for Meteorology (MPI-Met), Hamburg

Located in the university district of Hamburg, the MPI-Met contributes research into climate model development, investigates new methodologies of observation and measurement of the Earth–climate system and examines human–climate interactions that affect policy-making decisions. The institute is composed of three scientific divisions: biogeochemical systems, climate processes and physical systems, and one research group which itself has two scientific divisions: a regional climate group and a socioeconomic modeling group. The scientific divisions' activities focus on model formulation and application and are at present developing procedures to couple the models produced by the individual scientific departments and research groups with the goal of establishing a comprehensive model of the Earth–climate system.

United Kingdom

UK Universities Global Atmospheric Modelling Programme (UGAMP)

UGAMP is a network of university research centers that are primarily focusing on the development of large-scale numerical global climate models. The Natural Environmental Research Council (NERC), who fund the program, initiated UGAMP in 1987. There are nine affiliated university sites including London, Cambridge, Reading, Southampton, Rutherford (Appleton Lab), Oxford, East Anglia, Leicester and Edinburgh. Two universities in particular house the major climate and modeling centers while the other universities contribute to their work. These two centers are: the Center for Global and Atmospheric Modelling (CGAM) located at the University of Reading and the Atmospheric Chemistry Modelling Support

Unit (ACMSU) located at the University of Cambridge. The CGAM is the main group that supports the UGAMP network of research sites. It emphasizes model development for large-scale atmospheric circulations and has partnerships with modeling centers and activities in the rest of Europe, the United States, and Japan, as well as with their colleagues in the United Kingdom. They are responsible for maintenance and diagnostics of the General Circulation Models formulated by the UGAMP community. ACMSU essentially works to provide the chemical data and codes that the rest of the UGAMP community will need in model development.

Hadley Center for Climate Prediction and Research (HC) – London

The Hadley Center for Climate Prediction and Research is the climate research arm of the UK Meteorology Office. It uses a variety of models including GCM, coupled ocean–atmosphere models, regional climate models and atmospheric chemistry models. The research is divided into teams focusing on the following themes: model development, model parameterization, atmospheric chemistry and ecosystems, global and regional climate prediction, quantifying model uncertainties, rapid climate change, environmental stress, extreme events, climate monitoring, database development and interannual and interdecadal forecasting.

United States

Geophysical Fluid Dynamics Laboratory (GFDL), Princeton, New Jersey

The GFDL is a modeling center that is funded through the US Department of Commerce and the National Oceanic and Atmospheric Administration (NOAA). It has six research groups in it: Climate Dynamics, Hurricane Dynamics, Atmospheric Processes, Mesoscale Dynamics, Climate Diagnostics and Oceanic Circulation. There is also a technical support division that maintains the computing environment for the laboratory. They also maintain the Atmospheric and Oceanic Sciences Program (AOSP), a collaborative effort with Princeton University and funded by NOAA. This center is interested in developing atmospheric models at small and regional scales, as well as large-scale global circulation models. They have produced several models, notably the GFDL R15 and GFDL R30, which are coupled general circulation models of different spatial resolutions and the Modular Ocean Model, the most widely used global oceanic circulation model.

Lawrence Livermore Laboratory (LLL), Livermore, California

The LLL, operated under the US Department of Energy, includes the Program for Climate Model Diagnostic and Intercomparison Project (PCMDI) in which various atmospheric (Atmospheric Model Intercomparison Projects, AMIP), coupled (Coupled Model Intercomparison Projects (CMIP) and Paleoclimate models (PMIP)) are analyzed and compared in order to improve model development and reliability. These projects facilitate a community-based protocol that allows comparison and diagnostics of these models to be made. Models

formulated by researchers in research and modeling centers throughout the world participate.

MIT Center for Global Change Science Climate Modeling Initiative (CMI), Cambridge

The CMI, developed as an outgrowth of the existing MIT Center for Global Change Science to concentrate efforts in climate modeling in order to contribute to understanding the larger context of global change science. The main attention initially was to improve climate prediction by ascertaining the limits of predictability. Funding has come from both private and public sources.

One of the objectives of the CMI is to use a hierarchy of models to simulate different portions of the Earth-climate system so that certain specific research goals can be met. They are also interested in addressing the chaotic behavior of the climate system in order to reduce the errors of prediction and to minimize errors in setting initial conditions for the models. Currently the CMI is developing a new coupled-atmosphere-ocean general circulation model that will incorporate and enhance an existing model developed by the Max Planck Institute (MPI-Met) with their collaboration.

NASA Goddard Institute for Space Studies (GISS), New York

GISS is a research institute designed to research a number of disciplines in Earth and space sciences. The institute works closely with Columbia University's Earth Institute and Lamont-Doherty Earth Observatory. Many GISS scientists are also closely involved with Columbia's Center for Climate Systems Research. The primary objective of GISS in the atmospheric sciences is to produce research leading to the understanding of global climate change. The research tends to revolve around the following themes: climate modeling development, climate forcings and impacts, Earth observations, paleoclimatology, radiation studies, atmospheric chemistry and planetary atmospheres.

Most of Goddard's research in climate modeling involves the development and use of Global Circulation Models and coupled GCM and ocean models. Some research is also conducted using energy balance and radiative transfer models. The research primarily focuses on using models geared toward understanding climate sensitivities to a variety of potential perturbations, such as greenhouse gas emissions, aerosols and solar variability. The research is also applied to understanding the possible impacts to society that climate changes associated with these possibilities may produce.

National Center for Atmospheric Research (NCAR): Climate and Global Dynamics Division (CGD), Boulder, Colorado

NCAR is a center devoted specifically to all areas of the atmospheric sciences. It is directed under the auspices of the University Corporation for Atmospheric Research (UCAR) and funded through the National Science Foundation. The major climate modeling division of NCAR is the Climate and Global Dynamics Division (CGD). This division is responsible for developing global circulation models of varying resolutions and scope. The Climate System Model (CSM), which consists of

coupling models of the atmosphere, oceans, the land surface and sea-ice without the benefit of artificially providing flux adjustments, is the primary model that is being currently used. The CGD division of NCAR works closely with other divisions in NCAR, with the university research community and with other national and international laboratories to develop simulations using the CSM for use in other projects.

Other modeling and research institutions

There are many modeling centers and research institutions that are smaller in size, narrower in scope, or are part of larger organizations who do not have, as their primary function, climate or atmospheric research. The following is a list of laboratories and institutes and their locations that have climate modeling and research teams or divisions. Their contributions to model development and diagnosis cannot be underestimated.

Ames Research Center (NASA), Moffett Field, California
 Argonne National Laboratory (Energy), Chicago, Illinois
 Brookhaven National Laboratory (Energy), Upton, New York
 The Jet Propulsion Laboratory (NASA), Pasadena, California
 The Pacific Northwest National Laboratory, Richland, Washington
 The Scripps Institute for Oceanography, San Diego, California
 Woods Hole Oceanographic Institute, Woods Hole, Massachusetts

CLIMATE VARIATION: HISTORICAL

The basis of history is documentation, and given that database we can attempt to draw some conclusions; one might even try to use this historical record, in combination with the instrumental material of the last century or two, to anticipate the future. Experimental science should, ideally, provide the basis for prediction. In closed systems, like the chemists' test tube, prediction can be made with some degree of certainty. But in the open systems of the planet Earth—its atmosphere, ocean, magnetic fields, moon, sun and other planets—all these bodies and systems are interacting.

The trouble with the meteorological records is that they are too short to capture the “big picture.” Instrumental data provide a numerical, quantitative basis for working out the dynamic equations of atmospheric motion. They also offer a quantitative way of comparing day-to-day variables, the contrasts between winter and summer: a definite improvement on our intuitive, sensory, and memory-based impressions of hot and cold, moist and dry. In combination with computer-based storage facilities and sophisticated methods of statistical analysis, some hitherto unknown, or unproven, features are now beginning to emerge from the meteorological materials, such as the 14-month Chandler wobble pulse and the 18.6-year lunar nodal cycle. But what of the longer periodicities and peculiarities of the climatic machine? The agreed base for a standardized climatic average for any observing station, by convention of the World Meteorological Organization, is only 30 years. The climatic variation of the geologic record should indicate clearly that the day-month-year basis of instrumentally based climatology only scratches the surface. But the geological picture has a tendency to drift (sublimely) away from the human scale of things. This is where the historical record helps to fill in an essential gap. It takes us from the instrumental field of “hard numbers”

to ancient diaries, tax records, narratives, and eventually to the geological data sources, where the quantitative values must be calculated, albeit by highly sophisticated analytic techniques, not least the measurement of the time factors.

Definition

Historical climatology is seen in a variable context by different workers. (A sampling may be seen in several collections: Rotberg and Rabb, 1981; Wigley et al., 1981; Mörner and Karlén, 1984; Roberts, 1989, 1998; Burroughs, 1992; Shindell et al., 2001). Let us define historical climatology as the study of climate through the time-range of civilized *Homo sapiens*, during the period in which humans have developed the arts of writing and the construction of permanent dwellings and other structures relating to their maintenance and culture. Harding (1982) has provided a useful volume on climate in a context of Holocene archeology.

That time-range varies from region to region. In Britain it is about 3500 years (Stonehenge), but in Egypt it is more like 6000 years. The world's oldest continually inhabited town is said to be Jericho, in the Jordan Valley, which was established 10 000 years ago, or 8000 bc. This date, roughly is also the conventionally adopted date for the Pleistocene–Holocene boundary, agreed by a commission of INQUA—the International Union for Quaternary Research (Olausson, 1982; Fairbridge, 1983). Thus, the 10 000 years of the Holocene Epoch become the logical and ultimate time frame of historical climatology.

Pfister (1980) recognized two categories of data that are appropriately integrated to construct a historical record of climate for any region and interval of time within the designated range: (a) *documentary proxy data* and (b) *field data*.

(a) The use of documentary proxies has been made a special, life-long study by Hubert Lamb (1972, 1977), who integrated them closely with the instrumentally based meteorological standards. The documents provide varied types of information and are of varied quality. They range from diaries, which usually have the virtue of homogeneity (a single observer, living in a given place, and dated with reasonable accuracy), to records of particular events (often found in monastic documents, such things as eclipses, comets, auroras, floods, droughts, killing frosts), and eventually to folklore or sagas (weak in chronology but often helpful if used in conjunction with field data). The diaries may contain actual weather observations (temperatures, wind, precipitation), or they may generate proxy indicators (such as crop planting, harvest times, with yields and costs). Tax records are very illuminating, when interpreted by a skilled specialist (e.g. Pettersson, 1912, 1914, 1930).

(b) Field data are mostly geological, botanical, or glaciological, where the chronology is established on an incremental basis, usually year by year or perhaps century by century. The time-series may go backward from the instrumental era or it may be “hanging” chronology, intended to be integrated “some day.” The source material is generally stratigraphically layered (following the *Law of Superposition*), as in the seasonally varved bedding of a lake, or ice layers in a glacier, or the speleological accumulations of a limestone cave. It may be concentrically banded as in the inorganic growth rings of stalactites and stalagmites or in tree rings (*dendrochronology*). Event indicators include such things as volcanic ash layers (tephra, hence *tephrochronology*), frost or burn rings in dendrochronology, and coarse sediments in thick varves, indicating major flood years) or thickness increase in the dark layers of varves (thus higher

organic productivity). Seismic events (earthquakes) may be recorded by rock falls in cave deposits (archeological data often record such rude interruptions to the human occupancy), or by "neotectonic" faults or slumps in stratigraphic sequences.

World-class standard time-series

In this entry are listed selected examples of world-class historical standards within the Holocene Epoch that deserve maximum attention from climatologists. If twentieth-century climatologists ignore these mutually interlocking records, they do so at their own risk. History does not repeat itself, and *time's arrow* flies only in one way, but those who ignore history are condemned to repeat its errors. The mutual interlocking of chronologies has, up till recently, been a matter of hypothesis. But now the sheer volume of data is enough to prove that certain events and trends are of global significance, and cannot be dismissed with a shrug or sneering aspersions as to accuracy of dating or whatever. The error bars are often large, but the ever-narrowing ranges of those error bars now permit conclusions based on the convergence-of-evidence line of reasoning (Windelius and Carlberg, 1995).

As to accuracy of chronology, one may point to the vast accumulation of tree-ring data that is now being extended to the whole world (Stockton et al., 1985). Rings are counted year by year, and some sequences reach back to 13 000 BP and more. Errors can be made but, with multiple samples and multiple workers, the margin of error is gradually being refined to the ± 1 -year level or better. As will be noted below, de Geer's counting of annual varves, which started a century ago, was strongly attacked during his lifetime, but now a Swedish team of devoted workers has repeated his more than 10 000-year record. Small refinements and corrections have been made, to be sure, but the basic chronology is correct (Cato, 1985). More recently, ice cores have furnished a third system of year-by-year counting (Dansgaard et al., 1971). Again errors can occur, ablation can skim off a layer or two, but there are over 100 ice cores over 100 m deep from both hemispheres, which cannot all be wrong.

All three proxy calendars are recorded in *sidereal years*, documenting the seasonal regularity of the Earth's revolution about the sun. The invaluable radiocarbon-dating method, for all its built-in potential for errors, is now calibrated to the sidereal record, and so can be used for bringing "floating" chronologies into the firm records (Klein et al., 1982; Stuiver, 1982). With time measured in sidereal years we can now use astronomical parameters to retrodict planetary-solar-lunar events (Fairbridge, 1984a).

Ten world-class categories of examples of standard time-series are now discussed: ice cores, dendrochronology, lake varves, palynologic sequences, fluvial sediments, beach ridges, marine varves, the volcanic signal, the paleomagnetic signal, and the documentary archives.

Standard time-series

1. Arctic and Antarctic ice cores

One of the most promising fields of research in the scope of historical proxies is the drilling and study of glacial ice cores. The drilling reached 2164 m at Byrd Station (Antarctica) and 2035 m at Dye 3 (Greenland) and dates events back to more than 100 000 (Barry, 1985). The first analyses generated an invaluable ^{18}O - ^{16}O isotope curve that is believed to reflect the

temperature (and salinity) of the evaporated sea-surface waters (Dansgaard et al., 1971; Lorius et al., 1979). As remarked by Hecht (1985, p. 20), the reproduction of the "Dansgaard profile" in Flint's textbook (1971), "became a standard climate series against which other climatic records could be compared."

An examination of cores both in the Arctic and Antarctic showed that particulate contamination was very much higher during the glacial phases than during interglacials. At first it led to the idea of volcanic forcing of the major glaciations (Bray, 1976). A closer look at the particles, however, showed that they were dominated by desert dust, reflecting the worldwide aridity and greater meridional upper air flow of the glacial phases.

Volcanic activity, however, is recorded in the ice cores (Hammer et al., 1980). The invention of a rapid pH-measuring device opened the way to identifying specific annual layers of high acidity, reflecting volcanic SO₂ and CO₂ injections into the upper atmosphere. Precision counting of the ice layers, year by year for the last few millennia, has been rewarded by the discovery that within 12 months of almost all the major historic eruptions there is an acidic *spike* in the cores. Its intensity is presumed to be more or less proportional to the gas production in the eruption. Some eruptions generate only a little gas. Numbers of such spikes already have been found that lack known volcanic events, which only goes to show how little is really known of the Holocene sequences in many parts of the globe (See the AD 535 eruption in the Sunda Strait: Keys, 1999).

Acidity and particulate pollution are not the only variables that can be measured in the ice cores, in addition to the basic ^{18}O signal. Chloride, nitrate, and sulfate have been analyzed by Herron and Herron (1983) from Dye 3. The isotope beryllium-10 (^{10}Be), which is comparable to radiocarbon insofar as it is generated in the upper atmosphere by cosmic ray collisions, it may well serve to measure, inversely, the solar-activity modulation of the geomagnetic field.

Within the ^{18}O ice-core records, there is a prominent cyclicity, on the order of 90, 180, and 360 years. Unfortunately the sampling accuracy is not yet sufficiently refined to give a precise year-by-year variance. Nevertheless, these periodicities are dramatically close to those recorded in the beachridge studies (see subsection 6 below), as well as in sunspots and in known planetary cycles (Fairbridge, 1984a).

Precise attention to the microparticle deposition over the last millennium at the South Pole has shown that accumulation was maximal from AD 1450 to 1860 during the Little Ice Age (Mosley-Thompson and Thompson, 1982). It also provided a basis for calculating annual increments of snow. The Little Ice Age also was marked by the minimal rate of snow accumulation (1657–1686), whereas the warm phases of 1057–1086 (Little Climatic Optimum) and 1867–1896 were marked by maximal snow accumulation. On Greenland the pronounced warming of the Little Climatic Optimum (or Medieval Warm Period) made colonization feasible for the Viking voyagers, and the demonstrated cooling of the fifteenth century brought those colonies to their tragic end (Dansgaard et al., 1975). Even their Icelandic settlements nearly collapsed (see Ogilvie in Wigley et al., 1981).

A newly developed infrared laser spectroscopic technique has made it possible to analyze tiny gas bubbles in the ice and their CO₂ values (Neftel et al., 1982). This has led to the very important discovery (in the light of the present fossil-fuels controversy), that during the last glacial the CO₂ level in the atmosphere was 210 ppm, as compared to the modern 340 ppm. Several specialists regard CO₂ fluctuation as a biological

consequence of climate change, not a cause (e.g. Newell and Hsiung, 1984); because of increased upwelling and phytoplanktonic productivity, larger quantities of CO₂ are withdrawn from the atmosphere (and hydrosphere) during cold epochs.

2. The California dendrochronology

Counting tree rings has been carried from a fine art to a sophisticated science in the US Southwest, and is now being extended to the world (Stockton et al., 1985). The crowning achievement has been the radiocarbon analyses of the dendrochronologically dated Bristlecone Pine series from the Sierra Nevada by Hans Suess and a large team of associates. Over eight millennia of records now document the fluctuations of the ¹⁴C flux rate through the entire period. This provides an inverse quantification of solar emissions (see Sunspots), as discussed by Damon et al. (1978) and Eddy (1977). The actual ring width (and density), as an indicator of favorable growing climate, correlates precisely with the radiocarbon value in selected areas (Sonett and Suess, 1984). Refined studies have been accorded the rings of the last 2000 years (Stuiver, 1982), and later about 10 000 years (Stuiver and Braziunas, 1993) which permits correlation with the long-term climate proxies of northwest Europe. For a long time tree-ring counts in northwest Europe were in hanging chronologies, that is to say, not interconnected, but the whole sequence has now been unified (Hughes et al., 1982).

The main feature about tree-ring analyses for climatic interpretation (*dendroclimatology*) is that although one particular tree provides only a record of its own locality a regional picture can be constructed when a considerable number of samples are analyzed and integrated. Excessively large sample areas, however, are likely to smooth out the interesting signals, so that large numbers of individual tree-growth areas should be treated separately (Currie, 1984).

Tree-ring analysts are now extending their work to all continents. All latitudes, however, cannot be treated, because certain climatic belts do not furnish distinctive annual rings, as in the year-round wet regimes of the equatorial regions. In some settings the tree grows its thickest rings in the wettest years, but in others it grows them in the warmest years. In some low-latitude mountain areas the vertical zonation (and thus the meaning of the signal) will change dramatically several times in the course of the Holocene Epoch. Nevertheless, the dendroclimatology of the Holocene offers the most universally useful and potentially productive source of long-term climatic data and deserves the most energetic investigations.

3. The Swedish varve chronology (and other varves)

Nearly a century ago the Baron Gerard de Geer (1858–1943) began measuring the thickness of the annual sediment layers in Swedish clay pits (used for the brick industry). The clays were laid down in late glacial and postglacial lakes in distinctive couplet layers (varves, from the Swedish name), a dark band representing winter freezeover and a light band the summer meltwater input. The thickness of the light material is a measure of the melt season in the watershed area, and of the dark layer the organic productivity, and thus a good climatic proxy. Some layers contain volcanic ash impurities from eruptions in Iceland or elsewhere and can thus be used for teleconnections.

De Geer completed an integrated count of thousands of lake deposits, and thus provided a chronology for the entire Holocene, a time scale that for a long time represented the world's only

absolute (year-by-year) chronology. In northwestern Europe all other stratigraphic systems, from pollen analysis to archeology, to the stratigraphy of the Baltic, were dated by de Geer's method. His methodology was strongly criticized during his lifetime, but subsequently the Swedish Geological Survey has resurveyed the entire sequence, essentially confirming the old standard, but introducing small corrections here and there (Cato, 1985). It was de Geer's chronology that made it possible to date the sea-level fluctuations represented by the raised beach (strandline) deposits of southern Sweden. Those same sea-level changes were then identified in the South Pacific and dated by de Geer's chronology; subsequently, shells from those beaches were radiocarbon-dated and (after isotopic correction) found to be identical with Swedish standard (Fairbridge, 1961, 1981).

Varved lake clays also are found in Finland, Russia (Lake Saki), Iran (Lake Van), Patagonia, Canada, and the United States. Teleconnections between such far-removed areas are fraught with difficulties, but provided that an approximate correlation can be demonstrated, perhaps within a 100-year error range, then a "vernier tuning" can be applied, as demonstrated by Schove (1978, 1983). The method is based on the twentieth-century observation that the well-known 26-month QBO or quasi-biennial climate cycle sometimes breaks down, especially during sequences of weak solar cycles, to become a quasi-triennial cycle. The length and timing of such breakdowns are globally synchronous so that when they are isolated in hanging chronologies (tree rings, varves, ice cores, or whatever), the century error can be reduced to 1 or 2 years. With the contemporary interest shown by meteorologists and oceanographers in the QBO and ENSO (El Niño–Southern Oscillation), this is an attractive way of extending their statistical data base to 10 000 or more years by using the historical proxies.

Varved marine layers (see subsection 7 below) are much less well known than the fresh-water accumulations, because they are mostly in deep, isolated basins, requiring very costly core-sampling expeditions.

4. Palynology of peat and lake sequences

The science of palynology, usually treated as a branch of botany, treats with the collection, sampling, identification, correlation, and chronology of pollen and spores. Stratigraphic treatment of cored sections provides a continuous paleoecologic record for a specific region that can be compared with actual data (natural contemporary floras and their growth patterns). This comparison permits standardization of results in terms of climatic parameters (Birks and Birks, 1980).

Pioneer studies of this sort were carried out in the nineteenth-century by two Scandinavian botanists, A. Blytt (a Norwegian) and R. Sernander (a Swede), who subdivided the 10 000 years of Holocene time into a series of biozones: *Preboreal*, *Boreal*, *Atlantic*, *Subboreal*, and *Subatlantic*. For convenience they are often identified by the Danish system using Roman numerals: respectively, IV through IX (zones I–III are late glacial Pleistocene).

Mangerud et al. (1974) proposed that, because the local Scandinavian terms of Blytt and Sernander were so useful in designating paleoclimatically determined divisions of Holocene time elsewhere, they should be employed as global stratigraphic time labels, as *chronozones*, and they have been formally defined in terms of radiocarbon years.

Probably the most significant climatic event in the Holocene (Nilsson, 1983), terminating the warmer *Hypsithermal* or

Climatic Optimum phase (Atlantic chronozone, with its mixed-climax forests), was first identified from the palynological data as the Ulmus (Elm) Decline about 5000 ^{14}C -years BP (5800 sidereal years BP). All across northwest Europe this dramatic decrease in the elm forests has been attributed by some botanists either to Neolithic farming or the disease (like the one affecting elms in the twentieth-century). However, the same decline has now been traced by Soviet palynologists all across Asia as well (in Velichko, 1984) and evidence of a simultaneous climatic deterioration and neoglacial advances (Denton and Karlén, 1973) in Arctic Canada, Greenland, and southern hemisphere lands combine to show that it was a global phenomenon. In the temperate belt of eastern North America, according to Davis (1983), the time boundary 5000 ^{14}C -years BP. (5730 Cal. Yr) is marked by a widespread hemlock (*Tsuga*) decline, with a concurrent rise of hickory (*Carya*). In the western United States, in the central Rockies, from 5000 ^{14}C -years BP on, the tree line became distinctly lower, and is further evidence of the cooling climate. These examples are simply citations documenting a global event of climatic nature. A vast literature has already built up, documenting this one and many others during the Holocene.

A remarkable site is a peat swamp at Ozegahara moor, Japan, where a 4–5 m core has been obtained covering a continuous time-series for 7600 sidereal years (Sakaguchi, 1982). The closely sampled and sharp fluctuations offer a unique record that correlates well with the better-known history of Europe (Roberts, 1998).

Of importance for climatology has been the rising level of confidence in recent decades, that shows an appreciation of the reality of these fluctuations documented by the palynological stratigraphy. Instead of regarding them as local events, experimental error, or whatever, the chronological precision is becoming steadily more refined, and from the repeatability of the pollen diagrams it is becoming quite clear that we are looking at finely tuned paleoclimate records. Care must be taken, especially in the more densely populated areas, to avoid anthropogenic influences, but such problems hardly arise in such remote and sparsely inhabited areas as Finnish Lapland, eastern Siberia, northern Canada, and Patagonia. Yet in all those regions the strongly fluctuating palynologic records proclaim the varied climatic history of the last 10 000 or so years.

5. Nile floods

A unique data source is provided by the documentary record of the Nile floods, which have two peaks each year: the high summer peak reflects the northern hemisphere summer monsoonal rains in Ethiopia; the low, winter peak reflects the equatorial rains in East Africa and the overflow of Lake Victoria. Inasmuch as Egypt's agricultural wealth has always been gauged by the height of the annual Nile floods, and thus for tax reasons, the records have been carefully kept since the foundation of Islam (AD 622), with some gaps caused by social upheavals and invasion. Nevertheless, the record is enormously helpful, providing not only a tropical climatic standard, but also some global signals (Fairbridge, 1984b; Currie, 1995). Historical events such as persistent droughts have been correlated with it all across North Africa from Senegal to Ethiopia. One remarkable example was experienced during a succession of very low Nile floods in Egypt from 827 to 848, but in 828–832 the Nile is reported to have frozen over (presumably in the delta); this correlation of dry cycles with low temperatures is frequently noted in the subtropics. In some epochs the

dry cycles match sunspot minimums, but in others there is a phase shift to match the sunspot maximums.

The lowest Nile flood of the twentieth century (the year 1913) corresponded to the highest lunar declination in a millennium; similar low extremes were reported all across Africa. Particularly interesting is the fact that in some centuries there is a strong correlation with the lunar nodal cycle (18.6 years), but in others the solar (11 years) signals appear. This question has been discussed by Currie (1984, 1995). In the Senegal River flood-drought sequence Faure and Gac (1981) found a 30-year periodicity that could represent a beat frequency of these two, or perhaps the 31-year perigee-syzygy cycle of the moon.

Prior to the Islamic era the Nile records are more scattered, but pharaonic data are quite informative (Bell, 1975), especially when taken in conjunction with stratigraphic material. The latter can be dated by an integration of several methods: radiocarbon dating of freshwater shells (mollusca) and charcoal (from fireplaces) and by association with dated archeological cultures or with established structures such as temples.

Evidently the pharaohs, for all their interest in both taxes and immortality, had little idea of how much variance the annual flood could offer. Some of the temple walls show little white bands (of calcium carbonate) marking flood levels up to 3 m above the flood plain on which they were built. At Semna (above the Second Cataract) the writer measured the present maximum flood height at 8 m below a high watermark inscribed about 1800 BC during the reign of Amenemhat III. Such fluctuations correlate with the ups and downs of world sea level (Fairbridge, 1962), itself a proxy for sea-surface temperature (SST) and for glacier advance and retreat (glacial eustasy).

The Nile deposits (with their radiocarbon and historical data series) provided the first quantitative demonstration of the falsity of a long-accepted climatic premise: that chronologically the glacial epochs equaled pluvials (wet or snowy cycles), and interglacials equaled interpluvials (i.e. dry periods). The delusion goes back in the past century to biblical scholars who observed the wadi gravels of the Dead Sea region and elsewhere, associating them with the great rains of the Noachian flood. High lake levels in East Africa and high terraces on the Nile were easily drawn into the same net. On logical, climatological grounds, objections were raised in 1913 and 1928 by Albrecht Penck (citations and discussion in Fairbridge, 1962). A cold glacial-phase ocean did not lead to more evaporation, but less. Besides, it was eustatically smaller, and large areas were covered by sea ice, a 13% reduction in effective sea surface. Net evaporation may have dropped 40%. East African lakes were in fact low during glacial phases. The middle Nile valley became a desiccated inland delta because of the reduced discharge, and the high terraces seen today are relics of hyperarid phases when discharge failed to reach the Mediterranean; indeed, the middle valley filled up to 40 m with silt. Glacials were not pluvials; there was ice-age aridity in Africa (Fairbridge, 1962, 1976b).

A similar inland delta has been discovered on the Okawango of northern Botswana and another on the Niger, in Mali, upstream from Timbuktou. In the Sudan and Egypt the aridity ended with the overflow of Lake Victoria into the Nile around 13 000 BP, and this can be matched by similar pluvial activity all across North Africa to India and northern Australia. The monsoon, which had been brought to an end during the glacial phase by the year-round high-albedo and high-pressure system established over Central Asia by the growth of ice caps, began to reassert itself around 13 000 BP. Heavy seasonal rains, a real pluvial, set in as part of the usual monsoonal pattern. Oxygen-18 isotopic studies

and planktonic indicators in the surroundings of the Arabian sea confirm the story from the oceanographic side (Prell, 1984).

During the Holocene, from time to time, throughout the entire tropical region, there also were strong fluctuations of the climatic regime (Fairbridge, 1976b), just as is indicated by the Nile record. They are particularly interesting from the human point of view, because this same belt also happens to include the Cradle of Civilization. Climatic forcing of human migrations seems as real here as in central Asia (Huntington and Visher, 1922), although sociologically oriented historians seem to have a marked distaste for climatic determinism. There is no doubt that the nomadic Neolithic people were forced out of the north African savannas by the advance of the climatic (*not* human-induced) desertification of the Sahara. It was surely not a question of overpopulation or politics around 6000 BP! At this same time began the intensive settlements along the Nile that were associated with a meteoric rise in building, engineering, and irrigation skills. Equally well, during certain catastrophic climatic deteriorations, such as the desiccation of the Indus Valley around 3000 BP, one sees the total obliteration of a major culture, in this case Mohenjodaro (Bryson and Murray, 1977). Care needs to be taken, of course, to avoid psychological and viewpoint errors (Bryson and Padoch, 1980), but the large number of investigators is a fairly healthy insurance against jumping to conclusions.

6. Coastal beach ridges of Hudson Bay and elsewhere

Around the coastlines of the world certain areas are favored by gentle offshore gradients and large supplies of gravel, sand, or silt so that a prograding shore tends to develop. In regions of crustal subsidence such as the Mississippi or Rhine deltas, those shoreline deposits are progressively drowned and buried. In rather stable regions such as the shores of Western Australia, West Africa, and Brazil, the prograding systems develop sheaves of beach ridges across flat coastal plains. In uplift regions such as the glacioisostatic rebound coasts of Hudson Bay, the Canadian Arctic, Spitsbergen, Scotland, and Scandinavia those beach ridges are progressively uplifted, so that in protected places they form dramatic staircases of shore terraces. This third category is the best for the study of historical time-series, because the crustal uplift is a slow, steady, non-fluctuating motion and relatively easy to measure. The residual value in the elevation, which with the width ratio of the terraces, is a measure of past sea levels and degree of storminess.

The staircase beach ridges of Richmond Gulf on eastern Hudson Bay (Quebec) have been measured in the field in numerous traverses (thesis work of Hillaire-Marcel), and associated formations have been dated by radiocarbon with many cross-checks, so that chronology is considered well established (Fairbridge and Hillaire-Marcel, 1977; also discussion in Fairbridge, 1983). The area is near the former center of the maximum ice loading of the Laurentide (New Quebec) ice sheet and today is the site of maximum deglacial isostatic uplift. The oldest Marine Limit of 8300 BP is uplifted to around 315 m elevation. The Earth's crust here is still rising at about 8 mm per year. The rising eustatic sea level of the last post-glacial (Flandrian) phase caused sea water to intrude the Hudson Bay beneath the continental ice, leading to buoyancy and a very rapid calving, so that within a few hundred years of 8300 ^{14}C years BP the entire bay was emptied of icebergs and normal marine deposits began to accumulate. Concordant dates for this event are obtained all around the bay. A shallow-water marine inland sea of very large size (520 000 km 2) was created,

at first several hundred meters deep but today with an average depth of only about 100 m. It is thus hydrographically rather comparable to the Baltic, and subject to strong fluctuations of water level due to atmospheric pressure, wind, and seiche effects; with the addition of tides (of the order of 1 m) the annual water level fluctuation may thus be as much as 2.5 m.

The staircase of raised beach ridges is for the most part uniform, with 185 steps distributed from the present beach up to 315 m. There is a gradually increasing individual height toward the top, a phenomenon due to the initially rapid isostatic rebound, now gradually decreasing. The mean age difference between beaches is $45 \pm 1\text{--}5$ years. On average, they are 1 m high and 5 m wide, but exceptional ones are 3–4 times higher. The individual ridges represent relatively short periods (3–10 years) when the degree of storminess was high, those episodes being separated by longer intervals when only fine sands were moved by the waves and relative sea level was rather stable. The Hudson Bay, at the present time, freezes over for 7–9 months of the year, so it is only summer storminess that is involved. Meteorological and tide-gauge records provide a guide to this alternation between stormy and calm periods during the present century, but the duration of the ice-free to frozen-in states is documented rather well, back to the early 1700s, thanks to content analyses of the old fur-trading log books of the Hudson Bay Company (Catchpole and Ball, 1981).

On the south western Hudson Bay, a more gentle slope permitted the preservation of intermediate beach ridges at 22 and 11-yr intervals (Grant, 1993). Prior to about 3000 BP the higher isostatic emergence rate amplified the contrasts (Figure C18).

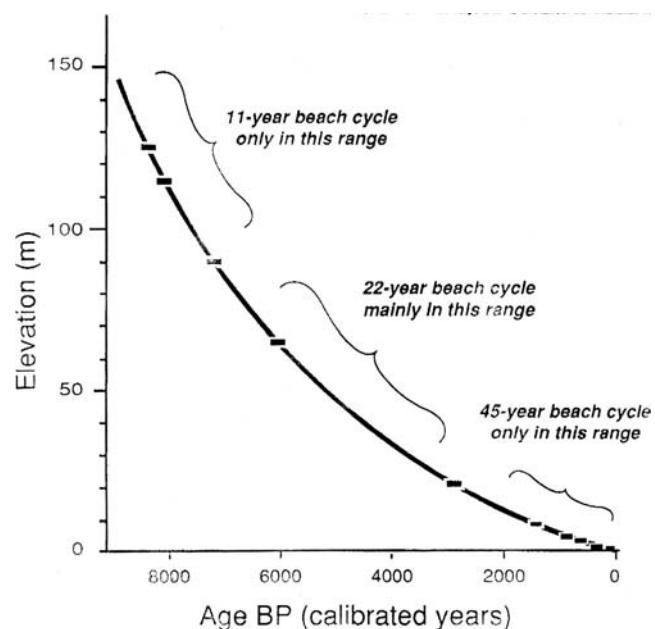

Figure C18 Holocene beach-emergence cycles in southwestern Hudson Bay, showing gradual decrease of glacio-isostatic recovery over the last 8000 years (courtesy: Douglas R. Grant, Geological Survey of Canada). Note: Progressive increase of storminess cycles from 11-year prominence, in the early stage, before 7000 yr BP (calibrated), through 22-yr before 3000 BP, down to 45 yr in last 3000 years. In the eastern coast, the 45 yr and longer cycles occur throughout the sequence (Fairbridge & Hillaire-Marcel, 1977).

Maximum beach building corresponds to longest periods of summer ice-free conditions and to the incidence of frontal storm systems across the bay. When the jet stream lies well to the south, the Arctic high-pressure cells move sluggishly across northern Canada from northwest to southeast, often remaining stationary over northern Quebec, causing cold easterly to northerly winds on the bay. In contrast, when the jet trajectory runs farther north, the frontal systems cross the bay, bringing in warm, wet, southerly and southwesterly air; a considerable storm fetch and wave set-up is then generated along the eastern margin of the bay.

From studies of pollen indicators and dune sand outbreaks in the same region, Filion (1983, 1984) discovered a correlation between the cold-dry climatic cycles, forest fires, dune building, and anomalous negative sea-level fluctuations that have a cyclicity of about 360 years, as noted earlier in the beach ridges by Fairbridge and Hillaire-Marcel (1977). Both amplitude and period are very similar to the Rocky Mountain tree-ring record of LaMarche (1974).

For convenient identification the ridges are numbered from no. 1 to no. 185, with 1 tentatively dated from tide-gauge and meteorological data as AD 1962. Beach 2 would be 1917, and so on. To calculate sidereal BP dates we create an imaginary beach 0 at 2007 which is 57 years AP (after present, the arbitrary astronomic and geochemical datum being 1950). Then for any beach number (n) we calculate: $(n \times 45) - 57 = \text{date (in sidereal years BP)}$

The most astonishing feature of these beach ridges is their regularity. No stochastic variance would seem possible for such a uniform cycle of 45 years. When plotted as a simple graph, with the isostatic component removed, it is evident that there is also a further modulation into sets of somewhat higher and somewhat lower ridges. The length of this secondary long-term oscillation seems to have at least two components, of the order of a half and a third of a millennium. What manner of cycles are these?

In view of the dramatic demonstrations by a number of workers (Currie, 1984 and others) that both solar and lunar cycles are clearly recorded in long-term historical series, we need to compare them with both the standard oscillations (i.e. the lunar nodal precession at 18.6 years and the solar activity cycle of 11–22 years, together with their harmonics) and various higher-order astronomic alignment periodicities. In the first paper (Fairbridge and Hillaire-Marcel, 1977), a double-Hale solar cycle of 45 years was suggested, and it is indeed observed that 11-year solar cycles are commonly arranged in groups of four (with increasing sunspot numbers). A 45-year periodicity is seen in eastern North American summer temperatures, in sea levels, and in the secular drift of the geomagnetic field. A careful analysis of Canadian Arctic winter temperature and pressure data (meteorology plus proxies) by Guiot (1985) show a phase coherence with Currie's solar and lunar results, as well as a volcanic dust signal. As mentioned earlier, the 18.6-year lunar tidal effect not only appears in sea-surface temperatures and sea tides but also triggers some earthquakes and volcanicity. Currie's work shows that its phase fluctuates by 180° regionally and over long time-series, and this was confirmed by Guiot for the northern Arctic region (including the area of the north magnetic pole). When the solar signal is strong the lunar one is often weak, and vice-versa. Maximum winter temperatures often correspond to the even-numbered (south positive) solar cycles that are most often weaker than the next cycle. Over the last centuries the solar (22-year) signal has been strongest over the Hudson Bay. However, after having established the most probable twentieth-

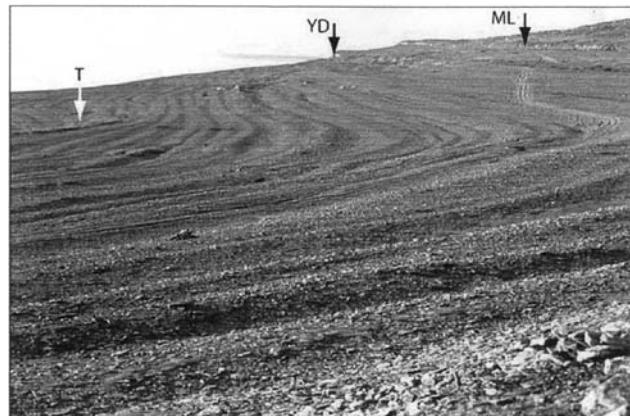

Figure C19 Emerged beach ridges facing the Barents Sea in northern Russia (Møller et al., 2002), the dates ranging from late Pleistocene to early Holocene, and the storminess frequency is less than on Hudson Bay. The "Marine Limit" (ML) here is probably Allerød, and the Younger Dryas (YD) is dated 9190 BC (Cal. 11,140 BP).

century dates (tide- and weather-based evidence) for the Richmond Gulf beaches 1 (1962) and 2 (1917), it is noticed that 1962 matches the lunar perigee-syzygy cycle (31-year) peak and 1917 matches the 18.6-year lunar-solar tidal maximum. The relationships of the lunar cycles to sea level and storm-flooding events are described by Wood (1978, 2001).

A systematic exploration of Arctic coasts was undertaken by the writer and associates (Fletcher et al., 1993), with comparable results except that in northern Norway and Russia (Møller et al., 2002) ice-borne boulders marked cold cycles with advance of Arctic sea ice (Figure C19).

Referring now to the long-term climatic oscillations on the Hudson Bay shown by Fairbridge and Hillaire-Marcel (1977), it is curious that the solar-planetary influences (178-year and 356-year cycles) seem to be most prominent since about 3000 BP, but prior to that the 556-year (50 × sunspot cycle), and 558-year lunar cycle (28 × nodal cycle and precession of lunar perigee) seem to be associated with larger fluctuations. From evidence in the Baltic history, Pettersson (1912, 1914, 1930) reached the conclusion that the long-term lunar cycles played a leading role in the regional oceanographically forced climatic behavior but recognized that they also were gravitationally tied-in to the sun. A long-term correlation with the Baltic herring fishery introduced an interesting economic overtone.

In nonglacial areas, dated series of prograding beach ridges have been described in Alaska, Mexico, and South Australia. Several hundred-odd beach ridge series north and south of Perth, Western Australia, again disclosed a 45-year periodicity with a larger fluctuation of *ca.* 360 years (Woods and Searle, 1983). This is remarkably interesting from the climatological viewpoint, because they are evidently responding to southern hemisphere weather systems as well as northern triggers.

7. Marine varves

Normally all deep-sea deposits are homogenized to about a 3000-year smoothing by bioturbation (burrowing worms and so on), but in a few isolated basins anoxic conditions isolate the bottom waters and annual layers are found, e.g. the Adriatic Sea, Red Sea, Cariaco Trench, and Gulf of California. Well-studied

records were those from the Santa Barbara Basin (Pisias, 1978). By analyzing the climatogenic significance of plankton carried by the California Current, he established sharp fluctuations in sea-surface temperatures over the last 8000 years. The major cycles are of the order of 500–1000 years, and disclose, for example, a variance of the mean February (midwinter) temperature of as much as 15°C. This astonishing range is apparently due to sort of northern hemisphere El Niño effect, whereby the normally cold south-setting California Current is replaced in some periods by warm tropical water. Pollen analyses disclose that the southern California landscape has been correspondingly vegetated at cold times by a dry, chaparral cactus and coastal sage scrub flora—the Sonora Desert type, which today exists 500 km farther south in Baja California. At warm times this flora was replaced by a mixed deciduous and pine forest, reflecting warm-wet conditions with southerly winds and summer rains.

Most significantly, the weakening of the California Current appears to match northward shifts in the Kuro Shio in the western Pacific, indicated in Japan by northerly appearance of reef-building corals in the littoral terraces, assumed to be partly eustatic (Taira, 1980). Chronologically, they seem to approximate those dated by Fairbridge (1961) and others from Australia and elsewhere in tropical seas. Climatologically, it appears that during the major warm cycles, the subtropical highs expand and migrate somewhat poleward, accompanied by a reduction in the equator-pole thermal gradient. Trade winds weaken and the equatorial Pacific westerly air flow increases. Sea-surface temperature rises and we have a super-El Niño effect. The major warm cycles were most prominent during the mid-Holocene (Fairbridge, 1993). In the coastal shell middens of Peru a remarkable shift from warm to cold-water mollusca is observed in the late Holocene.

8. Volcanic signal

As developed by Lamb (1972, 1977) and much favored by meteorologists and journalists in the present century, the concept of violent, dust- and gas-producing volcanic eruptions is important climatologically because they often distribute a dust veil into the stratosphere that effectively screens incoming solar radiation, thus cooling the Earth's surface. In the four largest of such eruptions of the recent historical era, Asama (Japan) in 1783, Tambora in 1815, Krakatau in 1883, and Agung in 1963, the effect may have been a planetary cooling that lowered the mean global temperature by as much as 0.5°C for up 2 years (Rampino and Self, 1982). Tambora dramatically made 1816 the ill-famed “Year without a Summer” (Stommel and Stommel, 1983). No longterm climatic effects have been demonstrated, but sociological effects were, in places, profound, ranging from forced migrations from New England, to famine in central Europe and Bengal. Even more dramatic results followed a Sunda Strait eruption in AD 535 (Keys, 1999), although its effects were mainly felt in AD 536.

Volcanic eruptions have been traced back and catalogued as far as possible for the whole 10 000-year interval of the Holocene Epoch (Simkin et al., 1981), but their climatic potential has been variously appraised. They have even been elevated to the role of controlling the primary cooling in the 100 000-year glacial-interglacial cycles (but see criticism by Huntington and Visher, 1922; Schwarzbach, 1950, 1974). Evidence for that hypothesis seems to be entirely in the wishful-thinking category. Volcanism, as a source of CO₂, might even lead to warm cycles, as suggested long ago by Fritz Frech (see discussion in

Schwarzbach, 1974, p. 291). Seen in a global context, volcanic eruptions are too brief and discontinuous to play a major role in long-term climatic cycles—either heating or cooling, although their effect on regional populations can be apocalyptic (Winchester, 2003).

Although they clearly modulate climatic fluctuations on a less-than-decadal basis, the major volcanic eruptions over the last few centuries, for which we possess good chronological data, all seem to have taken place during but not at the beginning of cooling cycles. Lag times are of the order of 10–20 years. This anomalous reversal of possible cause and effect was commented on long ago by Huntington and Visher (1922), who pointed out that a month-by-month global study by Arctowski showed that the great eruption of Katmai, in June 1912, coincided with a general cooling cycle. The volcanic school submit that only equatorial volcanoes should count because of the lower tropopause in low latitudes, but neither Agung, nor Krakatau, nor Tambora—all near the equator—had lasting effects.

Tambora, in 1815, was one of the largest eruptions and it was certainly associated with cooling, but the whole of the preceding decade was one of global cooling. Pettersson (1914) noted that the three coldest winters ever recorded in Stockholm were in 1805, 1809, and 1814. In 1809 a Russian army attacked Sweden by crossing over the Baltic on the ice from Finland, the general reporting to the czar an air temperature measured at –36°C. Napoleon’s retreat from Moscow was in December of 1810. For several winters even the southern Baltic was frozen over as far as the Kattegat. The East River (a salt-water channel) and lower harbor at New York City also froze over. The years leading up to 1815 were marked by one of the worst droughts in East Africa, subtropical droughts generally being associated with worldwide cooling phases. The year 1810 also marks the lowest point in mean sunspot numbers in the last two centuries.

An alternative hypothesis has therefore been offered: “Can rapid climatic change cause volcanic eruptions?” (Rampino et al., 1979). Climatic stress, notably atmospheric angular momentum for short pulses, and ice build-up and decay for longer cycles, is proposed as a trigger for crustal stress. Sudden accelerations in the atmosphere’s angular momentum (Rosen et al., 1984) are accompanied by changes in spin rate as well as in the rate of secular drift and intensity of the geomagnetic field. It seems hardly a random coincidence that the two largest changes in spin rate and geomagnetic field intensity in the twentieth century match the declination maximums of the lunar nodal cycle (1913, 1969) when that cycle correlates precisely with either sunspot maximums or minimums (Courtillot et al., 1982).

Long ago, Köppen 1914 proposed a correlation between air temperatures, sunspots, and volcanicity. Köppen had noticed as early as 1873 that a temperature–sunspot correlation could be seen in low-latitude records but not elsewhere. The cumulative factors of lunar periodicities combine to give 1913 the maximum crustal stress build-up in more than one millennium. The cool cycle at this time and the volcanic eruptions (of which Katmai in June of 1912 was only one) do not seem to be random occurrences. A statistical survey of large earthquakes in California (Kilston and Knopoff, 1983) shows a clear link to lunar periodicities, including the 18.6-year cycle, probably through tidal loading on the continental shelf. A similar periodicity is observed in oceanic tidal height, and in temperature (SST), reflecting enhanced water exchange. Russian geologists

have also observed the same 18.6-year period in the volcanic eruptions on Kamchatka (Shirokov, 1983).

During the Maunder Minimum (the sunspot dearth of 1645–1715) the incidence of global volcanic activity was twice as high as during the interval 1715–1800, and in the two decades 1680–1700 it was six times higher than for 1740–1760 (Fairbridge, 1980, p. 390). The coldest decades indicated by the Greenland ice-core oxygen-18 proxies were 1660–1680, preceding the volcanicity peak (see also Little Ice Age).

None of these complex relationships demonstrates conclusively a cause-and-effect situation. If the lunar declination cycle is locked into the sun's barycentric orbit and to solar radiation, as urged by Pettersson (1914), the 18.6-year period in historical climate proxies may also involve a solar pulse. The volcanic signal in long-term historical proxies thus deserves more far-reaching investigations, not so much as the cause of important climatic fluctuations but as a consequence, and also for their taphrochronological value, where they have a potential of providing a “golden spike” or a “silver thread” that runs through multiple proxy records, not least being the human observations of the actual eruption. Archeological documentations of the burial of villages or towns should be integrated into the record.

9. Paleomagnetic signal

The Earth's magnetic field is just beginning to be recognized as a major link between solar particulate radiations and their role in modulating terrestrial climates. This important geophysical parameter has been carefully studied and documented over a longer period than any other, initially because of its use in navigation. In 1692 Edmund Halley recognized that there was a secular westward drift of the magnetic field of some 0.2° per year, involving not only declination but also changes in inclination and total intensity. Because of the eccentric arrangement of the dipole and quadripolar fields, the actual readings of these variables at the Earth's surface are quite complicated and constantly changing; for navigational use they needed to be continuously monitored and mapped. Most significantly, the north and south magnetic poles (nonantipodal) are found to migrate some 5–10 km per year.

Prior to the documented historical period, i.e. the last five centuries or so, the record has been extended back by a technique known as *archeomagnetism*, whereby the former field characteristics may be measured in bricks or fireplace clays of archeologically established ages that have been heated and had cooled through their Curie point, thus preserving a fossil relic of the magnetic field of that time. The key observation was made in 1906 by a French geophysicist, Bernard Brunhes, studying the cooling of modern bricks (see Imbrie and Imbrie, 1979). Pioneer work on historical bricks was done much later by the Czech Geophysical Institute in Prague (Bucha, 1970). Recent studies with refined techniques confirm the general pattern, making the values stratigraphically useful.

The most striking result of this work was the discovery of a slow secular rise and fall of the total intensity field during the Holocene. At about 6000 BP (the Climatic Optimum of the Holocene Epoch), the dipole field moment strength was about 10% weaker than its present value. This variable is particularly interesting in connection with the flux rate of radiocarbon as determined from dendrochronological series (Suess, 1981), magnetic intensity being inversely proportional to radiocarbon value. That is to say, when the magnetic field intensity is weak,

the influx of the weakly radioactive ^{14}C isotope is high, and vice-versa.

The Earth's spin rate is influenced by both exogenous and endogenous variables. Most emphatic of these variables is the mass transfer from glacial to interglacial mode and vice-versa; ice build-up near the poles shifts the moment of inertia and increases the spin rate, whereas deglaciation slows it down. Angular momentum is conserved by differential motions of the Earth spheres and by changes in the lunar orbit, thus affecting ocean tides. Changes in spin rate affect the angular momentum of all fluid systems, from the outer core, and asthenosphere, to the hydrosphere and atmosphere. The last is the most fluid and reacts most rapidly. The atmosphere is also most subject to extraterrestrial energy input and thus is most likely to disclose evidence of the two disturbing factors, external and internal (see also subsection 8 above).

The Earth's principal magnetic field, the dipole field, appears to be generated largely by the dynamo-like turbulence in a 100-km layer of low strength in the semiliquid outer core. Inasmuch as the spin rate of the mantle and crust are repeatedly subject to sudden changes, a differential torque is generated. The nearest familiar analog in human experience is the automatic transmission and gearshift of the family car.

The geomagnetic field appears, in fact, to be modulated by three principal phenomena, generating cycles or fluctuations of variable length and intensity. These are still subject to much research but appear to be as follows: orbital variations, magnetic pole migration and westerly drift, and solar wind modulation of the Earth's magnetic field. All three appear to play distinctive roles in the Earth's climate either by affecting the geomagnetic field intensity or by the geographic location of the magnetic pole. The relevant climatic link is through their control over the amplitude and location of incoming solar particulate radiation, which modifies the atmospheric chemistry and dynamics. The three control mechanisms are briefly summarized here.

Orbital variations.

Most important in this context is the variation of the obliquity of the ecliptic (*ca.* 41 000 years; Williams, 1993), together with some input from the eccentricity cycle (*ca.* 96 000 years) and the precession cycle (*ca.* 23 000 years and 19 000 years). These orbital variations, as already mentioned, correlate very precisely with geological proxies (Imbrie and Imbrie, 1979), but it has been questioned whether insolation alone has the ability to produce the large glacial-interglacial fluctuations. The question is usually skirted by pointing to the powerful feedback mechanisms that come into play, but the geomagnetic factor should also be included in the model.

Studies of the paleomagnetic intensity of Pleistocene deep-sea cores suggest higher fields in the cold, high spin-rate intervals, but the glacial-cycle sediments themselves carry more terrigenous (and magnetic) particles, which weakens that argument. Nevertheless, cold episodes during the Holocene also correlate to higher intensity signals, without contamination, so that the interrelationship is probably nonetheless true. What triggers the reversals in the geological past is still a controversial problem, but it seems that rapid changes in the spin rate and tilt must accompany the intervals of rapid crustal break-up and redistribution. Long periods of no magnetic reversal seem to coincide with times of mild climates (e.g. the late Cretaceous). Conversely, the times of disturbed crustal distribution and cycles of ice-age glacier loading must affect both tilt and spin.

During the course of the Holocene Epoch there have been appreciable variations in the secular orbital parameters. In particular, the tilt angle is now nearly 2° less than at the beginning of the Holocene (Berger, 1978). This secular change may be the principal component in Bucha's archeomagnetic variation. Mörner (Mörner and Karlén, 1984, p. 489) has presented the concept of a paleogeoid, linked to a phase transition at the core-mantle boundary, that is paralleled during the last 10 000 years by the curves of archeomagnetism and ^{14}C production.

Magnetic pole migration and westerly drift.

Within a period of about 1800 years the eccentric dipole field migrates westward, as does the weaker quadripole field, but more slowly, giving it a relatively eastward component, having a period of about 2800 years. The magnetic pole migrates at about 5–10 km per year. Bucha (1984) illustrates the position of the geomagnetic north pole over the last 18 000 years based on values obtained in Czechoslovakia, Japan, and the United States, its trajectory appearing to follow a quasi-ovoid form over the period of historical measurements, with a four-leafed clover form in its longer records.

To obtain more detailed records of total intensity, declination, and inclination, a vigorous campaign of lake coring has been undertaken in Europe, North America, and Japan (e.g. Creer, 1981; King et al., 1983). Records are pushed back to beyond 15 000 BP. They show regular fluctuations of all three variables but, because of the field asymmetry, the pattern varies slightly from one region to the next and with a general lag corresponding to west drift. Eight inclination cycles occurred during the last 10 000 years.

It was proposed by Fairbridge and Hillaire-Marcel (1977) from evidence of alternating calm and storminess cycles in the Hudson Bay that the more westerly sites of the magnetic pole generated a higher continentality situation (cold and calm) in the Canadian Arctic, in contrast to the more easterly pole situations (more oceanic sites around Spitsbergen), which coincided with warmer temperatures, less summer ice, and increased stormwave action (Fletcher et al., 1993).

Bucha (1984) believes that during brief but highly energetic solar flares the site of the magnetic pole and its associated auroral oval favors the development of low-pressure systems and storminess, which in turn helps to maintain milder temperatures, and that this condition applied to the North Pacific–Aleutian area during the late Pleistocene (18 000–12 000 BP). This would explain the lack of ice sheets in eastern Siberia and Alaska at the time. In contrast, according to Bucha, the remoteness of the North Atlantic region from the north magnetic polar area during the last glaciation maximum permitted a stable high-pressure situation favoring meridional air flow and the build-up of major continental ice sheets in eastern North America and northwestern Europe. If these hypotheses are correct, then not only would historical Holocene climatic fluctuations but also the glacial–interglacial relationships have a geomagnetic component in the 1800-year range and its subharmonics.

When the geomagnetic field is in an extended weak cycle, as during the mid-Holocene, and is modulated by unusually weak, short-period solar cycles (Damon et al., 1978), there will be an enhanced effect of galactic cosmic radiation, marked by prominent spikes in the ^{14}C flux record (Suess, 1981; Stuiver and Braziunas, 1993). The cosmic rays lead to the nucleation of high cirrus clouds (Roberts and Olson, 1973). This stratospheric cloud screen would furnish a high-albedo, cooling screen for the midlatitudes and Arctic.

During magnetic excursions, field intensity drops away dramatically and the result can be catastrophic cooling events as shown by evidence from the Pleistocene Lake Biwa, Japan (Kawai et al., 1975). In contrast, when the long-term magnetic field is strong, as seems to be the case during glacial cycles when the spin rate is high, the solar signal will be largely suppressed.

Solar wind modulation of the Earth's magnetic field.

This exogenous factor provides a variable modulation of the internal field that can be identified in two independent ways. On a day-to-day basis, eruptions of giant solar flares (see Sunspots), observed astronomically, can be traced through a series of magnetosphere and ionosphere interactions, ultimately to their role in atmospheric chemistry.

The major flare events trigger upper atmosphere chemical reactions, particularly in the magnetic pole area, that in the troposphere at the 500-mb level lead to a dramatic warming (20–30°C) within 24 hours, accompanied by a drop in air pressure and the initiation of giant frontal weather systems that bring in a flow of warm humid air from as far away as the North Pacific. Such events trigger displacements of the jet stream and related atmospheric systems throughout the high- and mid-latitude belt of the northern hemisphere (Bucha, 1984).

One such solar–terrestrial event will not, of course, generate a climatic change, but the rate of incidence and magnitude of major solar flares is a variable that correlates roughly with the 11-year solar cycle. Landscheidt (1984) relates this variable to the crescendos of the torque stress developed by the spin and orbital positions of the planets. It is, therefore, an astronomically predictable quantity.

The most complete long-term record reflecting geomagnetic-climatic relations, now extending over almost the whole 10 750-year length of the Holocene, is provided by the radiocarbon flux-rate measurements made from dendrochronological series (Suess, 1981; Damon et al., 1978; Stuiver and Braziunas, 1993). These represent the ^{14}C isotope product of cosmic particle impacts on nitrogen in the stratosphere. The actual flux rate depends on two principal factors: (1) variation of the geomagnetic field strength in an inverse relationship—that is, when the field is weak, the flux rate is high; and (2) variation in the strength of the solar wind, which is modulated by planetary motion dynamics on the sun's photosphere (see Sunspots). A third but less frequent phenomenon is the modulation of galactic cosmic radiation by supernova events. Damon et al. (1978) commented on a very important aspect of these interrelationships already noted above in the subsection "Magnetic pole migration and westerly drift." When the internal geomagnetic field is weak, as in the mid-Holocene about 6000 BP, the amplitude of ^{14}C flux-rate departures is up to five times higher than their level during the high-field intensity intervals. These large fluctuations are noted at about 500–1000-year intervals (Figure C20). A similar oscillation may be seen in many of the standard climatic time-series noted in this entry: sea-level fluctuations, palynological diagrams, ice-core data, hydrological indicators, and so on.

From all these indications it is evident that the solar (i.e. exogenous) component is most important in terrestrial climate series in the 500–1000-year time frame. However, on the 10 000–100 000-year scale the endogenous components (controlled by spin-rate and tilt factors) are paramount.

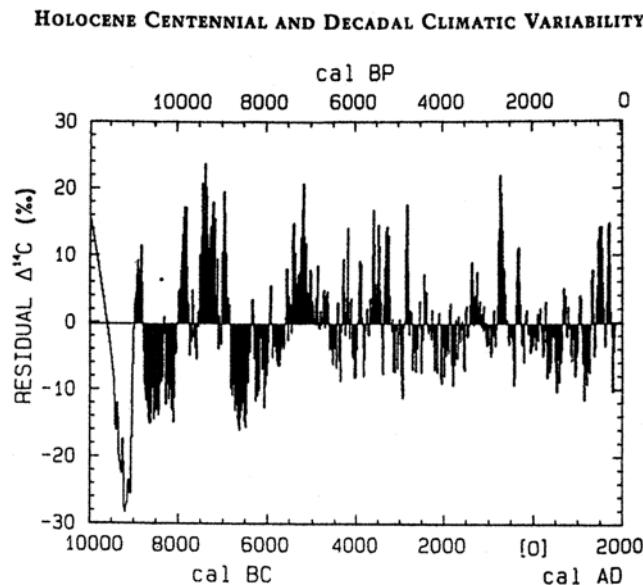

Figure C20 Solar variability, indicated by C-14 flux (inverse to solar activity) based on tree rings, and partly on corals (Stuiver and Braziunas, 1993). Maxima correspond to temperature minima in the Greenland ice cores. The post-Younger Dryas (cold spell, not shown) was followed by the dramatic warming of the Preterrestrial and its several oscillations. Glaciers tend to respond rather sluggishly, so that eustatic sea level shows a retardation (Fairbridge, 1961).

10. Climate–aurora–sunspots documentation of ancient China

A gratifying feature of the new cultural orientation in modern China is the liberal approach to science and an appreciation that the written archives of that country contain the largest storehouse of proxy climatic data outside of Europe (Chu, 1973; Wang, 1979). Studies of the aurora and sunspot records were undertaken by Schove (1955), assisted by expatriate Chinese scholars, and in this way the first long-term (2600-year) reconstruction of solar history became available. Subsequent improvements and reprints of the key literature have been published in Schove (1983). The aurora have been separately treated by Siscoe (1980). Spectrum analyses by Jelbring (1995) broadly confirm the Schove model.

A preliminary study of the long-term variables in China's climate has been offered by Ren and Li (1980), who came to the conclusion that its cyclicity was in phase with the All-Planet Synod, an approximately 178-year alignment of planets in quadrature. At such times, as demonstrated by Newton, the sun is displaced as much as 1.5×10^6 km from the barycenter (center of mass) of the solar system, its spin rate accelerates (up to 5% from the usual 27 days) and its photospheric convection is retarded, resulting in a decrease in solar emissions (see Sunspots). On Earth these sunspot-dearth periods are associated with cooling spells (see Little Ice Age).

A study of diary and yearbook records for the period AD 1470–1979 by Wang and Zhao (1981), using content analysis, has disclosed six spatial patterns for droughts and floods, using 25 stations in eastern China, arranged in east–west belts in more or less meridional distribution. The first eigenvector relates to long-term variations of the Southern Oscillation

Index, which is linked to the intensity of the western Pacific subtropical high. The second is linked to the same high, specifying whether its influence extends north or south of the Yangtze River. The third relates to the high-frequency variations of the East Asian Circulation Index.

The linkage to the Southern Oscillation makes these figures of global significance, especially for the Indo-Pacific subtropics and regions affected by the El Niño Southern Oscillation, which in the recent example (1982–1983) means practically the whole world. When the Southern Oscillation and Walker Circulation indices are both high, in the mid-Pacific there is low sea-surface temperature (SST), the Pacific Hadley cell weakens and the summer monsoon is strong in southeast Asia (Yoshino and Xie, 1983), and the Yangtze discharge level is high.

In an investigation of winter thunder from 250 BC to AD 1900 by Wang (1980), it was possible to show a correlation with cold airmasses associated with unusual winter front development. A close match was found with temperature records collected by Chu (1973). It is significant that the patterns also correlate with similar historical records from Japan based on the dates of the blossoming of cherry trees (an important ceremonial event) and the freezings of Lake Suwa (Arakawa, 1957).

Application of modern computer technology and statistical theory to the Chinese data for the Beijing (Peking) area was begun by Hameed et al. (1983), who found in the proxy drought–flood records since AD 1470 signals of both the 18.6-year lunar nodal periods, probably a tidally induced modulation, and the 11-year solar emission cycle. These conclusions were dismissed by Clegg and Wigley (1984), but in a study by Currie and Fairbridge (1986) the results of Hameed et al. were supported, and, in addition, the curious bistable phase reversals found elsewhere in the world (Currie, 1984) appeared once more. Currie employs the maximum entropy method (MEM) to develop power spectra, and then constructs waveforms for the principal cycles as indicated. This permits a visual comparison of phase and amplitude, which can then be conveniently compared with historical events.

Testing and modeling

In order to derive a useful scientific product from the vast store of historical data, documentary and field, evidence that are either available at the present time or merely potential and unexploited, it is desirable to develop programs of testing and modeling. This rich area of research endeavor has hardly been explored up to the present moment, except in the most sporadic or generalized way. Intuitive matching has been the usual, nonrigorous methodology, and the lack of adequate statistical procedures has been brought out by Pittock (1978, 1979, 1983), Currie (1984), and others. It is petulant and childish however to make fun of the pioneer investigations, many of which rested on the most limited or crudest of databases. Yet, almost miraculously, many of their preliminary conclusions have turned out to have more than a grain of truth, as may be seen from a careful reading of Lamb (1972, 1977), for example.

In the preceding sections dealing with standard time-series, 10 examples of historical data types covering the last 10 millennia are presented. They have been derived conceptually from a short contemporary base line of instrumentally observed processes, furnished by meteorology, oceanography, geology, botany, astronomy, and astrophysics. Building up on this minuscule chronologic base line we are able to construct an

array of time-series of varying quality but with sufficient common threads that the researcher gains confidence.

The last 10 millennia are today not a sea of unknowns. During the approximately 100 years that have elapsed since Blytt and Sernander constructed the first climatologically oriented chronology (covering the last 15 000 years), based on Scandinavian pollen analysis, we have now come to possess three independent time scales that have the potential of providing year-by-year chronologies and that are mutually verifiable. Probably their error bars are still in the range of ± 10 years, but the three methodologies have the potential of refinement and correction; they also can be extended to other (favorable) regions around the globe. An immense field of potential research is thus open and still largely unexploited.

The first and most ambitious attempt to develop a global model of the glacial-interglacial climatic fluctuation generated the CLIMAP (1976), which, for all its faults, was a remarkable first attempt. It exploited a largely oceanographic-paleontologic database to derive a broad picture of an instant in time during a glacial-phase maximum. Further endeavors have been made for modeling distinctive intermediate (Holocene) stages. Using the three year-by-year chronologies, supplemented by input from the other seven signals, an exciting vista is now open for establishing what *did* happen. The geologists have a pet phrase: What did happen, can happen! From that base comes the potential of explanation and prediction.

Summary of historical climatic epochs

In the space of one encyclopedia entry it is impossible to review the entire 10 000 years of climate history on a world basis. Here we concentrate on the best-known Scandinavian and northwest European data series with only brief references to events elsewhere. No book exists that summarizes the record, but several useful references deal with specific fields of research. Three excellent multiauthored volumes cover the Holocene history of coastal changes and deposits around the Baltic (Gudelis and Königsson, 1979), the North Sea (Oeie et al., 1979) and the Irish Sea (Kidson and Tooley, 1977). The general vegetational and climatic history of Europe has been summarized by Frenzel (1973). A single-volume, multiauthored work has been dedicated to the Holocene of the United States (Wright, 1983) and the Holocene is included in a companion volume on the Quaternary of the USSR (Velichko, 1984). Detailed investigations are covered in the journal *The Holocene* (vol. 1, no. 1, 1991).

There is now an abundance of professional papers but, alas, the much-needed syntheses are for the most part lacking. The explanation for this lack of what might appear to be a key area of scientific and humanistic literature is associated in part with the inherent costs and problems of dating, and in part with the multidisciplinary training that would be needed to study the whole field. The specialists are botanists, or malacologists, or archeologists or whatever; unfortunately very few scientists are trained today outside of their specialized fields. In as much as the Holocene Epoch is a segment of geologic time, there is primarily a problem in geological chronology. Its climate history is a derivative product that must be extracted from a proxy record that basically is stratigraphical and preserved in geologic strata, or ice, or tree rings.

Reasons of priority dictate that, all things being equal, the first classification worked out by any team of scientists for an interval of geologic time is the one used as a basis for future workers to build on. In the case of the Holocene it may appear

at first sight to be anomalous that the Blytt-Sernander botanical classification is commonly adopted (see earlier discussion under subsection 4: Palynology). This unusual action becomes understandable when it is remembered that the geologic basis for chronologic ordering is, first, the superposition rule, second, the fossil content of strata, and third, any absolute (geochemical) method of dating that may be appropriately applied to the formations in question. In this case it was the integration of pollen studies by Blytt and Sernander, in stratigraphic sequences of lake or swamp deposits, and provided with the varve counting by de Geer (see subsection 3), that furnished the first standard geologically based record of the last 10 000 years of Earth history.

This serendipitous combination of distinctive botanical fossils, sequential strata, and a precise year-by-year chronology placed Scandinavia in an extraordinarily advantageous position for presenting a world-standard historical record (Mangerud et al., 1974). Thanks to written documents and early scientific instrumental records, it would be additionally very helpful if this region could be selected for various stratotypes, i.e. chosen areas that contain well-preserved and well-analyzed records. It is unquestionably true that several other parts of the world could provide detailed, continuous stratigraphic records of the last 10 000 years of the Earth's history, but up till now no area has been proposed that has had the same rich, multidisciplinary background of study. Continuously cored lake or swamp deposits are now available from Britain, France, Nova Scotia, Minnesota, Japan, India, Colombia, and elsewhere. In time it is hoped much of the world will be brought into this chronological framework.

The smallest units of geological time, derived in the case of the Holocene from the original Scandinavian pollen-based stratigraphy, are categorized as *chronozones*. Five of these units, unequal in duration, are used to classify the epoch. In different parts of the world these boundaries are not always conveniently applicable to local records, and local terminologies need to be established. The purpose of a set of chronologic labels is simply that it is helpful to have a reference standard that is universally known to scientists. The local records should never be forced into a straitjacket of any assumed universality. Many natural boundaries are diachronous; this is particularly true when we are dealing with a eustatically rising sea level, where the beginning of a transgression may be hundreds of years earlier than its culmination. Ocean water warms or cools slowly; glacier melting involves latent heat and other delaying factors; again there will be lags or retardation. The purpose of agreed time planes is simply to coordinate our data within an internationally understood framework of time intervals, often called *epochs* or *ages* in an informal sense. (It may be noted, according to the internationally agreed stratigraphic code, that each term has a specified meaning in the chronostratigraphical hierarchy; and *epoch* is thus longer than an *age*, and shorter than a *period*.)

The Blytt-Sernander scheme of pollen stratigraphy was applied to every chronozone back to the first formations to emerge from the melting ice fronts of northwest Europe; that is, from about 14 000 BP, ranging up to the present. The earlier zones (14 000–10 000 BP) are classified as late Pleistocene (Weichselian or Wisconsinan glaciation). In this entry we only consider the Holocene, which includes five principal units. Several are now subdivided, giving 10 units in all.

The latest Pleistocene corresponds to the first part of the very rapid deglacial process, when the midlatitude glaciers were

melting at an astonishing rate, peaking in two warm phases (Bölling: 12 500–12 000 BP; and Alleröd, 11 800–11 000 BP) that were separated by three cooler fluctuations, known as the *Tundra* ages (Oldest, Older, and Younger Dryas). Heavy snowfalls consequent upon the oceanic warming (the Simpson principle), were probably responsible in part for glacial readvances in the mountains during those colder intervals. In the last one, the Loch Lomond Readvance in Scotland, glaciers actually reached down to sea level. Even in the tropical oceans signs of these cool fluctuations are seen in the oxygen-18 records.

Thus the stage was set for the beginning of the Holocene, the boundary being established, by international agreement, as the time when warm marine fossils replaced cold ones in the uplifted deposits of southwest Sweden (Olausson 1982; Fairbridge, 1983) the time was roughly 10 000 BP (by radiocarbon) \pm 300 years. (This time equivalent in sidereal years is believed to be approximately 8000 BC, but precise calibration is still controversial; Cato, 1985.) In other parts of the world another boundary might have seemed better. In tropical regions the dramatic postglacial warming was generally about 13 500 BP. In northern Canada or Alaska about 8000 BP or even 6000 BP might seem more appropriate. The local boundaries are always diachronous, so that only the somewhat arbitrary chronostratigraphic boundary should be shown as a horizontal plane on our diagrams, a “time line” that has been agreed to by a commission of the International Union for Quaternary Research (Olausson, 1982).

Holocene chronozones

We will now briefly review the 10 chronozones of the Holocene. The ages will be given first in sidereal (calendar) years, expressed as BC or AD, then in BP equivalent (before 1950), and finally in radiocarbon years, indicated as b.p. (lower case). Calibration tables for conversion of one to the other were provided by Klein et al. (1982), and subsequent authors, simplified in Roberts (1998). When precise astronomic equivalents are required, one should remember there is no year zero in the AD–BC system, so that the astronomical year – 100 is 101 BC and conversion to BP made by adding 1949 to the BC date, thus 2050 BP. Inasmuch as radiocarbon dates normally carry at least a \pm 100-year range of error, it is usual to round off calendar equivalents of such dates to the nearest 10 or 20 years. The chronozones are listed with abbreviated initials and with the Danish pollen zones (Roman numerals). Botanical aspects are treated in Birks and Birks (1980), for the North American setting by Davis (1983), for the Scandinerian setting by Berglund (1986).

Preboreal (PB, IV) 9350–7500 BC (11 300–8900 BP, 10 400–9650 b.p., calibration doubtful)

Glaciers still covered most of North America north of the St Lawrence and the Great Lakes, most of Scandinavia north of Stockholm and all of the central Alps. Sea level, at minus 40–45 m, had reached about halfway across the continental shelves in mid- to low-latitudes, introducing maritime air and leading to a rapidly rising humidity. The Baltic area was invaded by the Yoldia Sea. Marine formations of this age are isostatically uplifted today in the Oslo Fjord to 221 m and to lower elevations in southwest Sweden. In Finland the Yoldia strandline reaches 220 m. Tundra vegetation was quickly replaced by birch and pine forests across western Europe. In North America, boreal forests (mainly spruce) followed closely on the

retreating ice but in the northern plains was replaced by deciduous forest by 9500 b.p. The Champlain Sea, which had invaded the St Lawrence lowlands somewhat earlier, brought maritime influences to the lower Great Lakes; whale bones and other marine fossils are found from Quebec to Michigan. (Note: radiocarbon dates given for the early Holocene are not precise.)

Early Boreal (BO-1, V) 7500–6900 BC (9450–8750 BP, 9650–8550 b.p.)

Glaciers were in universal retreat. The *climatic optimum* (Europe) or *hypothermal* (North America), a diachronous rise of air temperatures to higher-than-present levels, reached southern Sweden, Britain, and much of North America except for the still-ice-covered areas of Keewatin and Quebec. Vegetation in northern Europe now became dominated by pine forests, but in favored areas in Sweden the hazel was flourishing, a thermal indicator requiring 2°C to 2.5°C warmer summers than today. Isostatic uplifts isolated the Baltic (the Aenkylus Lake) and emptied the St Lawrence Lowland largely of the Champlain Sea, leaving the Goldthwait Sea in its lower valley. In the plains of the United States, prairie grasslands began to replace deciduous forests.

Late Boreal (BO-2, VI) 6800–6200 BC (8750–8150 BP, 8550–7700 b.p.)

Glaciers in Scandinavia now shrank to the principal mountain axis but the Aenkylus Lake persisted until 8300 BP. In North America the Keewatin Ice Sheet and Laurantide (New Quebec) Ice Sheet became separate, with Hudson Bay open to the sea. Ice remnants still remained on the high ground of the Maritime Provinces and Maine. A strong zonal (westerly) air flow began to affect most of Europe and North America and northern Mexico, with Gulf air limited to the southeast United States. Alaska and most of Canada were influenced by a strong Arctic airmass. In northern Europe, pines and spruce were progressively replaced by mixed oak forests.

Early Atlantic (AT-1, VII-a), 6200–5500 BC (8150–7450 BP, 7700–6600 b.p.)

Glaciers became limited to high mountains in Scandinavia and to residual patches in northern Quebec and Keewatin. Sea level rose to within 20 m of its present level, and a warm-water marine transgression invaded the Baltic (the Littorina Sea). Progressive isostatic uplift has left former Littorina strandlines (high eustatic oscillations) in parallel belts around the coasts. Mixed oak forests spread across most of Europe and North America. Strong westerly air flows maintained highly maritime climates. Even in northern India winter rains were almost as important as the summer monsoon. The AT-1–AT-2 boundary is marked in Greenland ^{18}O ice cores by a distinctive cooling indication, and likewise in the California tree-ring ^{14}C series.

Late or Main Atlantic (AT-2, VII-b), 5500–4200 BC (7450–6150 BP, 6500–5300 b.p.)

The last ice patch disappeared from northern Quebec. Only mountain glaciers and polar latitude glaciers persisted for the rest of the Holocene. Around 6500–6000 BP eustatic sea level reached its present height and has only fluctuated somewhat

(+1 m to +3 m) since then. The late Atlantic is marked by the 3-m *Early Peron* shore terrace in the tropic and the *Nizza* terrace in the Mediterranean. Successive uplifted Littorina strand-lines rim the Baltic. Climatic optimum warmth now reached its farthest northerly influence. In northern Canada the boreal (spruce) forest-tundra boundary almost reached the Arctic shore. In eastern North America and Europe mixed oak-elm forests reached climax states. From the Swedish flora, in 1910, Andersson determined that the mean temperature was 2.5°C above present. This value is about 20% of the total glacial-interglacial range for this latitude. In the tropics the East African rains were much heavier than today and the Nile floods were on average three times above today's. The Early Kingdom pharaonic culture was established in Egypt and the Mohenjodaro civilization developed along the Indus valley.

Early Subboreal (SB-1, VIII-a), 4200–2300 BC (6150–4250 BP, 5300–4000 b.p.)

In most latitudes this chronozone marks the beginning of the fall in global temperatures from the peak of the climatic optimum or hysithermal. Its beginning is marked all across Eurasia, from Britain to Siberia by the *Ulmus* (elm) decline, with a dramatic change in the climax mixed forests. The progressive cooling is well shown by the gradual reduction in tree-ring widths; in the Bristlecone Pine series (White Mountains, California), they reached an initial low point about 2800 BC (matched by a high level of ^{14}C flux, evidence of low solar activity). This corresponds to the *Bahama Emergence* (−3 m) on tropical coasts. In the upper Midwest (Elk-Lake core, Minnesota), the same interval is marked by a 300-year period of reduced varve thickness and drop in diatom (*Melosira*) frequency; it was followed by an abrupt rise in varve thickness to a peak around 2000 BC (late Subboreal). Mountain glaciers showed repeated advances, corresponding to sharp ^{14}C flux peaks.

Late Subboreal (SB-2, VIII-b), 2300–900 BC (4250–2850 BP, 3800–2900 b.p.)

What is sometimes called a *mid-Subboreal* mild phase generated warmer climates for about five centuries in Scandinavia and elsewhere. Then from 1400 to 1000 BC the Bristlecone Pine and most pollen series show a major climatic deterioration, marked by a high ^{14}C flux; it was paralleled by the *Crane Key Emergence* in the tropical seas, followed shortly after by the *Pelham Bay Emergence* about 800 BC, both being certainly glacioeustatic in view of important neoglacial readvances in the interval 1350–450 BC (Denton and Karlén, 1973). In northern Canada the forest-tundra border retreated. Culturally this epoch was marked in Europe by the Bronze Age.

Early Subatlantic (SA-1, IX-a), 900 BC–AD 175 (2850–1775 BP, 2775–1700 b.p.)

In northern Europe this chronozone was characterized by cool to mild and moist conditions, accompanied by the general spread of beech forests. The Mediterranean saw the rise of the Etruscans, and of the Roman Empire. Sea level dropped from a high around +2 m in the classical Greek period, to a low around −1 m around the first century AD, followed by a progressive rise (late and post-Roman transgressions). Culturally and economically this sequence had a significant impact: Roman port facilities all

around the Mediterranean are today at least partly submerged and commonly built over by Medieval structures. The coastal salt-pan economy was ruined by the rising sea level and salt mines were developed inland (Spain, Austria, Germany, Dead Sea), coastal farmers, particularly in France and the North Sea area, were forced inland or started to build dikes.

Mid-Subatlantic (SA-2, IX-aa), AD 175–750 (1775–1200 BP, 1700–1150 b.p.)

Corresponding to the late Roman/Byzantine cultural phase, the coasts of northern Europe were extensively inundated of the Mediterranean region was plagued by droughts and famines, which in the Middle East favored the rise of Islam.

Late Subatlantic (SA-3, IX-b), AD 750–present (1300–1 BP, 1300–1 b.p.)

In broad terms the youngest chronozone is divided into three: the *Medieval Warming* or *Little Climatic Optimum* (q.r.) from AD 950 until about 1250, the *Little Ice Age* (with two maxima, divided by a slight fifteenth-century warming (about 1390–1540), and finally the late nineteenth-twentieth-century warming that brings us up till today. The ^{14}C flux according to the California dendrochronological series remained fairly stable until about AD 1250, after which a precipitous decline is registered with minima about AD 1350 and 1700, after which, with a minor low around 1810–1820, it rose to modern levels; after 1950 it becomes grossly contaminated by nuclear bomb pollution, followed by anthropogenic burning of fossil fuels and deforestation.

Sea level rose during the Medieval Warming to about 0.5 m above present, as may be seen from raised coral platforms and shell banks in the tropics (Rottne Submergence in Australia), and from anomalously high Viking beaches in Sweden. It fell to at least −0.5 m during the Little Ice Age, after which its fluctuating upward trace is recorded by the Amsterdam tide gauge installed in 1682. With decadal fluctuations of around 5 cm, it rose to a peak around 1770 and then sank again to a low about 1820, since when it has been mostly rising (after correction for subsidence; Fairbridge, 1961, p. 104). The Little Ice Age regression has been called the *Paria Emergence*, from South American data.

As mentioned in the entry on the Little Ice Age, the most striking development of that interval was the enormous expansion of sea ice in the Greenland Sea, which around 1600 reached a peak of 26 weeks of ice cover on the north coast of Iceland each winter. The effect on the albedo was appreciable and long-term average temperatures in western Europe fell by 1–2°C. Around 1600 the north magnetic pole came to lie northeast of Iceland, and the low solar activity phases like the Wolf, Spörer and Maunder minima led to excessive fluxes of cosmic radiation (shown by high ^{14}C and ^{10}Be values). According to the Roberts and Olson (1973) model, the geomagnetic screen is weakened during those solar activity minima and the amplified cosmic ray flux created frequent high-altitude cirrus cloud cover, thus generating a primary stratospheric albedo.

Summary

Why study the historical geological record of the last 10 000 years? To the climatologist, trained on the straightforward hard data of meteorological instrument observations, who would

perhaps ask that question, it might be useful to summarize some key points:

1. The current Quaternary Ice Age (of the last 2 million years or so) alternates rather abruptly between two modes: glacial and interglacial. We are living in one of the latter, the Holocene Epoch of geology, its lower boundary being $10\,750 \pm 300$ BP.
2. During these 10 millennia, sea level has achieved its present level glacioeustatically, that is, mainly by the melting of midlatitude continental ice sheets. The last traces of the latter were gone by 6000 BP.
3. Following the Milankovitch theory of orbital control of terrestrial insolation, the last peak of effective radiation was about 9000 BP, around which time the sea-surface and low-latitude land temperatures (in areas not dominated by the residual ice sheets) a *climatic optimum* or *hypothermal* climatic regime developed. Gradual deterioration (global Cooling and desiccation) began after about 5000 BP.
4. The last 5000 years have been marked by remarkably non-linear climate, glacial, and sea-level record. Fluctuations are mostly in saw-toothed patterns of various scales, progressive cooling with abrupt deviations to a generally warm mode; the upper thermal bound is episodically interrupted by cold spikes which vary in length from 1 year to a century or more. The amplitude of the fluctuations has oscillated or even increased, not decreased toward the present (Figure C21).
5. The nature of the cooling episodes is highly varied and subject to considerable research effort. The longer ones clearly relate to solar radiation (cf. ^{14}C data). More or less random spikes of 1–2 years correlate with specific incidents of volcanism, particular explosions leading to a gross loading of the *dust veil index* (DVI).
6. More or less regular quasi-biennial or quasi-triennial climate cycles relate to equatorial stratospheric winds and the Walker circulation; the El Niño and Southern Oscillation are well-recognized expressions of these systems, which are controversial in origin, variously explained as stochastic (endogenous thermodynamics), or as produced by solar–lunar forcing (exogenous: radiational and tidal).
7. Time-series of millennial and multimillennial length furnished by ice cores, varves, and tree rings provide a sound statistical basis for exploring the nature of longer climate cycles. The solar (11- and 22-year) and lunar nodal (18.6-year) periods are now well established, but are associated with *noise* generated by complex feedback processes, ranging from magnetic and electrical fields to oceanic circulation and lagging sea-surface temperatures.
8. Long solar–lunar periodicities of the order of 45, 79, 93, 180, 360, 558, 1112, 1850 and more years have been studied only in a very preliminary way. Clearly, there is a strong astronomical pulse recognizable in all the long time-series but far more investigation is still needed.
9. The role of CO_2 in climate change, both long-term and anthropogenic, is complex and remains to be resolved.
10. Finally, a word about the future. We cannot yet confidently make predictions, even for a few months. For the curious and the dedicated, however, the historical record offers a vast reservoir of information that is simply waiting to be tapped. The stratigraphic and other natural repositories have only just begun to be explored.

Rhodes W. Fairbridge

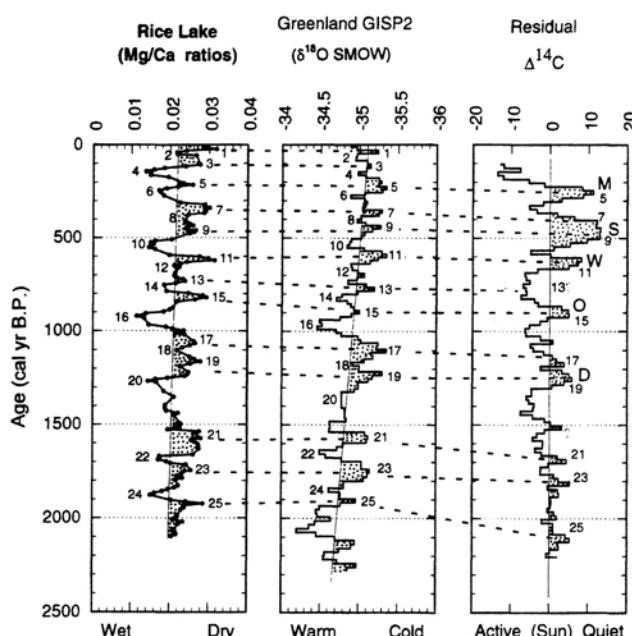

Figure C21 Three examples of cyclic climatic signals spanning the last 2000 years. Left: a lake core in western Canada (Rice Lake). Middle: an ice from Greenland (GISP-2). Right: bidecadal residual C-14 from tree rings (Stuiver & Reimer, 1993). With slight modifications for simplicity (R.W.F.). Abbreviations: **M** (Maunder Minimum: AD 1645–1715); **S** (Spoerer minimum: AD 1420–1530); **W** (Wolf minimum: AD 1280–1340); **O** (Oort minimum: AD 1010–1050); **D** (Dark Age minimum: AD 660–740). Each represents low levels of solar activity (sunspots), corresponding high O-18 levels in ice cores, i.e. cold episodes, and cool-dry climates in western Canada.

CLIMATE VARIATION: INSTRUMENTAL DATA

Climate is often regarded as the average state of weather. Although this definition is not incorrect, it can lead (incorrectly) to an interpretation of climate as a constant, unchanging phenomenon. On the contrary, the climate system is characterized by constant change. Climatic variations result in the modification of the average, variability, and frequency of extreme values of temperature, precipitation, pressure and other meteorological variables. Such changes, which may happen in all temporal and spatial scales beyond those of individual weather events, are defined by the Intergovernmental Panel on Climate Change (IPCC) as *climatic variability*. Statistically significant changes in the mean state of climate or its expected variability, which persist for an extended period (decades or longer), are referred to as *climatic change* (IPCC, 2001).

Causes of climatic variability and change include: natural internal processes such as dynamic and thermodynamic interactions between the atmosphere and oceans; volcanic eruptions; external forcing, like e.g. changes of intrinsic solar radiation, or persistent anthropogenic changes in the composition of the atmosphere, or changes in land use. Such factors may affect climate directly by altering the local atmospheric heat budget and/or indirectly by modifying the planetary wind and ocean current circulation by which local climate to a large extent is regulated. The effects of climatic variation are numerous and often affect socioeconomic and natural systems.

Geographically, climatic changes are so extensive that they deserve to be treated as an integrated planetary phenomenon. Indeed, a hemispheric or global viewpoint is required in order to evaluate cause-and-effect relationships. On a worldwide basis, variations of the mean state of surface climate can be described with good confidence from instrumental observations since the mid-nineteenth century, although analyses of surface variability and extremes, and the climate of the upper atmosphere, are more limited.

Climatic analyses require homogeneous data, and this is particularly important for analyses of climate change and variability. A homogeneous climatic time series is defined as one where variations are caused only by variations in climate. Unfortunately, most long-term climatological time series have been affected by a number of non-climatic factors that make these data unrepresentative of the actual climate variation occurring over time. These factors include changes in: instruments, observing practices, station locations, formulae used to calculate derived quantities, and station environment, among others. Some changes cause sharp discontinuities while other changes, particularly a change in the environment around the station, can cause gradual biases in the data. All of these inhomogeneities can bias a time series and lead to misinterpretations. Climate researchers must carefully remove all these non-climatic biases or inhomogeneities or at least determine the possible error they may cause before drawing conclusions from data (Aguilar et al., 2004).

The available instrumental record broadly covers the period of anthropogenically induced increases in CO₂ and other greenhouse gas concentrations and the contemporary global warming. Global warming has led to a more extreme climate, an increase in global precipitation and atmospheric water vapor content, an increase in ocean heat content and a sea level rise, a

reduction in mountain glacier extent and snow coverage, a shortening of the seasons of lake and river ice and a systematic decrease in spring and summer ice in the Arctic regions, among other effects.

Observational data contribute to the knowledge of paleoclimatic variations, helping to calibrate the relationship between proxy data (tree rings, ice cores, boreholes, sediments, corals, historical documents) and meteorological variables. Finally, instrumental data are needed too for the climate models which can predict the future evolution of climate and assess the goodness-of-fit of their results. The next section will focus on the analysis of temperature and precipitation evolution.

Climatic variations in the instrumental record

Global temperatures can be reconstructed through instrumental data back to the mid-nineteenth century, as shown in Figure C22 (IPCC, 2001). The average global land surface temperature has increased by 0.6°C since 1860 (Folland et al., 2001). Warming is found to be significant for the aforementioned period annually and in all seasons. Independently compiled, homogenized and analyzed datasets (Peterson and Vose, 1997; Hansen et al., 1999; Jones et al., 2001) agree and show two remarkable warming phases, 1910–1945 and 1976 to present, as the most distinctive features of the observational record. Sea surface temperatures have experienced similar pulses, although variations and trends have been slightly less pronounced. As for land data, different compilations of oceanic data agree on similar results (Quayle et al., 1999; Jones et al., 2001; Reynolds et al., 2002).

The late nineteenth century was the coldest period in the instrumental record. This is true not only for the global estimates extending back to 1860, but also when some longer temperature records for central England, Fennoscandia and central Europe, going back to the eighteenth century, are considered (Jones, 2001). The early twentieth century showed positive anomalies, mainly concentrated in the North Atlantic and nearby regions, with a contrary cooling tendency prevailing in parts of North America, southern Eurasia, and the southern hemisphere.

The ongoing warming is qualitatively consistent with some climate model projections driven by anthropogenic forcing (Mitchell et al., 2001), and has a nearly global extent, although some oceanic areas and Antarctica (excluding the Antarctic Peninsula) are still cooling. Global temperatures – including land and ocean – have been rising at about 0.165°C per decade between 1977 and 2001. Trends are larger over land than over oceans and, as a consequence, the northern hemisphere warming (0.223°C per decade) is much larger than that observed for the southern hemisphere (0.106°C per decade). The highest regional year-round warming rates are found over Europe and the Arctic, and – on a seasonal basis – winter and spring over North America and Eurasia show the largest increase (Jones and Moberg, 2003), probably in relation to the enhanced westerly flow caused by the maintained positive phase of the North Atlantic/Arctic Oscillation.

The described warming trend places the 1990s decade as the warmest in the observational record, and probably the warmest (at least in the northern hemisphere) of the last 1800 years as derived from multi-proxy data reconstructions (Mann and Jones, 2003). This happened even with the short-lived cooling influence of the 1991 eruption of the Pinatubo volcano (Parker et al., 1996). The year 1998, affected by the strong 1997/1998 El Niño, is, up to this writing (late 2003),

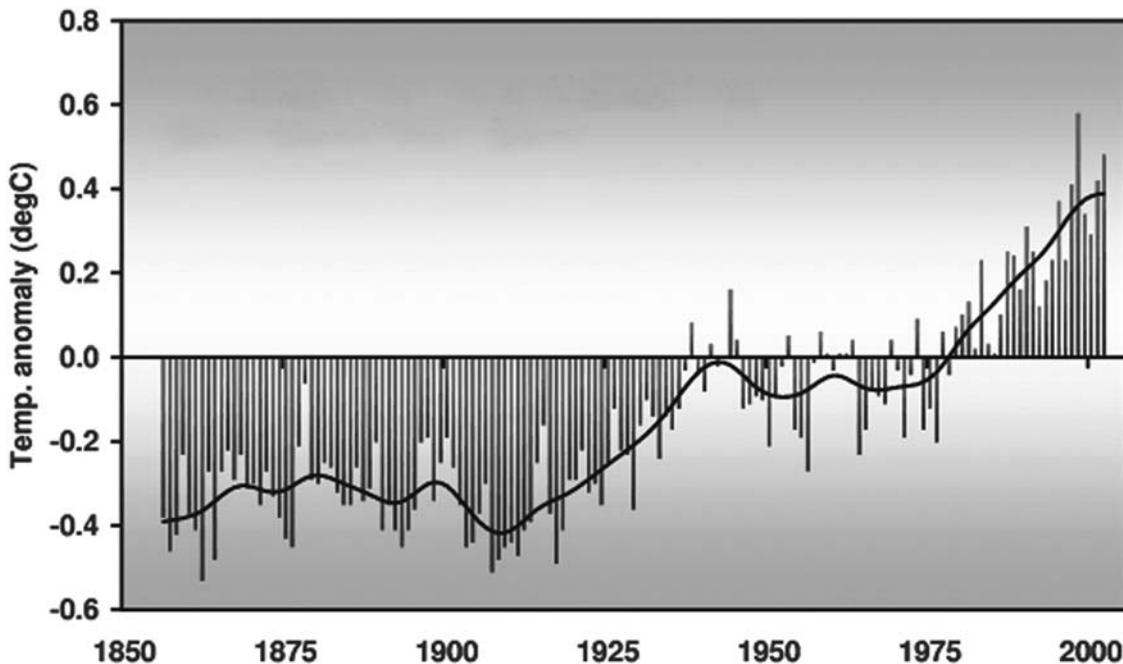

Figure C22 Global air temperature (HadCRUT2v), 2002 anomaly +0.48°C (second-warmest on record). Reproduced by kind permission of the Climatic Research Unit, University of East Anglia, Norwich, U.K., to whom any queries should be directed (cru@uea.ac.uk). Copyright: Climatic Research Unit.

the warmest year on record, with an anomaly of roughly +0.5°C with respect to the 1961–1990 normal period. The El Niño – Southern Oscillation (ENSO) phenomenon has shown an increased occurrence, persistence, and intensity of its warm phase (El Niño) in recent decades, which enhances the global positive anomalies of the climate. The intensities of the 1982/1983 and the 1997/1998 El Niños were unprecedented in the observational record. The most recent event led to much warmer global temperatures, in spite of the offsetting effect of the 1982 El Chichón volcanic eruption, in part because of a warmer starting point in 1998. The initial decade of the twenty first century, continues with the warming trend started in the mid-1970s. The year 2002 was the second warmest in the instrumental record and the warmest for latitudes poleward of 30°N (Waple and Lawrimore 2003). If the current trend is maintained a future El Niño event will easily lead to a new record high global temperature.

During the second part of the twentieth century the DTR (diurnal temperature range or difference between daytime and nighttime temperature) has been reduced on a global basis by 0.1°C per decade. This happened, in agreement with an observed increase in global cloudiness, because three-quarters of the observed warming over land areas has been attributed to nighttime (usually daily minimum) temperatures and the remaining to daily maxima (Easterling et al., 1997). Nevertheless, several regions do not follow the planetary pattern – among them, eastern North America, middle Canada, portions of Europe, parts of Southern Africa, India, Nepal, Japan, New Zealand, the western tropical Pacific Islands, Australia, Antarctica and Spain display no change or slight increase of the day–night temperature differences (Karl et al., 1994; Horton, 1995; Brunet et al., 2001).

In the 50 years of available radiosonde data, upper air tropospheric temperatures (roughly the lowest 10–15 km of the

atmosphere) have experienced warming, in agreement with the surface observations, and also in agreement (for thermodynamic reasons) with the observed stratospheric cooling. The extra-tropical northern hemispheric troposphere concentrated its warming since the mid-late 1970s, while the austral mid to high-latitude troposphere started warming earlier in the record (Lanzante et al., 2003).

Increases in global temperatures are very likely to be reflected in changes in precipitation and atmospheric moisture via induced changes in the atmospheric circulation; a more active hydrological cycle; increases in the water vapor holding capacity throughout the atmosphere (Folland et al., 2001); and changes in the leading modes of interannual variability, e.g. ENSO, the Arctic Oscillation, and the North Atlantic Oscillation. Different rain-gauge datasets (Peterson and Vose, 1997; Rudolf et al., 1999; New et al., 2001) and satellite measurements, available since the late 1970s (Xie and Arkin, 1996; Huffman et al., 1997; Doherty et al., 1999; Huffman et al., 2000) can be combined to produce global and regional estimates of changes in precipitation (New et al., 2001). The later authors reported a global precipitation increase of 0.89 mm per decade, mainly the result of an increase of 40 mm from 1901 to the mid-1950s, when global precipitation peaked. This trend was not globally uniform. Between the late nineteenth century and the mid-twentieth, precipitation in the tropics and along the east coasts of the continents decreased by roughly 10%. Some investigators believe this decrease occurred quite abruptly around the turn of the century. Pressure data point to a slight, gradual weakening of the general circulation during the same period, in the northern hemisphere at least, and to a contraction of the zonal westerly wind belt in temperate latitudes toward higher latitudes (analogous to its annual contraction from winter to summer).

The magnitude of the century-long trend (9 mm) appears to be modest when compared to the interdecadal and interannual variability of precipitation. Spatially, larger increases came from the mid and high northern hemisphere latitudes (40–80°N). The year 1998 was the wettest year on record for latitudes exceeding 55°N (Folland et al., 2001). Precipitation in the Northern Subtropics did not show significant trends and was rather characterized by strong subdecadal variability. Finally, areas between 20°N and 40°N experienced a decrease of 6.3 mm per decade, most of it after the mid-1950s. The southern hemisphere tropics and midlatitude precipitation remained steady in the last 100 years, when the austral subtropics showed an increase of 3.6 mm per decade (New et al., 2001).

Besides the analysis of the mean state of climate and its variability, it is crucial to understand the evolution of the extreme values. Extremes tend to have a notorious impact on natural and socioeconomic systems. Relatively modest changes in the mean state of climate can lead to large changes in the frequency of extremes (Katz, 1999). Despite a good degree of spatial differences, and the lack of data for significant parts of the southern hemisphere, it is safe to say that a significant proportion of the global land area was increasingly affected by significant changes in climatic extremes during the second half of the twentieth century. During this period, days with cold temperatures have diminished and, consequently, the number of frost days has been reduced; the frequency of extremely cold days has been reduced, and the number of days with extremely warm temperatures seems to be increasing (a result of increased variances), as well as the number of days with heavy rainfall and the total amount of precipitation coming from wet spells (Frich et al., 2002).

Causes of climatic variation

The immediate meteorological causes of observed local climatic variation involve changes of the general atmospheric circulation pattern. In this respect many regional anomalies in the world-average variation can be understood. However, it is unlikely that the net world-average variations of temperature and precipitation are traceable to circulation changes alone; rather, they are caused by more fundamental environmental changes that can affect both climate and circulation. Ultimate causes of climatic variation have not yet been identified with certainty, but they are thought to be several. The most likely among these fall into the first four of the following five main categories.

1. *Air-sea interaction.* Since the atmosphere is closely coupled with the oceans both dynamically and thermally, the relatively much slower rates of mixing and circulation of the oceans, together with their enormous heat-storage capacity, open up many possibilities for the oceans to stimulate long-term variations of climate. Air-sea interactions are, in fact, a probable source of much of the observed variability of climate on all scales of time from years to centuries to millennia. In general, the longer the time scale of variation involved, the deeper are the oceanic depths involved in the interaction. On interannual time scales a principal mode of air-sea interaction is the ENSO phenomenon, centered in the tropical Pacific Ocean, but whose effects on climate are of worldwide extent (Rasmusson and Wallace, 1983). The strong El Niño event of 1982–1983 was accompanied by extremely wet weather in parts of the Americas and, concurrently, by severe drought in parts of Australasia.

2. *Explosive volcanic activity.* In modern times, explosive volcanic eruptions like that of Krakatoa in 1883, violent enough to inject large amounts of fine ash and sulfurous gases into the midstratosphere (altitudes of 20–30 km), have occurred with an average frequency of several per century. Some such eruptions have produced veils of ash and sulfuric acid aerosols that have spread worldwide in the stratosphere with lifetimes of 2 or more years. Because such volcanic veils scatter and absorb significant amounts of incoming solar radiation while having little effect on outgoing terrestrial radiation, they are capable of cooling worldwide climate by a fraction of a degree Celsius over a period of years (Newell and Deepak, 1982). The warming of world climate during the 1920s and 1930s can be attributed in part to the absence of such volcanic eruptions at that time, and the cooling that culminated in the 1960s can be partly attributed to a renewal of eruptive activity that included the major eruption of Agung in 1963. The more recent major eruption of El Chichón in Mexico in the spring of 1982 was expected to result in a climatic cooling in the years following. This cooling, however, is not readily apparent in the temperature record (see Figure C22), a fact that may be explained by the contrary warming effect of the great El Niño event of 1982–1983 in which enormous quantities of heat were transferred to the atmosphere from the warmer-than-normal tropical Pacific Ocean.
3. *Changes of atmospheric composition.* Changes of the gaseous composition of the atmosphere may alter the terrestrial heat balance if the gases are selective absorbers of radiation such as water vapor, carbon dioxide (CO₂), and ozone (O₃). Carbon dioxide has accumulated in the atmosphere in the past two centuries, partly owing to vast deforestation for agriculture and fuel wood and sharply increasing use of fossil fuels. The net accumulation of CO₂ in the atmosphere has by now increased from preindustrial levels of about 280 parts per million by volume to levels of about 360 ppmv (as of 2003). Other trace gases of industrial origin, such as nitrous oxide and chlorofluorocarbons as well as methane, are also increasing. These other gases behave in the manner of CO₂, to cause a “greenhouse” warming of climate. Their combined effect on climate is thought to have been a warming since 1880 of about 0.6°C (0.9°F); further warming at an accelerating pace will likely continue into the future as long as these gases continue to accumulate as expected (IPCC, 2001). Changes of “greenhouse” gas concentrations to date are a likely cause of much of the net warming of climate observed in the past century (see Figure C22).
4. *Solar radiation changes.* Solar radiation may vary in several respects, including the total solar constant, its ultraviolet component, and solar wind intensity. Long-term changes of total solar constant, if real, would clearly affect climate but evidence of such changes other than those of a fraction of 1% in the past few years of direct satellite measurement is as yet unverified (Foukal, 2002). Possibly larger changes may have occurred over the 80–90-year Gleissberg cycle of solar activity or in the course of longer historical solar disturbances such as the Maunder Minimum, a time of unusual solar inactivity between about 1650 and 1710. Changes of ultraviolet emissions are known to parallel the 11-year solar cycle, and may influence surface climate indirectly via their effect on upper atmospheric conditions such as ozone amount. Changes of solar wind intensity may likewise be capable of altering the behavior of atmospheric circulation through subtle

- effects on upper-atmospheric temperatures and winds and the “ducting” of Rossby-wave energy in the troposphere (Geophysics Study Committee, 1982). To date, however, such presumed solar–climate relationships lack adequate observational and theoretical confirmation.
5. *Impacts by large asteroids.* Though extremely rare (with time scales of hundreds of thousands to hundreds of millions of years), impacts by comets or asteroids have the potential to cause massive climatic changes via mechanisms similar to volcanic eruptions. Such impacts are thought to have resulted in a few mass extinctions in the geological record. No such event has ever been recorded in the instrumental record.

CLIMATE VULNERABILITY

To be vulnerable is to be “susceptible of receiving wounds or physical injury” (*Oxford English Dictionary*). The phrase “climate vulnerability” raises an immediate question: what is it that might be injured? Climate might be affected by the actions of or changes in natural and social systems. Or natural and social systems experience impacts from changes in climate. Or the phrase may mean both of these interpretations.

Vulnerability of climate

Climate – the assemblage of atmospheric properties and behaviors, in the mean and with their inherent and characteristic variances – responds to the state, and changes of state, of the hydrosphere, cryosphere, and biosphere. Conversely, and reflexively, those

natural systems are conditioned by the state of global climate. As a simple example, the poles are frozen due to the fundamentals of global climate; the extent of Arctic pack ice responds to episodes of hemispheric warming or cooling; hemispheric climate responds to the state of the surface of the Arctic basin. Most models of climate consider coupled natural systems, describing sensitivities and feedbacks, but not “vulnerabilities” in the colloquial sense of the term. In the case of social systems, where there are direct and indirect effects from alterations in atmospheric composition and of biosphere, it does make sense to think of climate being vulnerable. Much research in global climate change at the turn of the millennium focuses on these processes, patterns, and implications (see, for example, the IPCC Working Group I assessment; Houghton et al., 2001).

Strongest among the evidence that human activity can effect change in the climate system is the relationship of global temperature and “greenhouse gases”. Concentrations of carbon dioxide, methane, nitrous oxides, and other gases have increased exponentially during the industrial era, i.e. since the beginning of the eighteenth century. Theory about atmospheric chemistry and radiative forcing of climate suggests that those changes should produce atmospheric warming, and models suggest a good fit of observed global surface temperatures with the records of gas concentrations. Models of likely socio-economic futures, greenhouse gas emissions and resultant concentrations in the atmosphere, suggest that, even with marked reductions in greenhouse gas production, the atmosphere and thus the climate system will remain perturbed for a century or more (cf. the summary by Albritton and Meira Filho, 2001, and the more detailed reviews within Houghton et al., 2001).

The notion that human alteration of surface features at a regional scale might change the climate is not new (Brooks, 1970, originally published 1926). In late nineteenth-century America, for example, a popular idea was that “rain follows the plow”; conversion of the vast central grasslands to agriculture would increase precipitation of the area, to the benefit of agriculture (Lawson, 1974). In the latter half of the twentieth century, speculations about the effects of other major landscape alterations were made, often without aid of global circulation models: redirection of northward-flowing rivers in Asia; Amazon deforestation; expansion of desertification in Africa. Models are less successful at – or perhaps have paid less attention to – reproducing the effects of land surface changes on climate, perhaps because of the complexity of the climate system and because most attention has focused on atmospheric chemistry and the impacts of climate change on natural and human systems.

Vulnerability to climate

The dictionary definition cited at the head of this article implies a straightforward model of impacts: the characteristics of an entity (or system) are changed in a deleterious sense due to the action of outside forces. Application of the concept in natural sciences such as ecology led to notions of degree of vulnerability. Entities might, for example, not exhibit any evidence of impact until external actions (uniquely or cumulatively) surpassed some threshold beyond which the entity could not continue as it had been. If the entity returned to its original condition after an impact had occurred, it was said to be resilient. In some usage, resilience is the ability to withstand change, to persist. Thus, vulnerability and resilience are related concepts, although they are not – as might be the usage in

colloquial speech – antonyms. More on this point follows in the paragraphs below.

The concept of vulnerability has broadened considerably in the work on climate change and adaptations that emerged toward the end of the twentieth century. In the Third Assessment Report of the IPCC, Working Group II specifically addressed climate impacts, adaptations and vulnerability (McCarthy et al., 2001). The 19 sectoral and regional chapters of this volume provide the most comprehensive review of the topic. The overview chapter (Schneider and Sarukhan, 2001), the final chapter that synthesizes vulnerability to climate change and reasons for concern (Smith et al., 2001), and the extensive bibliographies therein, are of particular relevance to this item. The other chapters and their bibliographies should not be ignored. Much of what follows in this article is drawn from this volume.

Definitions

The IPCC’s working definition of climate vulnerability is “the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes” (McCarthy et al., 2001, p. 995). That is, vulnerability is “the extent to which a natural or social system is susceptible to sustaining damage from climate change” (Schneider and Sarukhan, 2001, p. 89). These definitions are notably more expansive than the classical concept stated at the outset of this article, incorporating fundamental ideas from earlier definitions in the hazards and development (poverty) literatures. Whereas the simple definition contained the idea of exposure to a hazard and resultant impacts, the IPCC’s definition integrates hazard, exposure, consequences, and adaptive capacity. In this sense it is akin to the concept of “risk” in the risk-assessment literature.

What makes an entity or system vulnerable to climatic impact? Vulnerability is a function of both the climate change or variability to which the system is exposed, and the nature of the system in terms of its sensitivity to climatic control and its adaptive capacity. Exposure is a function of the climatic event or change – its character or direction, its magnitude, its rate of onset, and its duration.

Sensitivity is “the degree to which a system will respond to a given change in climate, including beneficial and harmful effects” (Schneider and Sarukhan, 2001, p. 89). Effects may be direct, such as crop yield responses to changes in temperature or precipitation; or they may be indirect, via intermediary actions, such as coastal flooding by sea-level rise due to climate change. Thus impacts might be sequential, nested, or hierarchical, and vulnerability may be immediate or delayed, and muted to lesser or greater degree (cf. Kates, 1986).

Adaptive capacity is “the ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences” (McCarthy et al., 2001, p. 982). Adaptations in social systems may be made by adjustments in practices (institutions), structures (infrastructure), or processes (mitigation). Many natural systems, or elements thereof, may be limited in adaptive capacity because of human alteration of the globe. For example, ecosystems will not adjust en masse, but as the suite of species responses; some species may be unable to adjust fast enough, or to find suitable habitat because of fragmentation and destruction of ecosystems that has already occurred.

"[A] highly vulnerable system would be a system that is very sensitive to modest changes in climate, where the sensitivity includes the potential for substantial harmful effects, and for which the ability to adapt is severely constrained" (Schneider and Sarukhan, 2001, p. 89). Many researchers believe "[s]ocial systems generally are more resilient than natural systems because of the potential for deliberate adaptation" (Schneider and Sarukhan, 2001, p. 91). Natural systems cannot access coping mechanisms or strategies beyond the autochthonous, whereas social systems can draw upon or invent purposeful adaptations. Synergies among purposeful adaptations may also yield additional coping capacity.

A system with low vulnerability is often termed resilient. Resilience results from adaptive measures, whether in reaction to actual impact or in anticipation of potential impact. The Resilience Alliance (2002) goes so far as to state that "[t]he antonym of resilience is often denoted vulnerability". Adger (2003) calls resilience "the ability to persist and the ability to adapt". A system's resilience is determined by: the magnitude of perturbations it can absorb without changing its overall function; the system's capacity for self-organization; and the system's capacity for learning and adapting (Adger, 2003, p. 2). It is not correct, however, to think of persistence merely as stasis, such that the system returns to the pre-existing state that prevailed prior to impact. Such was the classic systems view of the steady state. Rather, the current concept of resilience recognizes change as an essential characteristic, as the system adapts to new conditions, incorporating learning and adjustment.

Implications for assessment

The first generation of climate change assessments looked like an impacts model with (simple) feedback (see Kates, 1986, for impact and interaction models). Adaptation comes at the end of a causal chain between climate and impact, and is not an integral part of the system from the start. Such assessments, as in the Second Assessment Report of the IPCC (Watson et al., 1995), addressed the following questions: How will climate change? What first-order impacts will there be on natural systems? What will be the effects of those impacts on humans? How might human society adapt? How might the adaptations alter the impacts? (Leary, 2003).

Climate change assessments of the second generation, as the Third Assessment Report typifies, resemble adaptation models with synergies between natural and social systems (cf. Kates, 1986). Vulnerability and adaptation occupy a central place in these assessments. The latest generation of assessments builds upon the earlier in four major ways. First, vulnerability and adaptation to climate change are assessed: who is vulnerable, the source and nature of that vulnerability, and capacities for coping with current variability and extremes (and implications for the future). Second, stakeholders are integrated with scientists in the process: who needs to know what, and how can they be involved in production of credible and relevant information? Third, risk-assessment approaches are utilized. Fourth, scenarios of future environmental and socioeconomic conditions are integrated with climate change scenarios (Leary, 2003).

The emphasis on vulnerability permeates the Third Assessment Report to a much greater degree than previous reports. This focus can be seen by the attention paid to: adaptation to climate change; links between climate change, sustainable development, and equity; vulnerability to changes in climate variability; discontinuous responses to climate

change; emphasis on ranges of outcomes using subjective probabilities; and other matters.

Vulnerability of agriculture

Agriculture is arguably the social system in which vulnerability might be easiest to define and earliest to be noted. Food production is of course important to existence and well-being, as well as livelihood and social structure. Agriculture exists at the interface of environmental and social systems, and forms a nexus with water resources not easily subdivided into components.

Agricultural production is, at base, affected by water and nutrient availability, and temperature. Human factors – genetic manipulation whether by traditional breeding or biotechnological engineering; artificial inputs; and so on – modify but do not replace these natural controls. Global temperature increases may allow cultivation in subpolar areas now inhospitable because of short growing seasons, if soil conditions in those areas are amenable. In other areas, however – tropics, drylands – heat or drought stress might increase, limiting productivity. Many of the least-developed countries are in the tropics, and have limited adaptive capacities for socioeconomic and political reasons. At moderate global warming (*c.* 1°C), subpolar and midlatitudes may benefit; above *c.* 2.5°C that productivity is modeled to diminish, and tropical decreases are more severe. Thus, it is possible to imagine an increased disparity in food production between developed and developing nations under scenarios of climate change for the twenty-first century (Schneider and Sarukhan, 2003; Smith et al., 2003).

Water resources are controlled to a great extent by precipitation and (temperature-related) evaporation. Climate scenarios suggest precipitation increases in high-latitude and some equatorial regions, which would decrease water stress, but decreases in many midlatitude, subtropical, and semiarid areas, which would increase water stress. These changes imply respective positive and negative impacts for rain-fed and irrigation agricultural productivity in these regions. With growing population, urbanization, and improving living standards, there will be increased demand for urban and municipal uses of water, thus increasing competition for scarce water at the same time that agricultural demand increases. There is marked disagreement in the literature about prospects for meeting food demands. Some see growing populations as necessitating great expansion of agricultural lands into marginal areas (and climate change may also require shifts in agricultural areas or make expansion infeasible). Others say intensification of activity, with technological improvements, will meet demand, satisfy growth in nutritional standards, and save land for ecosystem functions (but socioeconomic factors mitigating against agricultural lifestyles, growing urbanization, and competition for water may confound these prospects) (Smith et al., 2003).

Differential vulnerability

Some physical systems, by virtue of their size, location, or sensitivity to climate factors, are highly vulnerable to anticipated direction and magnitude of climate change. Among those so identified are: tropical glaciers, such as in the Andes Mountains of South America; and small lakes of interior drainage, such as in central Asia. Similarly, unique and threatened biological systems include: montane systems, where high-elevation species have nowhere higher to go; prairie wetlands and remnant native grasslands of North America, because of extensive

alteration and fragmentation; coldwater fish habitat of northern latitudes; ecosystems overlying permafrost in circum-Arctic locations; ice-edge ecosystems of polar latitudes; neotropical cloud forests; coral reefs and mangroves ecosystems of tropical latitudes; and ecotones between existing ecosystems (Schneider and Sarukhan, 2001).

On a global scale some human systems are thought to be particularly vulnerable by virtue of poverty, isolation, size, or dependence on ecosystems of limited extent or diversity. Among those so identified are: small island states, especially atoll nations in the Pacific and Indian Oceans; and indigenous communities with low levels of technological development. Within developed nations the hazards literature indicates differential vulnerability between and within populations. Socially or economically disadvantaged groups – the young, the elderly, females, ethnic minorities, the poor, among other social strata – are found to be particularly at risk; that is, vulnerable. Further, vulnerability may be situational; that is, it may vary depending on the kind, character, or combination of hazards (Bohle et al., 1994; Buckle et al., 2000).

In general, “[s]ystems that are exposed to multiple pressures (synergistic effects) usually are more vulnerable to climate changes than systems that are not” (Schneider and Sarukhan, 2001, p. 91). Such pressures include current and projected demands on resources, unsustainable management, pollution, and fragmentation of natural areas.

Has climate made a difference?

There is a large literature of long standing about impacts of and adaptations to extreme weather events. Extreme weather, however, does not constitute climate, although scenarios of future climate suggest that present-day extremes may be more frequent (Albritton and Meira Filho, 2001). Assessments of vulnerability to recent climate variability are hampered by the limited range of climatic experience in the recent record. While responses to events such as those anticipated in the future – drought, say – may provide some indication of impacts and adaptations, we just have not had the magnitude and duration of changes that scenarios suggest might be in our future. However, the IPCC reviews suggested that many ecosystem changes that had been reported during the twentieth century were either associated with observed climatic changes, or in the directions expected as responses to directions of climate change (Schneider and Sarukhan, 2001; Smith et al., 2001).

Because climate change, system vulnerability, and adaptation involve changes in natural and social systems over time, as well as the synergistic and cumulative effects of multiple events, there is a need to aggregate over time and to accumulate over occurrences. There is a smaller body of literature that looks to the historical record for evidence of impacts of climate on society (Wigley et al., 1981; Rotberg and Rabb, 1981; Jones et al., 2001). Some papers in these sources concern themselves with the search for appropriate methodologies. How are we to know that social changes over historical time are the results of impacts by and adjustments to climate, apart from social, political, and economic developments? One methodological example is Parry's (1978) multi-stage “postdictive” approach: climate sensitivity of agricultural production was modeled by relating crop yields to various climatic factors; a history of climate was produced from the paleobotanical and other records, independent of the record of human activity; impacts on agriculture were postdicted by applying the sensitivity analysis to the climate record;

the reconstructed record of impacts was interpreted in terms of implications for human settlement at the margins of sustainable agriculture; and the historical record of settlement was then compared to the postdicted impacts for verification.

The historical and archeological evidence suggests that societies, especially those at the margins of sustainability, have exhibited vulnerabilities to climate variability, yet have also learned to adapt in some ways (among the adaptations selected by pre-modern societies has been abandonment of inhospitable areas; cf. Burton et al., 1983, for the categorization of choices available to society as adaptations to hazards). More research using historical materials, with refined methods based on the above postdiction model, should combine with the more quantitatively detailed modeling of interactions from recent records, to produce a fuller understanding of vulnerabilities.

CLIMATE ZONES

A climate zone is a world area or region distinguished from a neighbor by a major physical climatic characteristic that is of global scale. Climate zones are bounded by limits that parallel lines of latitude to form “belts” that mostly extend around the globe; the word “zone” is actually derived from the Greek word meaning belt, and it is from classical Greek times that the concept of zones is derived.

History of the zonal concept

Beginning in the sixth century BC, Greek scholars identified zones of the Earth based upon astronomical knowledge and position of the overhead sun as related to changes in length of daylight. These illumination zones were called *klimata* (a word that is the origin of our word climate) and differentiated (1) a torrid zone (where the noonday sun was never far from overhead), (2) a temperate zone, and (3) a frigid polar zone. It was in the fourth century BC that Aristotle identified the parallels that gave the identified zones actual boundaries. He named the Tropics of Cancer ($23\frac{1}{2}^{\circ}$ N), and Capricorn ($23\frac{1}{2}^{\circ}$ S), and the Arctic ($66\frac{1}{2}^{\circ}$ N) and Antarctic ($66\frac{1}{2}^{\circ}$ S) Circles as lines separating the zones. Aristotle, however, also adhered to the viewpoint that the Torrid Zone was too hot and the Polar Zone too frigid for human habitation.

Claudius Ptolemy (AD 100–170) made use of earlier Greek ideas and, as part of his extensive geographic writings, divided the Earth into seven zones based upon length of daylight.

Ptolemy’s zones of the Earth remained in effect for many centuries. Although their utility was questioned by such Arabic scholars as Ibn Hauqal in the ninth century, and modified by Idrisi in the twelfth century, they still formed the basis of the highly popular work of the Dutch Renaissance geographer Bernhardus Varenius (1622–1650). He presented a system of geography in which a table of zones relating day length at the summer solstice to latitude was titled *climata*, climates to the English-speaking world.

Temperature zones

Edmond Halley was perhaps the first to suggest that heat rather than day-length hours provided a more meaningful way

to identify climatic zones; in his 1686 work he came to the conclusion that winds were caused by solar heating. Halley’s suggestion to identify zones by temperature could not be undertaken until actual temperature data for world areas became available. This did not occur until 1817 when Alexander von Humboldt used observed data to draw the first isothermal map. By 1848 H.W. Dove was able to prepare maps of average temperatures of individual months. A new zonality was born; that based upon heat rather than day length.

The first modern map of climatic zones was devised by A. Supan in 1879. The division was based upon mean annual temperature and the temperature of the warmest month (Table C13a). Shortly after, in 1884, Wladimir Köppen (whose climatic classification remains widely used today) gave a detailed listing of temperature zones based upon the number of months above or below selected thresholds. As Table C13b shows, this introduces the concept of duration of a given climatic factor, quite different from the use of mean annual values.

Numerous other authors suggested alternate temperature zones of the Earth, but all show a similarity in that hot,

Table C13 Temperature zones: selected examples

(a) Supan’s 1879 thermal zones

	Annual mean temperature		Mean temperature of warmest month	
	°C	°F	°C	°F
Hot	Over 20	Over 68	Over 10	Over 50
Temperate	Under 20	Under 68	Over 10	Over 50
Cold	Under 20	Under 68	Under 10	Under 50

(b) Köppen’s 1884 thermal zones

	Duration in months of critical temperatures		
	Above 20°C (68°F)	10–20°C (50–68°F)	Below 10°C (below 50°F)
Tropical	12	—	—
Subtropical	4–11	1–8	—
Temperate	Less than 4	4–12	Less than 4
Cold	—	1–4	8–11
Polar	—	—	12

(c) Herbertson’s 1905 thermal zones and economic belts

Economic belt	Temperature limits (°C)
No Crops	<10
Very few crops	0–10
Temperate Climate Crops	10–20
Tropical Crops	<20

(d) Miller’s 1951 thermal zones

	Number of months 43°F or warmer
Warm temperate	12
Cool temperate	6–12
Cold	3–5
Arctic	1–2
Polar	0

temperate and cold zones are identified. In some instances, as in the case of Herbertson's 1905 thermal regions, the identified zones were used to delineate other variables, including economic zones as shown in Table C13c. As part of the development of climatic zones, many new concepts were introduced. For example, in 1951 A.A. Miller used the idea of month-degree and accumulated temperature. This identifies the length of the growing season for broadleaf trees and extends the relationships between zonal climates and vegetation growth. The idea of relating climatic zones to vegetation zones was not new; Köppen, for example, had relied heavily upon the work of plant geographers in devising his climatic zones and classification.

While the identification of thermal zonation initially relied upon the new availability of data, it soon became apparent that the zone designated "temperate" contained some of the most extreme conditions on Earth, and was in fact highly "intemperate" in terms of temperatures. This led to a number of variations in the way in which zonal maps were prepared. For example, Figure C23, taken from a 1901 publication by Dryer, is based upon the following rationale: "The tropics and polar circles do not divide the face of the earth into zones of temperature but of insolation. The true temperature zones are bounded by isotherms. By drawing isotherms of 70° and 30° for January and July upon one map, we obtain a set of zones which are not shifting but fixed, and reveal in striking manner the temperature conditions of the globe." Despite attempts to provide a more meaningful delineation of the temperate zone, it is now more appropriate to call the area between the tropics and the Arctic

and Antarctic circles the mid- or middle-latitude climatic zone when dealing with anything other than the Greek concept of temperate.

Circulation zones

The availability of actual climatic data, that permitted the construction of thermometric zones in the late nineteenth century, also permitted identification of other zonal concepts, especially those based upon atmospheric circulation. In 1735 Hadley had postulated a simple atmospheric circulation and later the general motion he identified became known as a Hadley Cell. The Hadley Cell was incorporated into models of global circulation by, for example, Maury (1855), Ferrell (1856 and 1889), and Thompson (1857). While in such representations the use of the term "zone" is limited, the term "belt" is used and, essentially, each of the other circulation characteristics is a zone; thus, the Horse Latitude calms, the Trade Wind zone, and the Westerly Wind zone are zonal concepts based upon wind patterns.

The simplicity of the zonal concept of circulation, while attractive, had great limitations. During the twentieth century, meteorologists and climatologists have striven for more realism in model construction and the broad zones identified by the three-cell zonal concept proved unacceptable. New ideas, in-depth studies and, in some cases, actual hostility to the zonal concept demoted its representation to highly general introductory books about the atmosphere. In meteorology today, the term "zonal" invariably implies a zonal circulation type in

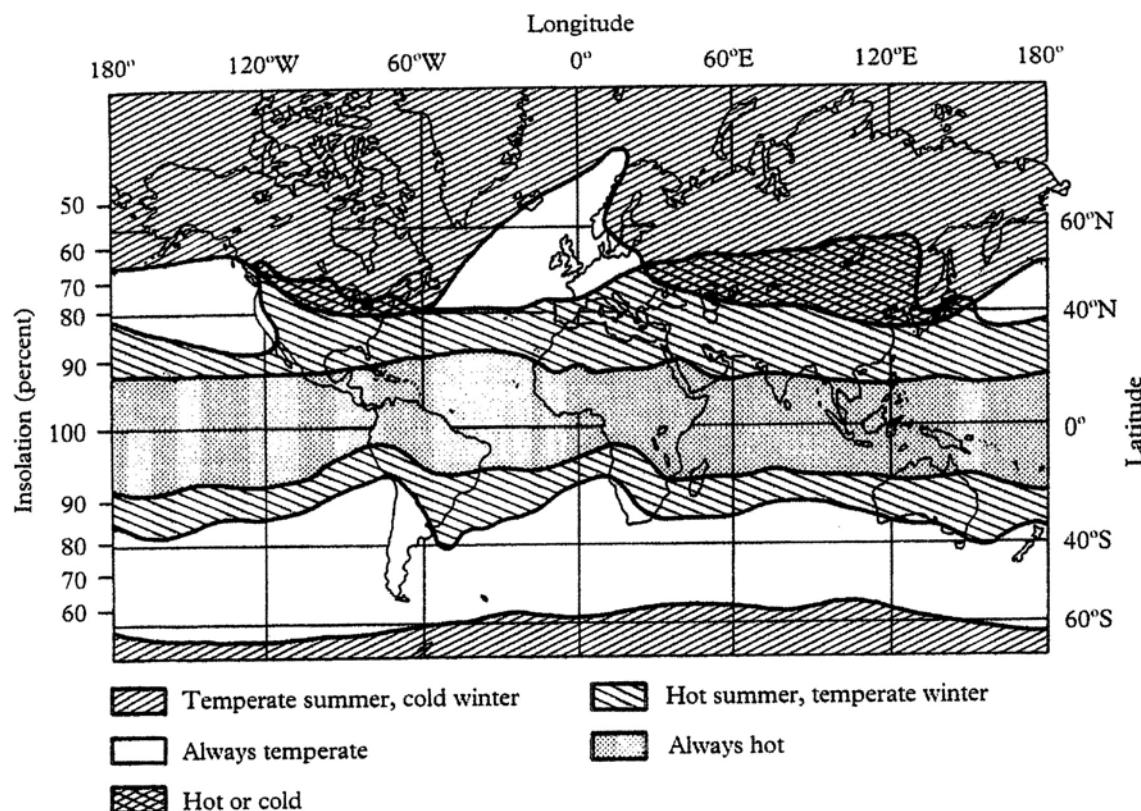

Figure C23 Redrawn from a 1901 map by Dryer, the map represents an earlier attempt to provide meaningful limits to temperature zones using winter and summer isotherms.

Table C14 de Candolle's (1874) plant zones

Symbol	Physiologic plant group	Temperature limit (°F)
*	Megistotherms	Over 86
A	Megatherms	68–86
B ^a	Xerophiles	
C	Mesotherms	59–68
D	Microtherms	32–59
E	Hekistotherms	Below 32

* Found only in high temperatures of geologic past or in hot springs.

^a Plants adapted to dry conditions.

which flows, especially those in the upper air westerlies, were essentially in an east–west pattern. Nonzonal flow, or meridional, indicates a more significant north–south component.

Related zonal systems

The nineteenth-century development of climatology was strongly influenced by botanists. Köppen's boundaries for climatic zones were initially based upon vegetation zones identified by de Candolle, who had published his work in 1874. As Table C14 indicates, his physiologic plant groups are based upon the same temperature limits as those used by Köppen in his classification of climates.

The concept of vegetation zonation was, at least in part, emphasized in the monumental work of the German botanist Schimper, published in 1898. Schimper noted that certain plant orders and families are limited by high or low temperature limits, as found in the tropics and polar realms. As a result, the plant cover of the Earth is arranged in more or less parallel zones of different systematic characteristics. He further noted, however, that temperature zones cannot be equated to floristic and ecological characteristics, and these are identified regionally rather than zonally.

A similar zonal relationship exists in relation to the identification of soils. The Russian soil scientist Dokuchaev is credited, in a 1898 publication, with identifying soil zones of the northern hemisphere. These are (a) the Boreal or Tundra zone, (b) the Taiga or Forest Zone, (c) the Black-Earth Zone, (d) the Dry Subtropical Zone and (e) the Red-earth or Laterite Zone. This organization of hemispheric soil types resulted in a much-used soil classification based upon climatic processes. It is only in recent years, with the production of the soil taxonomy system, that it has been replaced.

CLIMATOLOGY

Climatology is the science of climate, which in turn is the composite of all weather events. It should be noted at the outset that climate fluctuates on all time scales: monthly, yearly, decadally, centennially, and millennially. Thus, climate is a statistical collective. It has often been described in terms of mean values of particular climatic elements, but it encompasses a wide range of values, including occasional extremes. Although atmospheric conditions and variations follow well-known physical laws, the day-to-day variations and those for longer intervals can, for many purposes, be treated like quasirandom variables. They can be represented by statistical distributions applicable to stochastic universes.

Climatology has multiple aims. In its historical development first efforts were directed toward a geographical inventory of climates, which led to attempts at climate classification. As a physical science, developments led to theories of the causation of global as well as regional and local climates. Because of the influence of climate on human activities, much effort has been devoted to applying the knowledge gained about climate for human welfare, including attempts to develop schemes for prediction of future climatic conditions. A major motivation for this has been to assess the potential for anthropogenic alterations of climate.

Areas of study

The wide range of the physical controls and the impacts of climate have led to the development of specialized realms of study in climatology. The major realms are considered here.

Physical climatology

The incorporation of physical principles in explaining climate is examined under the title of physical climatology, a subject area that deals with mass and energy exchanges at or close to the surface of the Earth. The focus is on energy and water balances and budgets and upon boundary layer studies.

Energy budget studies concern the availability of solar energy at a location, the transformations of that energy and its transfer through the atmosphere. Because the amount of solar radiation striking the Earth varies over both time and space, and because the Earth's surface is made up of materials of varying properties, then the physical climatology of any particular surface is unique. The patterns and exchanges are complicated by the special physical attributes of water and the exchanges of energy when water changes from one form to another.

These energy and water exchanges are dealt with in terms of boundary layer studies. Differing surfaces of the Earth result in highly variable boundary characteristics and hence different

types of energy/mass exchanges and eventually different climates. Studies concern natural surfaces as well as those modified through human activities. The most modified type of surface occurs in cities; as a result, urban climatology has become an important component of the study of physical climatology.

Dynamic and synoptic climatology

The term dynamic climatology was first used by Tor Bergeron in 1929 when he outlined how the concept of airmasses and fronts might be adapted to develop a comprehensive dynamic climatology. Since then, the approach used by dynamic climatologists has evolved into studies based upon atmospheric motion characteristics and the thermodynamic processes that produce them. Of major importance today is modeling the dynamics of selected systems.

Most modeling is used to study the reaction of climate to forced changes in various physical parameters; these are the sensitivity studies. The most popular of these at the present time are models related to the increase of greenhouse gases and the attendant change of global temperatures. At the same time important studies in dynamic climatology concern such topics as sea surface temperatures and the role of mountains in determining dynamics of the atmosphere.

Synoptic climatology may be defined as the study of climate from the viewpoint of atmospheric circulation with emphasis upon the connections between circulation patterns and climatic differences. The term was first used in the 1940s when military services became concerned with the climatology of weather types and surface/air transport. While dynamic climatology is often global in scope, synoptic largely concerns hemispheric and local climatologies. In relation to the former, hemispheric teleconnections, such as ENSO events, have been investigated; at the local scale many types of studies, such as the relationships between circulation features and severe weather, are of interest.

Regional climatology

As its name implies, this concerns the climate of regions. The size of the region can vary but is often synonymous with identified geographic regions; the Great Plains, the Paris Basin, Southern China, providing apt examples. The manner in which the climatology is presented can range from highly descriptive, such as in the classic climatography of the early twentieth century, or can be based purely upon derived climatic indices, such as in component analysis.

To compare the climate of regions and to derive analog climates, regional climatologies often use a climatic classification. Earliest classifications were often based upon a single variable, such as temperature or daylight hours. By the nineteenth century increased data availability permitted a more quantitative approach and the use of more than one variable. Vegetation distribution strongly influenced the development of climatic regions in classification systems, with that devised by Wladimir Köppen proving the most durable. The Köppen approach provides a unique shorthand system based upon numeric rules for classifying climates, and the system remains in wide use today. Many other climatic classification systems have been devised, most for special-purpose uses such as human comfort or crop distribution. Such systems, based upon observed data, are termed

empirical classifications. Regionalization by cause is dealt with in genetic classification systems, often based upon airmass climatology. To demonstrate the nature of classification, Table C15 shows a 13-category scheme with some prototypes shown as examples.

Applied climatology

Applications of climatology have risen rapidly in recent years. Aside from agriculture, the construction industry makes major use of climatic data. Temperature, wind, and humidity statistics permit rational design of buildings and dwellings, as well as their heating and cooling plants. Siting of factories and power plants requires analysis of wind and vertical atmospheric stability parameters to judge the pollution potential of effluents. In the case of nuclear power plants, climatological analysis is mandated. For major structures such as bridges, broadcast towers, and electric transmission towers, data on extreme wind speeds, low-level icing, and exposure to lightning are needed, although they must often be inferred from locations other than the building site. The transference of climatic information from an observing site to a "silent" area has become an important part of applied climatology. A combination of the use of interpolated data from a climatological observing network and site-specific interpretations from a series of synoptic weather maps is an applicable technique.

Climatological information also enters into the housing problems of farm animals. Climate affects the design of clothing and its seasonal distribution and marketing. The effect of climatic conditions has had a major impact on transportation and packaging and storage of goods, especially foodstuffs.

A major role for combined climatic-synoptic analysis is in the planning of dam construction, both for water-resource conservation and for flood control. Floods still remain a major hazard and their probability of occurrence has entered into calculations for setting insurance premium rates. Estimates of extreme values of precipitation leading to floods, as well as for extreme values of other damaging weather events, has resulted in the use of a variety of statistical techniques. These are attempts to simulate the frequency distribution of past rare events and high values. There are a number of such extreme value distributions. Such extreme value probability analyses can be used for predictions without date. They can inform a planner or construction engineer as to what extreme value of a particular climatic element can be expected at least once in 50 or 100 years. Such information, while not indicating when this value will occur, will at least permit the necessary safety factors to be included in the design. Aside from wind speeds, maximum precipitation amounts, and extreme temperatures, this type of analysis is also particularly useful for estimates of high snow loads, especially on places of public assembly.

The causation of climate

In regard to the causation of climate, the principal factor is the astronomical position of the Earth with respect to the sun, which is the source of all energy. The distance between the Earth and the sun governs the total energy received from the sun. There are seasonal differences in that distance and

* Precipitation not measurable because of drifting snow.

long-term changes in the eccentricity of the Earth's orbit. Of equal importance is the inclination of the Earth's axis with respect to the ecliptic. This too is subject to cyclical changes; it is presently 23.5° . This inclination causes the seasons, with the poles during the respective summer seasons of the hemispheres inclined toward the sun and away from the sun in winter. Thus the polar regions change from complete daylight to complete darkness during the course of the yearly revolution of the Earth around the sun. The axis tilt therefore governs the amount of solar radiation as the seasons change. This fact was well known in ancient times and is reflected in the Greek word *klima*, which means slope.

The cyclical elements in the astronomical position of the Earth – namely, the *precession* of the spring point (~21 000 years), the tilt of the Earth's axis (~41 000 years), and the change of the *eccentricity* of the Earth's path (~97 000 years) – lead to different radiation conditions at various latitudes. Determination of these elements has led to formulation of a model of climatic changes by Milutin Milankovitch. The model permits calculation of radiation energy received as a time series prior to the present. For the past half million years, during which continents and oceans have been in their present position, the radiation curve coincides with the glaciations and interglacials derived from geologic and isotopic evidence. Whether or not the model is adequate to explain the initiation of glaciation remains controversial. Evidence for changes in solar energy output exists, but quantitative measurements have been available only in recent years from satellites; prior to that, sunspot observations were used as corollaries to climatic fluctuations since the eighteenth century, but statistical tests indicate that less than 10% of the variance can be accounted for, both for temperature and precipitation.

If the sun ceased radiating energy to the Earth, it has been estimated that atmospheric motions would cease in about 2 weeks. Satellite determinations of the energy received from the sun at the boundary of the atmosphere gives values between ~ 1360 and $\sim 1378 \text{ W m}^{-2}$. Partitioned over a spherical surface this fixes the solar energy amount entering the atmosphere at $\sim 340\text{--}344 \text{ W m}^{-2}$.

As solar radiation enters the atmosphere and penetrates to the surface, a complex system of interaction comes into play. Atmospheric gases, clouds, and conditions of the surface partition the solar radiative flux. At the surface reflectivity plays a key role; it varies from the high reflectivity of areas covered with snow and ice to intermediate reflectivity (albedo) of desert and vegetated land areas, and low albedos of water surfaces. The high albedo of the frozen surfaces contributes to their maintenance. The low albedo of water leads to large heat absorption in the oceans, which become the principal secondary energy source of the atmosphere. These effects have led to the designation of climate as an atmospheric–oceanic–cryospheric system. In the energy exchanges the interception of outgoing long-wave radiation from the Earth by atmospheric gases, principally water vapor and carbon dioxide, keeps the Earth at temperatures favorable for biota. The depletion of the solar radiation in various spectral regions is shown in Figure C24, which also shows the wavelengths in which radiation escapes from the Earth to space. The atmospheric gases are nearly opaque to the long-wave infrared radiation from the Earth, except for a few “windows” in the spectral absorption of water vapor and carbon dioxide. It is these few escaping infrared fluxes that

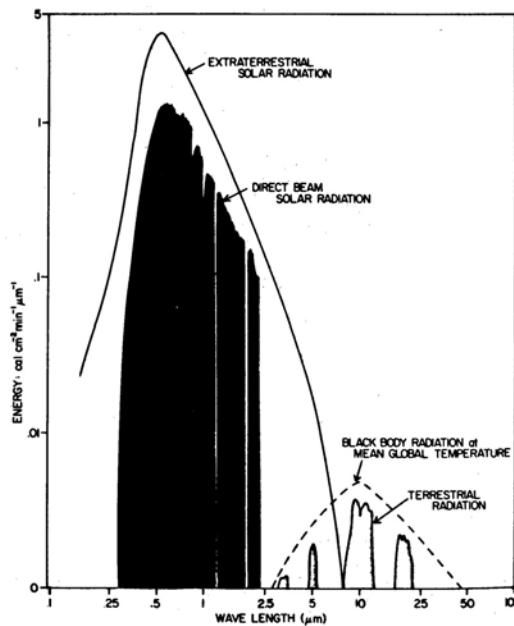

Figure C24 Spectral distribution of solar beam (left); shaded area showing flux reaching the Earth's surface, depletion caused by absorbing gases; terrestrial radiation to space (right); shaded areas showing the only fluxes escaping through the so-called atmospheric “windows” in the water vapor and carbon dioxide absorption bands.

make satellite scanning of atmospheric and surface temperatures possible.

A relative partitioning of the various radiative fluxes of Earth and atmosphere (in percent of the incoming solar radiation) are shown in Figure C25. This diagram also shows clearly that more radiative energy transactions take place in the atmosphere than at the surface. Radiation is the primary element in the climate-forming processes. For this reason energy balance models have gained a dominant place in modern climatology. They sum up all energy fluxes of an area or locality and incorporate incoming solar radiation, albedo, longwave outgoing radiation, as well as the terrestrial processes of evaporation, which adds latent heat to the atmosphere, and sensible heat transfers. On a hemispheric scale, some of these components are shown in Figure C26 for hemispheric summer and winter as zonal averages. High-energy incomes are indicated for summer, but no solar energy is received in polar regions during winter. The net energy income is positive for the whole summer hemisphere but negative for most extratropical regions in winter. The latent heat values stay at the high level throughout, and hence play a role as a major heat source in the atmosphere.

Global circulation

Satellite observations have given better insight into the net radiation balance of various parts of the globe. Not only the areas of high latitudes show net heat loss, but large areas at high altitude in Asia as well. Some of the North African and Arabian desert regions show radiation balance deficits. The tropics and major ocean areas are the areas of positive

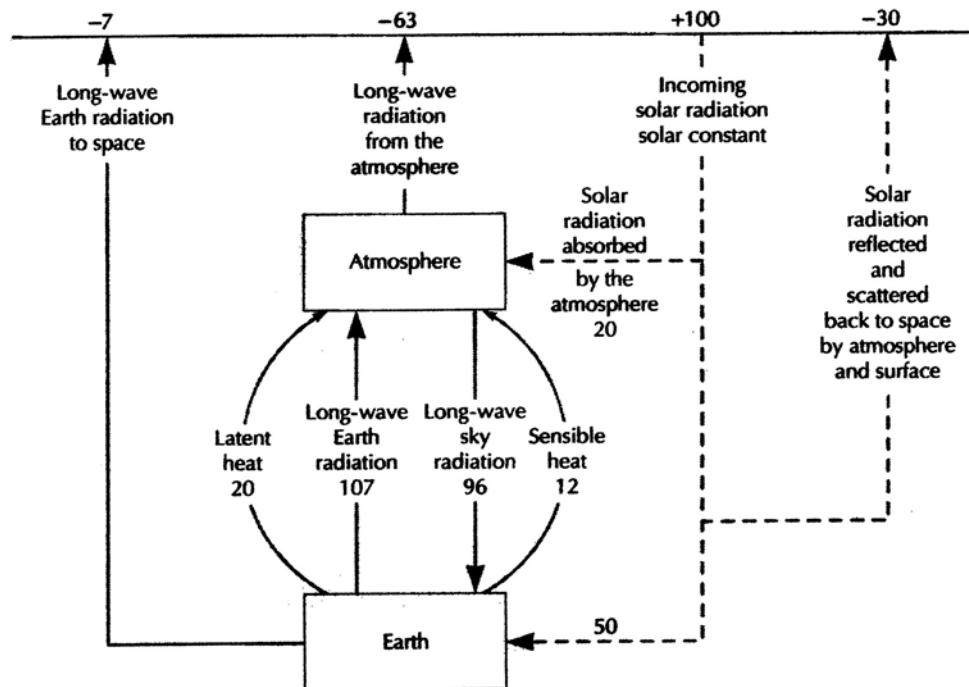

Figure C25 Radiative fluxes in and through the Earth's atmosphere, in percent of the solar radiation received at the boundary of the atmosphere.

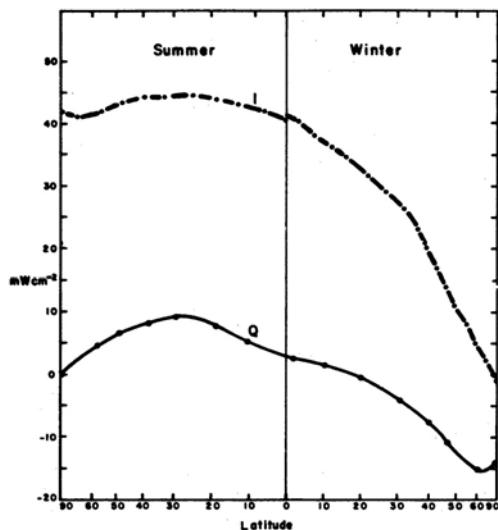

Figure C26 Zonal distribution of incoming solar radiation flux I and net radiation (gain or loss) Q , for hemispheric summer and winter.

radiation balance. These differences are the driving force of the global circulation in atmosphere and oceans. Changing air pressures transport heat from the areas of surplus to those of deficit and try to smooth out the differences. Radiation imbalance is the principal ingredient of climate. About half of the heat transfer from low to high latitudes takes place in

the ocean. Oceanic currents are very important in climatogenesis of many areas of the globe. In the atmosphere the heat contrasts lead to a multicellular circulation, which follows the principles of fluid dynamics as modified by the rotation of the Earth. This leads to the existence of three meridional circulation cells in each hemisphere, causing different dynamic processes. Between the equator and the tropics, or subtropics, is a direct circulation of air from warmer to cooler areas, the so-called Hadley cell, with low pressure near the equator and high pressure in the subtropics. The resulting wind system produces the trade winds over the oceans, northeasterly in the northern hemisphere, southeasterly in the southern hemisphere. Near the equator in an area of weak winds – the doldrums – the trade winds create a convergence zone with cloud bands and convective precipitation. This intertropical convergence zone migrates somewhat, following the seasonal changes.

In the polar regions another direct circulation cell exists. The cold air forming there breaks out in irregular bursts toward the warmer areas. This is delineated by a notable discontinuity, the polar front, toward the lower latitudes. Its thermodynamic interaction with the warmer air forming in the lower latitudes, usually generously endowed with latent heat from evaporated water vapor, causes migrating pressure systems in an indirect cell, the Ferrel cell. These bring various midlatitude areas under rapidly changing weather regimes with alternations of warm and cold airmasses and wet and dry spells. A schematic representation of the atmospheric circulation is shown in Figure C27, which shows another globally important circulation that is zonal in character. This is imposed over the other circulations in the tropical area and is rather weak and slow, but it has important temporal effects on

both atmospheric and oceanic currents. This so-called Walker circulation affects the intertropical convergence zone and the monsoonal circulations.

Although the general atmospheric and oceanic circulations affect the broad-scale distributions of climate over the globe, the fine fabric is created by the differentiation of the surface. Mountains and their orientation with respect to the general circulation are extremely influential. Windward and leeward sides have radically different climates. Proximity to water surfaces, both oceanic and inland, are other factors causing

climatic differences. The presence or absence of vegetation and the land use by humans also cause notable climatic differences. Anthropogenic effluents are the cause of changes in atmospheric composition. Their local influences have been explored for decades, but there are potential global repercussions if the concentration of heat-absorbing gases becomes sufficiently large to cause measurable alterations of climate. An uncertain, sporadic factor in the climatic conditions of individual years, and perhaps longer intervals, are volcanic eruptions. These can cause changes in the radiation balance of the globe. Even a limited analysis of climatogenic factors shows so many feedback mechanisms that one can begin to visualize the diversified mosaic of climate in space and time. In Figure C28 some of the various elements of climatogenesis and some of the mutual interactions are reflected. The many agents having effects on climate make their exact representation in climatic models difficult, and hence these remain currently inadequate to represent the rich fabric of terrestrial climates.

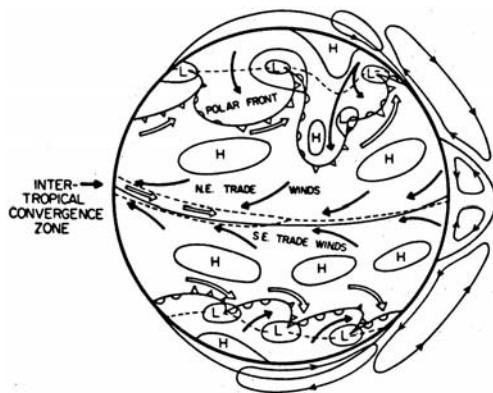

Figure C27 Schematic representation of the global atmospheric circulation showing principal frontal systems, high (H) and low (L) pressure areas and wind systems.

Global patterns

Systematic instrumental observations of the surface climate of the Earth have been carried on in most land areas for over a century, and in some localities for two centuries. In central England over 300 years of temperature observations are available. Time series of the various climatic elements such as pressure, temperature, precipitation, sunshine, cloudiness and wind show notable fluctuations from year to year. Even longer intervals can show marked differences, yet the mean value of

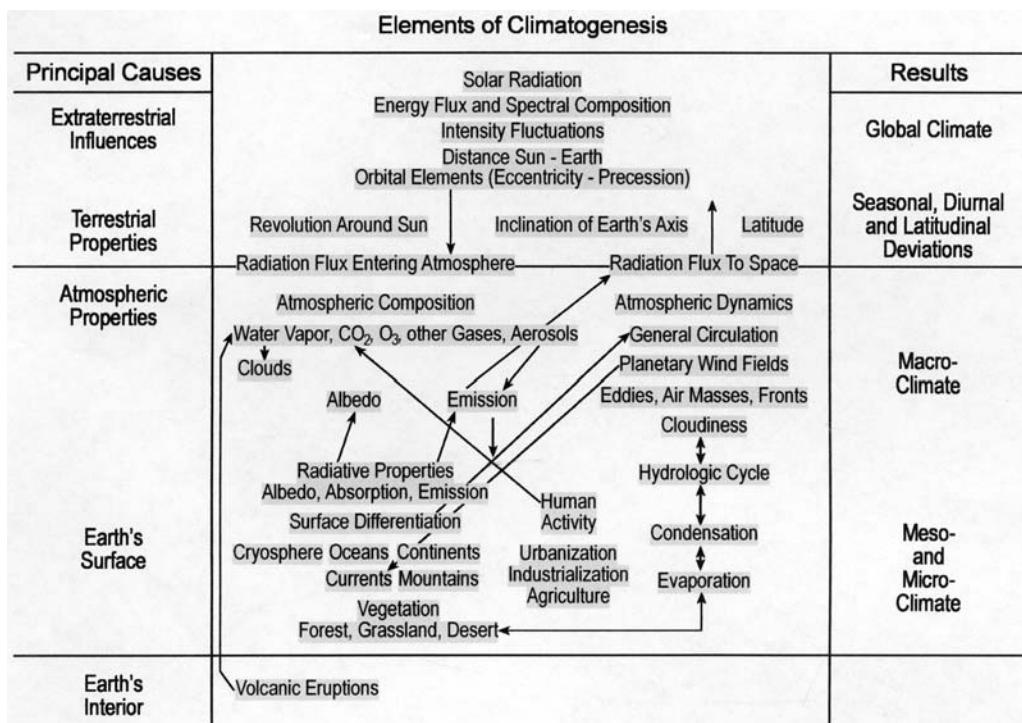

Figure C28 Principal climatogenetic factors on Earth with limited indications of feedback mechanisms.

the various elements has traditionally been used to represent climate. Although this has shortcomings, it permits broad-scale comparisons of geographical areas. The mean pressure distribution, as shown for January and July in Figures C29 and C30, shows the great differences in flow patterns between the two hemispheres caused by the greatly different distribution of land and sea. In January the two great centers of action are the Aleutian and the Icelandic low-pressure systems. These reflect the steady stream of cyclonic disturbances along the polar front bringing alternating outbreaks of cold air and intrusions of warmer subtropical air, generally accompanied by precipitation, to the middle northern latitudes. The sunny subtropical high-pressure cells have migrated southward, as has the intertropical convergence zone, which is now south of the equator. The strong Asiatic anticyclone not only coincides

with intense Siberian cold, but its outflow controls the dry winter monsoon in south and east Asia. In the southern hemisphere there are some vestiges of heat lows over the continents and some inflow of moist air from the oceans, but in the great southern west wind belt the winds keep roaring at the 40th parallel.

In July the southern hemisphere has not changed much. The subtropical high-pressure cells have strengthened. Sunshine, and often drought, prevails over the continents. The Intertropical Convergence Zone has migrated north of the equator. The oceans show higher pressure than the continents and oceanic air influx to the land brings monsoonal rains. The classical monsoonal region is east Asia, especially the Indian subcontinent. Even though there are large year-to-year fluctuations, the broad general patterns have persisted.

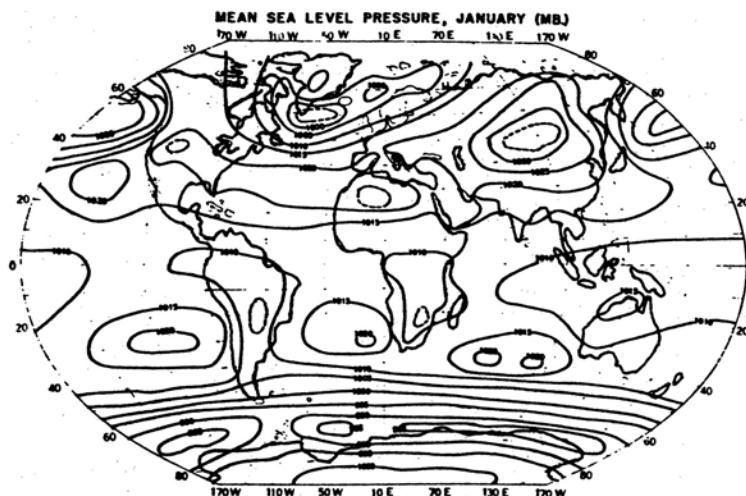

Figure C29 Mean sea-level pressure in January, in millibars (hPa).

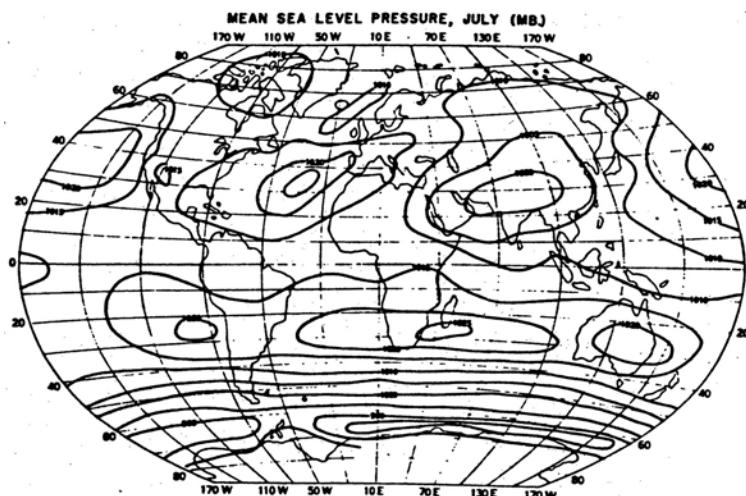

Figure C30 Mean sea-level pressure in July, in millibars (hPa).

These circulation patterns are reflected in the meridional distribution of cloudiness and precipitation (Figure C31). The cloudiness shows three major belts: the subpolar latitudes in both hemispheres and the equatorial zone. The precipitation amounts are somewhat less strikingly distributed latitudinally, but the zone just north of the equator shows a notable maximum. Equally pronounced are the subtropical dry zones where the prevalent high-pressure belts produced by the subsiding branches of the Hadley circulation create vast desert areas, especially in the northern hemisphere. But within the prevailing structure of global circulation, numerous other controls shape and modify the climate. Among these are proximity to the ocean or other large water bodies, and position with respect to mountain ranges. Oceanic currents exercise profound influences. Thus the North Atlantic Gulf stream and its continuation, the North Atlantic Drift, create a notable asymmetry of latitudinal temperature distribution between the east coast of North America and west coast of Europe. Whereas along the American Atlantic shore there is a wide annual

range of temperature and cold winters prevail, the west coast of Europe far north into Scandinavia has a much smaller range and mild winters.

Other coastal climates are equally influenced by oceanic currents. Some of them are tied to the broad flow patterns of the general circulation, others are produced by more local air flow. The interaction of wind and currents can produce coastal upwelling of cold water from greater depths at sea. Such coastal cold waters not only have ecological benefits for fisheries, but also modify the regional climate. Cold currents cause coastal dry zones or even deserts and often cause high fog frequency. In perspective, the arid and semiarid areas of the globe cover 48×10^6 km² or 31% of the land areas, excluding the Antarctic continent. If one adds the 12% glaciated areas, which usually have very little precipitation, to the 31% of arid areas, the great contrasts of climate on a planet covered 70% by ocean becomes clear.

Precipitation is the climatic element that shows the greatest variability in time and space. Some extremes, together with those of other elements, are shown in Table C16. As the time

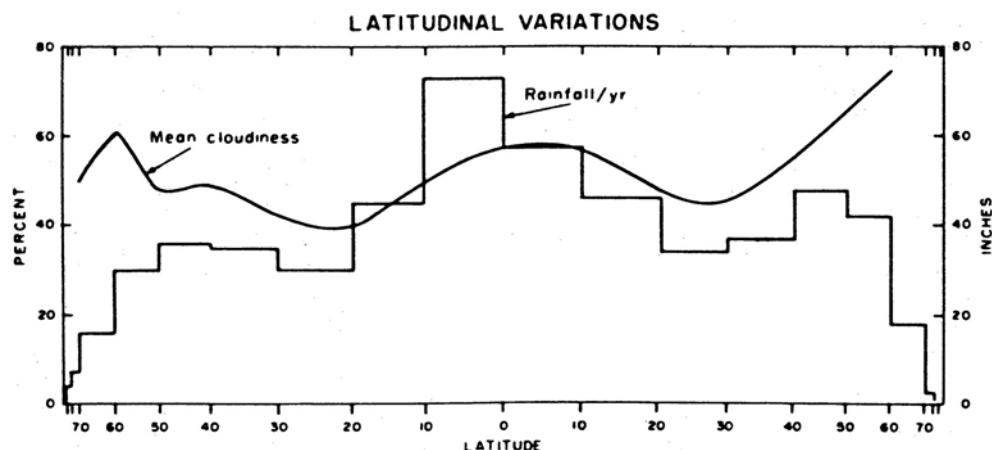

Figure C31 Zonal distribution of mean rainfall (in right scale) and mean cloudiness (percent, left scale) on Earth.

Table C16 Some extremes of climatic elements at the surface of the Earth (observed through 2000)

Element	Measurement	Globe location	Measurement	US location
<i>Temperature (°C)</i>				
Highest	58	Azizia, Libya	57	Death Valley, California
Lowest	-89	Vostok, Antarctica	-63	Snag, Yukon, Canada
<i>Pressure (mb)</i>				
Highest	1084	Agata, USSR	1068	Barrow, Alaska
Lowest	870	Typhoon Tip, Ocean	892	Matecumbe Key, Florida
<i>Precipitation (cm)</i>				
1 minute	3.12	Unionville, Maryland	3.12	Unionville, Maryland
24 hours	187.0	Cilaos, La Reunion, Indian Ocean	109.2	Alvin, Texas
1 month	923.0	Cherrapunji, Assam, India	271.8	Kukui, Maui, Hawaii
1 year	2647	Cherrapunji Assam, India	271.8	Kukui, Maui, Hawaii
Greatest annual mean	1168.4	Mt. Waialeale, Kauai, Hawaii	1168.4	Mt. Waialeale, Kauai, Hawaii
<i>Windspeed (km/h)</i>				
	372	Mt Washington, New Hampshire	372	Mt. Washington, New Hampshire
<i>Longest rainless period</i>				
	14 years	Arica, Chile	993 days	Bagdad, California

interval of observations and their spatial coverage increase, new extremes can be expected. It might be noted here that areas subjected to tropical cyclones are particularly apt to experience rainfall and wind extremes. Most of these storms occur in the northern hemisphere, with a peak frequency in fall. Much of their energy is derived from the latent heat of water vapor condensation, which derives from evaporation at the ocean surface, using the large energy income from the warm season. The tropical storms balance the water vapor excess in the northern hemisphere and adjust the vapor pressure to the seasonal temperatures.

Of all the features of global circulation, the seasonal winds called "monsoons" have the greatest climatic significance. About half the population of the globe is affected by monsoonal currents. These are most marked in the northern hemisphere and are most conspicuous in India and Southeast Asia. There are, however, monsoonal currents in West Africa, Australia, Western Europe and southern North America. The basic cause is the seasonal contrast of temperatures between land and adjacent oceans due to changes in radiation balance between the different types of surfaces. This creates high pressure over land and lower pressure over the sea in winter. The reverse is true in summer. Thus the winter monsoon creates outflow of air from the continent and the summer monsoon, inflow into the continent. This flow pattern results in dry winters and rainy summers. In India and Southeast Asia the rain tendency in summer is reinforced by the migration of the Intertropical Convergence Zone to almost 20°N latitude. The early spring heating of the Tibetan Plateau also plays a major role in initiating the summer monsoon. The seasonal shift in wind directions is another principal character of the monsoons, additional to the precipitation patterns (Figure C32).

Airmass frequencies are useful adjuncts to describe climatic conditions other than by numerical values of climatic elements. Prevalence of a given airmass indicates a stable, uniform climate whereas frequent airmass changes indicate a turbulent climate. Higher frequency of maritime airmasses over continental airmasses indicates a marine influence and probability of a rainy climate. If the continental types dominate, a dry climate is likely to prevail. Similarly, if the polar airmasses dominate,

cool or cold climate is indicated. High frequency of tropical airmasses will be associated with a warm climate. Seasonal changes in the frequency of various airmasses readily indicate the annual course of climate.

Scale and time in climatology

It need be appreciated that climatology can be considered at almost any spatial scale and over any time period that is long enough to establish a climatic record.

Scale

The smallest area scale is considered as microclimatology, which is characterized, for example, by the climate that might occur in an individual field or around a single building. A microclimate may extend horizontally from less than 1 m to 100 m, vertically from the surface to 100 m.

A local climate comprises a number of microclimates that make up a distinctive surface such as a forest or a city. The size of a local climate may extend horizontally from 100 m to 10 000 m and vertically to 100 m. A mesoclimate may contain a number of individual landscape types but often having a similar physiographic component. Thus the neighboring states within the Great Plains may be part of the same mesoclimate, with a vertical extent ranging to 6000 m. Macroclimatology concerns the climates of continents and, eventually, global climates.

Time

Climatology considers many time scales. In terms of the reconstruction of past climates, studies vary depending upon the type of information available. Given that reliable and extensive climatic data have been available for little more than 100 years, climatologists rely upon proxy data for interpreting past climates. Table C17 provides a listing of the common types of proxy data used. The level of sophistication of interpretation of proxy data is a function of time. The more recent the event, the more information that is available. Thus, the representation of climates of, for example, the Paleozoic is much more general than that of say, the Pleistocene. When people began to observe the conditions around them, and eventually describe them in writing, proxy data had a new dimension added. The type of information used to reconstruct conditions of, for example, the Little Ice Age, illustrates how such data are used. Contributing to reconstruction of such climates are descriptions of unusual events, at least in terms of today's climate; the cited frequency of river freezes, reported crop failures, writings describing "years without summers", contemporary paintings and etchings showing wintry conditions, are some examples.

Timed predictions of climatic developments have been attempted for decades, so far with only limited success. Nearly all of the schemes are based on persistence, lag correlations, and teleconnections of climatic elements. The emphasis has been on temperature and precipitation projections for a month or season. Some skill is shown for temperatures but very little for precipitation. Relations to solar activity have proved elusive and no reliable prediction models for energy emission from the sun have so far been found. Periodicities have also been ardently searched for. There are some indications that a small amount of the variance in both temperature and precipitation that might be explained by solar fluctuations in long climatic

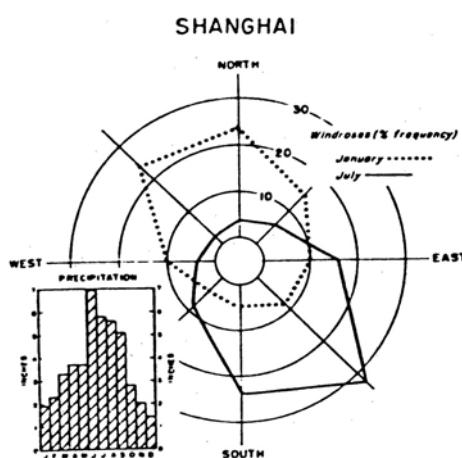

Figure C32 Wind roses for midwinter and midsummer showing the monsoonal wind shift in east Asia at Shanghai and the associated rainfall distribution (lower left).

Table C17 Palaeoclimatic data sources

Data Source	Variable measured	Potential geographical coverage	Period open to study (years BP)	Climate Inference
Ocean sediments (cores, accumulation rate of < 2 cm/1000 years)	Isotopic composition of planktonic fossils; benthic fossils; mineralogic composition			Sea-surface temperature, global ice volume; bottom temperature and bottom-water flux; bottom-water chemistry
Ancient soils	Soil type	Lower and midlatitudes	1 000 000	Temperature, precipitation, drainage
Marine shorelines	Coastal features, reef growth	Stable coasts, oceanic islands	400 000	Sea level, ice volume
Ocean sediments (common deep-sea cores, 2–5 cm/1000 years)	Ash and sand accumulation	Global ocean (outside red clay areas)	200 000	Wind direction
Ocean sediments (common deep-sea cores, 2–5 cm/1000 years)	Fossil plankton composition	Global ocean (outside red clay areas)	200 000	Sea-surface temperature, surface salinity, sea-ice extent
Ocean sediments (common deep-sea cores, 2–5 cm/1000 years)	Isotopic composition of planktonic fossils; benthic fossils; mineralogic composition	Global ocean (above CaCO_3 compensation level)	200 000	Surface temperature, global ice volume; bottom temperature and bottom-water flux; bottom-water chemistry
Layered ice cores	Oxygen-isotope concentration (long cores)	Antarctica; Greenland	100 000+	Temperature
Closed-basin lakes	Lake level	Lower and midlatitudes	50 000	Evaporation, runoff, precipitation, temperature
Mountain glaciers	Terminal positions	45°S to 70°N	50 000	Extent of mountain glaciers
Ice sheets	Terminal positions	Midlatitudes, high latitudes	25 000 to 1 000 000	Area of ice sheets
Bog or lake sediments	Pollen-type and concentration; mineralogic composition	50°S to 70°N	10 000+ to 200 000	Temperature, precipitation, soil moisture
Ocean sediments (rare cores, > 10 cm/1000 years)	Isotopic composition of planktonic fossils; benthic fossils; mineralogic composition	Along continental margins	10 000+	Surface temperature, global ice volume; bottom temperature and bottom-water flux; bottom-water chemistry
Layered ice cores	Oxygen-isotope concentration, thickness (short cores)	Antarctica; Greenland	10 000+	Temperature, accumulation
Layered lake sediments	Pollen type and concentration (annually layered core)	Midlatitude continents	10 000+	Temperature, precipitation, soil moisture
Tree rings	Ring width anomaly, density, isotopic composition	Midlatitude and high-latitude continents	1000 to 8000	Temperature, runoff, precipitation, soil moisture
Written records	Phenology, weather logs, sailing logs, etc.	Global	1000+	Varied
Archeological records	Varied	Global	10 000+	Varied

After various sources.

time series, is generally less than 10% of the total. In the Western United States a coherence of the extent of drought areas, as found by tree ring analysis with the double sunspot rhythm (Hale cycle), has been found; it has only limited prediction value. Similarly, the persistent quasibiennial oscillation found in many time series of climatic elements seems to wax and wane in time and space to prevent practical predictive use.

The Southern Oscillation, a large-scale pressure see-saw in the South Pacific Ocean, is repetitious on a 5–7-year time scale. It influences the intensity of the Indian summer monsoon and the occasional warm water current El Niño off the Peruvian coast.

Of considerable interest to climate researchers are the identification of climatic analogs, periods of climate in the past that can be considered analogous to those of the present or of

the possible future. Thus warm climates of the past, such as the Eemian interglacial (125 000–130 000 years BP) or the Holocene “climatic optimum” (5000–6000 years BP) have been used in attempts to assess future greenhouse climates. For the limited period for which observed climatic data are available, climatologists use numerous statistical methods to search for trends, periodicities or iterations. The specter of global warming, as promulgated in the 1980s, has resulted in extensive examination of observed data with attempts to standardize and validate them.

The forecasting of climate is a difficult task. At present there are two main methods of attempting to determine what lies ahead. The first uses climatic analogs which, as earlier noted, are time periods in the past that resemble conditions as they may soon be if the Earth’s climate were to warm. Second, climate models are generated. Climatologists use various types of models but of particular importance at present are general circulation models (GCM). Modern GCM are a product of computers’ calculating capability for GCM, attempt to solve equations of motion, thermodynamics and conservation for moisture and mass in a defined global area through various atmospheric levels. A number of models have been run, and while problems still exist, the output of such models is becoming more acceptable.

Climatic data

All of the understanding within the science of climatology must rest upon the availability of data. For climates preceding the instrumental period actual measurements are not available, and proxy data are used. Since about 1850, especially for land surfaces in the northern hemisphere, monitoring and data collection have gradually improved. Today, routine measurements of the atmosphere are accumulated for many world locations and are stored in archives. For most climatic analysis the statistics derived for a 30-year period are adequate. Unless otherwise noted, the cited average data of most locations represents the most recent 30-year block, ending in a decennial year. Thus 1951–1980 observations are replaced by those of 1961–1990 and so on.

For examination of climatic trends and periodicities, periods longer than 30 years are needed. Often, errors enter into older data from such things as change of observing location or modified instruments. Such is true in many urban locations where the development of an urban heat island causes the observed data to differ from surrounding areas. Climatologists check historic data carefully before assuming it is error-free. Despite the gains made in collection, quality control and archiving of climatic data, there should be improvements especially over the oceans and in underrepresented global areas. Climate is a basic global resource, and for managing and comprehending this resource, climatologists must have good data. Certainly, without such a base, the important task of predicting future climates becomes even more difficult.

CLIMATOLOGY, HISTORY OF

Since the mid-1980s the content and research topics of climatology have broadened considerably. Less-developed topics, such as teleconnections and periodicities, have attained new significance. Additionally, during this period the ready availability of data and information via the worldwide web and the enhancement of data processing and modeling have also produced new research directions. This more recent history is dealt with in many pages of this volume. As a result the historical perspective provided here provides information up to the time prior to the explosive development of paleoclimatology and the paradoxes of global warming. It deals with the history of climatology to the mid-1980s.

Introduction

In one sense climatology has no special history. Outdoor people – farmers, foresters, sailors – have always been aware of their environment, its physical and chemical dimensions, and its biological effects. As Brooks (1948, p. 155) said: “Anyone who has lived here [Charlottesville, Virginia] a decade or two can give you a pretty clear picture of the climate”, but records and instrumental readings are needed when comparisons or explanations are wanted. Measurements of state, e.g. temperature of air or soil, and of fluxes, such as solar radiation, are required for these purposes: (1) to picture the variability of a climate and to assess risks of extreme conditions for personal, agricultural, or economic planning; (2) to compare one place with another or to describe a remote, perhaps never-visited place, and answer the perennial question, what is it like there? (3) to understand how climate is formed, how it relates to plants, soil, landforms, and water bodies and the rest of the environment; and (4) to define the roles that solar energy or marine influences play, and what is the outcome of the eternal conflict between local, indigenous processes, and inflows of energy or water from outside. These kinds of understanding make it possible to apply science to models of crop growth, moisture stress, and stream-flow, and for climatology to contribute to its sister sciences of hydrology and meteorology, ecology, forestry and agronomy, the geophysical and geological sciences, as well as to the management of regional resources and national economic health.

Early observations

The Greeks, who lived under cloudless summer skies, were aware of how the height of the daytime sun differed in the desert to the south of them and in the cold lands to the north. Their zonation of climate (= angle of inclination of the sun to the surface of the Earth) is reasonable, emphasizing the role of the Earth–air interface (Tweedie, 1967). Later expressed as day length, this zonation of the globe persisted into the period of Arabian science (Blüthgen and Weischet, 1980). Meanwhile, the Chinese were living where a cloudy, wet summer is the productive season of the year, and they thought of their environment in terms of abundance or failure of the rains. In about the same period as the Greeks, they apparently were recording variations in their environment in terms of the rainfall that determined harvests and tax revenues. They recorded floods from the second century, dry periods from the seventh century, and severe winters from the eleventh century (Needham and Ling, 1959).

The Mediterranean center emphasized the sun and latitude, which seemed to be associated with the range from the warmth of the deserts of northern Africa to the cold of Scythia and to the miserable winters beyond the Alps where the legionnaires huddled around the warm springs of Baden. The effect of the sea was recognized, especially at places exposed to the steady winds used in navigation. During the same time period that the Greeks built the Tower of the Winds, the Chinese began to record wind direction, which was associated with air streams delivering water; they measured rainfall even earlier than the thirteenth-century records in Korea (Needham and Ling, 1959), measured snowfall, and apparently organized networks that reported these readings to the central government. The Greeks gave the winds names and qualities (Wright, 1925), Cicero spoke of the marine climate of England (Khrgian, 1959), and the general effects of the sea and of mountain barriers against polar winds were well known (Wright, 1925). During the late

Middle Ages weather diaries and phenological observations provided climatological information, much of it as yet unused.

When fifteenth-century navigators moved out of the Mediterranean into the lower latitudes of the eastern Atlantic, they encountered the steady trade winds, which differed from the seasonal winds of the Mediterranean or the monsoons of the South Asian seas (Landsberg, 1985). When continuing southward they encountered another belt of trade winds, the low-latitude elements of the global circulation. Halley, who had been studying the relation between land elevation and barometric pressure, turned in 1686 to the winds associated with pressure readings and recognized a thermal driving force for the trades (Frisinger, 1977), and in 1735 G. Hadley developed the first general circulation model (Lorenz, 1983).

As settlers moved westward from Europe and eastward from Russia into new lands, they encountered more severe climates. The cold winters and overheated summers of North America forced changes in the pattern of farming and subsistence (US Department of Agriculture, 1941), and seventeenth-century reports on Siberia discussed whether or not grain could be grown (Khrgian, 1959). Concern about the effects of the climatic environment on plant and human health promoted the use of instruments, especially the barometer and thermometer, which were just being developed in Western Europe. These were first employed by scientists in different fields who shared an interest in their environment; some of the earliest observations were made at astronomical observatories (Blüthgen and Weischet, 1980), and it may be recalled that many eighteenth-century discoveries in chemistry arose out of interest in the atmosphere. These early measurements, made carefully and systematically, gave climatology numerical data to enjoy centuries before geology, geomorphology, ecology, or other field sciences had such materials. In fact, the word *climatology* came to be used for the ordering of any variable displaying an annual regime. We have a climatology of Atlantic shelf water, of wind stress on the oceans, of clouds, and of upper-atmosphere conditions. Time series of early measurements have been recently constructed by Landsberg (1985).

The nineteenth century

At the beginning of the nineteenth century A. von Humboldt, during his expeditions in the New World, noted differences in climates, mapped them by isotherms, and recognized the effect of altitude on air temperature in the Andes (Leighly, 1949a; Khrgian, 1959). This work brought the end of the mathematical formalisms that had so oversimplified climatic distributions, although Fourier series continued to be published as summaries of diurnal and annual regimes at individual places (Leighly, 1949a).

As records at particular places accumulated, it became possible to describe the climate of a city, as L. Howard did for London in 1818 (Landsberg, 1981), E. Renou for Paris in 1855, and M.F. Spasskii for Moscow in 1847; some pointed out urban-rural differences, others the variability from year to year. Single-station observations of the seventeenth and eighteenth centuries expanded into networks (Rigby, 1965), the system in the Rhineland beginning in 1780 was “decisive for the history of climatology” (Landsberg, 1985, p. 58). Not much later (1818), the Surgeon General of the United States began receiving and publishing regular climatic reports from military posts (Landsberg, 1964). This network and those in several states, which later merged into the Smithsonian network, served as

models for a Russian system that started in 1839 (Landsberg, 1964). The value of these networks can be seen in early handbooks on climate (Hellman, 1922), which dealt with plants (1822, 1827), forestry and agriculture (1840, 1853), that were generally associated with air temperature, as by H.W. Dove (Khrgian, 1959). The climate of mountains, e.g., Humboldt in 1831 and 1843, introduced the question of sea-level reduction of shelter temperature readings, which continued, parallel to the question of the decrease in temperature of the free air with height, through much of the century. The measurement networks provided data for national surveys of climate like those of L. Blodget for the United States (Leighly, 1949a) and K.S. Veselovskii for Russia (Khrgian, 1959), which represented a high degree of literary skill as well as concern for practical applications. Both were published in 1857.

Extension to the worldwide scale had already taken place for temperature with Humboldt’s isotherm maps of 1817, L.F. Kämtz’s (1831–1836) discussions of temperature and wind patterns and Dove’s polar and tropical air streams (Khrgian, 1959). Humboldt’s research in the 1840s on the mountains and climates of central Asia led him to a concept of a solar climate (Flohn, 1971) that was a comprehensive expression of physical climatology. World maps of the winds, pressure, and rainfall followed (Leighly, 1949a); temperature maps became less schematic. Many world maps were products of the Smithsonian Institution in the years before 1870, when it still operated both climatological and synoptic services (Leighly, 1954).

Observations from all over the world, on sea as on land, flowed into the scientific community. J.F. Maury had enlisted the maritime nations in standardized observations at sea in the 1850s and sketched a general circulation model. Later, W. Köppen, at the Deutsche Seewarte in Hamburg, had at hand worldwide flows of data of interest to seamen and merchants. J. von Hann, an editor in Vienna for decades, developed a worldwide network of correspondents whose reports appeared in his journals. A.I. Voeikov, who had traveled widely and worked in many scientific institutions such as the Smithsonian, had similar global contacts and experiences, especially of the influences of climate on agriculture and settlement in the Americas and east Asia. Voeikov, Köppen, and Hann studied the general circulation and, with the scientists of the Smithsonian and other organizations, created the classic period of climatology that occurred during the middle third of the century from about 1855 to 1885 (Leighly, 1949a).

While Maury (1806–1873) preceded the others, it is notable that three of these founders of climatology were born within a few years of one another. Hann lived from 1839 to 1921, Voeikov from 1842 to 1916, and Köppen from 1846 to 1940 (within our own times). Similarly, V.V. Dokuchaev lived from 1846 to 1903 and studied global soils in their climatic context.

By midcentury the most easily measured climatic elements on land, shelter temperature, and rainfall were observed widely; cloudiness, wind, and humidity were observed at fewer places; radiation, notwithstanding its recognized role in the energetics of climate, still remained beyond reach. As observations accumulated, the global circulation of the atmosphere expanded and deepened into a global view of climate. Cartographic analyses, one of the major strands of climatology in the nineteenth century (Leighly, 1949a), drew attention to problems of causation, but much effort still went into futile attempts to reproduce the zonation of shelter temperature and to cast global energy budgets. These were an improvement over the earlier trigonometrical formulas for global temperature but failed because of lack of

data on the thermodynamic properties of the underlying surface, which either went unrecognized or were incorrectly assumed, as was albedo for many years (Miller, 1969). Physical laws of climate stated by Spasskii included absorption of radiation, heat conduction, evaporation, and so on (Khrgian, 1959) but could not be investigated because of the lack of accurate measurements of solar radiation and the late discovery of longwave radiation.

Local climates, though not explained, could be described from phenological observations in both their year-to-year variability and their spatial patterns, as well as by tables, maps, and verbal discussion of such variables of state as shelter temperature. These descriptions make up a large part of the classic books that essentially defined the field of climatology (Hann, 1883; Voeikov, 1884). These two gave rise to books in English and Italian (Hellmann, 1922); Voeikov's papers from his travels in Japan influenced the development of climatology in that country (Fukui, 1977). Explanatory power increased as time went on; for example, Voeikov's ideas on the effect of snow cover on climate were introduced in the second edition of Hann's handbook (1897), and near the end of the century a few rough data on radiation began to appear.

New directions in energetics

Maury (1861) outlined the components of ocean surface energetics, and Spasskii and Voeikov those of the land interface. The gaps mentioned in radiation data remained and augmented the lack of knowledge of properties of the interface, which influences not only the atmosphere as a whole, but particularly its lowest meters in which biological activity and physical interactions are concentrated. As a result, the effects of climate on agriculture, for instance, in any but gross features remained inadequate, and basic understanding of climatic genesis was absent. Voeikov's book and papers pointed out the importance of this interface for climatic energetics, the bookkeeping of solar energy receipts, and included such indicators of a regional climate as the temperatures of lakes and rivers, presence and effects of a snow cover on air and soil climate, and mutual interactions between vegetation cover and the lower air. Following Russian observations of soil freezing and temperature, Homén's heat-budget measurements (1897) in three sites in Finland centered on heat fluxes in the substrates. A number of investigators subsequently concerned themselves with heat storage in soil and water bodies. Radiation observations at the surface of the Earth – although considered as early as L.W. Meech's mathematical work in 1857 (Miller, 1969) – were just appearing. Nineteenth-century radiation work had been chiefly a matter of instrument development (Khrgian, 1959) on both sides of the Atlantic, much of it near the 60th parallel north (St Petersburg–Leningrad, Helsinki, Stockholm, and later Tartu). Radiation studies in Vienna entered climatology after the work of J. Stefan and L. Boltzmann, and a long period of productive work in that city and the Alps began. By the 1920s the capability to measure radiation fluxes converged with studies on the survival and growth of plants, especially in central Europe (Munich, the Alps) because plant growth could not be explained by shelter temperature. Field studies in dissected terrain by foresters, ecologists and meteorologists resulted in data that, in other hands, could sometimes be given a physical interpretation. In doing this R. Geiger (1927) invented the discipline of microclimatology, which in subsequent decades proved invaluable to climatology at larger spatial

scales (Miller, 1969). Another biological connection was made by A.E. Douglass's work on tree rings (Fritts, 1976), in collaboration with archeologists trying to extend the climatic record back in time. Brooks (1926) associated climate changes with drops in energy gained from solar radiation resulting from volcanism or high polar albedo.

Also at this time, the feeling that recent changes in climate might be measured in terms of changes in glaciers led Scandinavian scientists to examine mass balances of snow-fields, where summer melting rates express both solar and advected energy. Energy budgets were developed by A. Ångström in the 1920s and subsequently by H.U. Sverdrup (1942), H.W. Ahlmann, and C. C. Wallén (1948–1949).

Sverdrup also did notable work on turbulent processes at the interface, which had been studied by Schmidt (1925) and others, completing the roster of energy fluxes in climate. Leighly (1938, 1942) applied energetics reasoning to assess the influence of advection on the regional climates of California and the Great Lakes area. By 1940 Albrecht had calculated budgets for several parts of the Earth, including one from detailed observations brought back from an expedition into Central Asia. Unfortunately, cities remained refractory subjects for energetic analysis, but their mosaics of climates were described in detail in terms of state variables – principally air temperature (Kratzer, 1937), radiation and microscale interface temperature (courtyards, streets, walls) by Viennese climatologists.

Energetics, which is central in the calculations at each grid point in large-scale climate models and provides a tool to explain the genesis of climate, forms in addition a link between the climate as environment and the environed organisms. Energy budgets were cast for plant leaves in the 1950s and for animals in the 1960s. For the first time such physically significant characteristics of the Earth's vegetation cover as the geometry, mass, radiative properties, and ventilation of crop and forest canopies were measured and introduced into energy budgets (Gates, 1962; Rauner, 1972; Ross, 1975). Such budgets were able to assess the effect of forest on the atmosphere, and also to explain and predict the way living organisms utilize time and space. Embodying the same radiative and turbulent fluxes that figure in the interface budget, they defined the true impact of environment on an organism's thermoregulation, productivity, water and nutrient needs, behavior during the diurnal and annual cycles, and even its life strategy and evolution. Climatology took on a new immediacy and precision.

The water flux

The fluxes of water in climate, difficult to approach on a global basis because of lack of data over the oceans, never gave rise to the studies of merely state variables that had slowed progress in climatic energetics. Perhaps European scientists, like Dove, considered water a secondary factor, and this attitude persisted through much of the nineteenth century. It had been known since the late seventeenth century that rainfall supplied enough water to support rivers, not only, as E. Halley thought (Middleton, 1965), to mountains in the center of land masses, but even in lowlands like the basin of the Seine (Biswas, 1970). However, without knowledge of the partitioning and conversions of water at the interface, late nineteenth-century efforts to evaluate the true role of moisture in climate and to bring it into climatic typing and classification were in vain, even after it had become clear by 1900 that rainfall by itself was an inadequate

variable. Trials of many combinations of rainfall and shelter temperature were made to make various schemes of classifying climates fit vegetation better (Leighly, 1949a). The most notable of these were the successive stages Köppen went through from 1874 up until the 1930s (Leighly, 1949a; Khrgian, 1959). None of these classifications, however, turned out to have lasting physical relevance; partly, at least, because of the error in the assumption that the kind of observations established in the first half of the nineteenth century provided sufficient data for solving the problems of climate (Leighly, 1954).

Agricultural climatology was, from the beginning, an important part of the subject and was well summarized in 1941 by *Climate and Man*, a yearbook of the US Department of Agriculture. This compendium discussed agricultural settlement of major climatic regions along with chapters on corn, cotton and other crops affected by the conventional elements of shelter temperature and rainfall, especially as measured by the network of cooperative stations, then at its peak. Because administrative shifts later separated this work from interface and synoptic climatology, a hiatus followed. *Climate and Man* marked, along with the Köppen-Geiger *Handbuch der Klimatologie* of the 1930s and especially Conrad's volume (1936) on the dependence of climatic elements on terrestrial influences, a summing-up of the early twentieth century.

The lag in the hydrologic dimension of climate behind energetics and microclimatology ended in the 1930s when flood-mitigation programs and droughts in the United States revealed the deficiencies of direct rainfall-to-runoff transfers. R.E. Horton and others emphasized soil moisture as a dimension of drought and a condition of infiltration during rainstorms. Evaluating soil moisture, in turn, called attention to evapotranspiration. This long-sought convergence of water and energy burst into prominence in 1948, when important papers were published by C.W. Thornthwaite, H.L. Penman, and M.I. Budyko (see references in Miller, 1977). These three papers, which recognized the role of energetics, made it possible for the first time to provide an adequate representation of moisture in climate (Tweedie, 1967). Their energetics aspect stimulated research on all the exchanges between the interface and the atmosphere (Thornthwaite, 1961), especially radiation. Lettau's partitioning (1952) of sensible heat between substrate and atmosphere supplemented this work on latent heat and rounded out the theory for interface effects on climate, despite the fact that observational data remained scanty in most kinds of terrain. These methods have been adapted to faster computation methods in such applications as drought indices, probabilities of soil-moisture stress, streamflow modeling, flood frequencies, irrigation scheduling, and crop-growth models. Water-budget methods developed in Thornthwaite's Laboratory of Climatology were applied to reforested uplands, coastal marshes and estuaries, stream flow, and biological phenomena such as decomposition of litter (Muller, 1972; Mather, 1978). Ocean climatology used the methods of interface energetics to outline large-scale patterns of evaporation and hence salinity as a factor in ocean dynamics. Sverdrup (1942) discussed radiation, energy budgets, and sensible-heat exchanges with the air, all related to evaporation.

Circulation

Large-scale climatology benefited from advances in meteorology following 1920, when frontal and air-stream analyses

(Namias, 1983), combined with upper-air observations, sparked research in a science stagnant for half a century (Bergeron, 1959) that had been a drag on climatology whenever the two were associated in governmental weather-forecasting services. Some studies of airmass formation, e.g. the classic by Wexler (1936), added to knowledge of climate genesis by virtue of developing interface energy budgets; Flohn (1971) applied energy budgets of the Arctic vs. Antarctic to explain the strength and steadiness of the circulation of the southern hemisphere and budgets of Tibet to evaluate the effects of the injection of heat into the middle troposphere. Many investigators, especially in England and Germany, found air streams useful entities for typing climates; calendars of synoptic air flow pursued the beginnings that Köppen in 1874 (Leighly, 1949a) and others had made toward stratifying climatic events by direction and vorticity of air flow. These became a comprehensive synoptic climatology in World War II (Jacobs, 1947; Hare, 1955; Court, 1957) and served as frameworks in regional climatologies like that of the Paris Basin (Pédelaborde, 1957), or baseline climatic data for New Orleans (Muller, 1977). On a larger scale, circulation analyses provided indexes related to meltwater generation in anticyclonic conditions and to glacial accumulation (Leighly, 1949b). Circulation types over the northern hemisphere (Dzerdzevskii, 1968) and vapor transport in monsoon climates (Yoshino, 1971) were evaluated. They provided a basis for climatic classifications (Flohn, 1971), revisions in general circulation models (Lorenz, 1983), world maps (Hendl, 1963), and study of climatic genesis and fluctuations (Flohn, 1971; Lamb, 1972, 1977). Fluctuations of large magnitude presumably reflected circulation changes, which could be associated with profiles of pollen and other sediments and statistical properties of tree-ring measurements (Fritts, 1976).

Evaluation of atmospheric vapor transport (Benton and Estoque, 1954) provided an independent check on assessments of evapotranspiration at the underlying interface and not only had hydrologic value but also showed the ties of a regional climate to other parts of the world. Such studies assessed the strength of advection from other regions *vis-à-vis* local factors, as for example, the Andean *altiplano*, a nearly autochthonous climatic region (Hendl, 1963) that receives little advection (Gutman and Schwerdtfeger, 1965). Postcirculations are sketched on the basis of plate tectonic data on locations of the continents as far back as the Cambrian (National Research Council, Geophysics Study Committee, 1982; Budyko, 1982).

Expanding applications of climatology

Applications of climatology increased greatly during World War II, particularly in the US Air Force. The worldwide distribution and diverse nature of these applications, including the design of equipment and clothing to meet climatic conditions anywhere in the world, had important effects on the whole field. Among other things, they showed the inadequacy of the old hope that a single classification could meet all needs of science (Landsberg, 1958). Networks expanded, archives grew and were put into computable form and machine methods for sorting and summarizing data became standard. This effort was aided by a series of initiatives by the World Meteorological Organization's Committee on Climatology, first chaired by C.W. Thornthwaite. Large-scale statistical programs that had started in the late 1930s with marine data and research on drought, developed machine methods that made possible

frequency analyses on an unheard-of scale, as well as correlations, principal-component analysis and other ways to identify major features of a regional climate. Statistical techniques were transferred from agricultural and biological research and developed within climatology (Court, 1951). As storage and computing techniques grew more powerful, however, the gritty problem of assuring the quality of field measurements, especially those not immediately and directly utilized in forecasting the weather, persisted, and in spite of efforts of the World Meteorological Organization, records have lost homogeneity.

Concern in the 1970s about variations in climate that threatened world food production revealed the fact that serious questions of uniformity of series and representativeness of stations had grown up, questions that had been thoroughly examined a century before but forgotten in many countries. The struggles to maintain even a skeleton network of benchmark stations to detect changes in temperature of the kind Mitchell (1963) investigated revealed the difficulty of these historic problems of reliability. The question of change was also examined from the 56-year record of circulation types (Dzerdzevskii, 1962) and upper-air records. The study of climatic changes at longer time scales, i.e. in the preinstrumental periods, which had been stimulated by nineteenth-century research on glaciation, was again aided by geological research beginning in the 1960s on oceanic sediments (CLIMAP Project Members, 1976) and plate tectonics (Frakes, 1979; National Research Council, Geophysics Study Committee, 1982; Budyko, 1982). For example, the movement of the Australian plate into the latitude of the subtropical anticyclones caused a decrease in rainfall, changes in the structure and fire regime of the vegetation cover and its microclimatic habitats. These geological and geochemical studies indicate that carbon dioxide and water vapor have been components of the atmosphere since the earliest times and stabilize the planet's energetics against "greenhouse" overheating or a cooling to a condition of complete glaciation or a "white earth" (Budyko, 1982, p. 131). The Earth has a long climatic history, only glimpsed in part at the present time.

A large program in energetics at the Voeikov Main Geophysical Observatory in Leningrad (Budyko, 1956, 1971) began with physical research on energy and water fluxes at the interface, tested the results in expeditions to desert, forest and mountain locations, and applied them to calculate national and global patterns of distribution (Budyko, 1963) and to analyze changes (Budyko, 1982). This expansion to global scale paralleled the climatologically based soil science of V. V. Dokuchaev (Khrgian, 1959). The results of the energetics program provided better data for research because of the foundation in adequate measurements of physical exchanges at the interface, a consideration lacked by some earlier research on global climatology (Miller, 1969). This program was supplemented by energetics research in several regional hydrometeorological institutes, e.g. that at Tashkent (Aizenshtat, 1960), where soil climate had been measured for half a century and radiation for several decades; at Tbilisi, another old observatory, at Kiev, and at Tartu, for radiation (Ross, 1975); and in a program developed by Dzerdzevskii (1962) and Rauner (1972) to examine the influence of forested regions on the atmosphere. Many of the global patterns became inputs to large-scale computer models of the circulation that examined possible changes caused by alterations in atmospheric composition, interface characteristics such as sea ice and continental snow cover or albedo, remotely sensed over extensive areas or in the intake of solar energy. Examining the annual march of climate affords a useful

approach to its physical causes, a method used earlier (Leighly, 1938) and well adapted to quantitative computation techniques exploring solar forcing of climatic fluctuations.

Meteorological observations that expanded during and after World War II into the low latitudes and in the 1950s into the polar regions, filled in gaps in the patterns of world climates and added variables desired since Hann and Voeikov, but not earlier measured in routine programs. The results are summed up in the many volumes of Landsberg's *World Survey of Climatology* (1969–1984) and made possible worldwide water budgeting in several countries. Intensified observations of radiation and other heat fluxes in the USSR and Western Europe served for both applied purposes and definition of large-scale patterns, which were also shown by improved upper-air observations, the measurement of sea ice, snow cover, and interface temperature at sea by remote sensing, with its potential for synchronous and macroscale surveillance. Short field programs over the low-latitude oceans in the 1970s might have climatological significance for the light they cast on the phenomenon that is the major exception to the astronomical regimes that otherwise dominate climatology: the Southern Oscillation and El Niño, with their wide teleconnections.

The climatology of the energy budget influenced ecology and agriculture; one-third of Chang's text (1968) is devoted to radiation and photosynthesis and more than a third to evapo-transpiration; shelter temperature receives only part of a chapter. Agricultural climatology advanced in practicality in most countries, including China, where much use of radiation data is made (Huang, 1981), and in many states of the United States, which developed their own observational networks to support these methods. A phase of this work was the growth of "near real-time" climatology, which called on the relevant observations of antecedent atmospheric and soil conditions to make direct recommendations on the management of rainfed cropland, fire hazards in wildlands, irrigation of crops, resources of polar lands of Canada, and to predict crop harvests. This time dimension of application was expressed most clearly in mesoscale and regional climatology, though the basic physical and biological relations were generally microscale.

Because most applications of climatology, as distinguished from attempts to improve weather forecasting, dealt with management of water resources or crop production, which operate at regional scales, information at this scale was most useful. For example, new data on mountain climates in practical energy and water terms came from programs in snow hydrology in three mountain ranges of the western United States, to provide data for reservoir design and scheduling, and from investigations at the timberline in Austria and Switzerland to determine how to regenerate forests in avalanche source areas. These programs included multidisciplinary work on the soil, topographic, and biological conditions associated with the energetics of the water and biomass yields of mountain climates.

Lettau's climatology (1969) centered on the energy budget, using as forcing functions rainfall and solar radiation, which are independent at the regional scale, to develop the regimes of the state variables of soil moisture and interface temperature and of the flux of latent heat. These quantities are basic in agricultural climatology as it developed in several midwestern states of the United States, making use of observational programs in radiation, soil temperature, and soil moisture, as well as a dense network of recording rain gauges. Concern in several states about energy supplies in the 1970s encouraged research in wind and solar energy climatology at regional and

mesoscales. Basic factors in small-scale climatology were classified by Yoshino (1975) as topography, local air streams and atmospheric disturbances, and interface characteristics of open land, forests, and cities. Urban regions received attention beyond the old heat-island idea as their pollution thickened, but while descriptions of urban climates included more physical considerations (Landsberg, 1981) it was generally in spatially averaged terms, although patterns of rain and pollutants were examined in the Metromex program in 1971–1976 (Changnon, 1981).

Addition of chemistry to the usual energetics and hydrology of climatological analysis caught observation programs and climatologists unaware, and much research on diffusion of pollutants neglected important climatological considerations. Some pollutants, such as ozone, were found to be transported on a regional scale, and some, like acid rain, following C.G. Rossby's revival of interest in precipitation chemistry on even larger scales; modeling these transports and studying their effects entered the area of global climatology. Concern about possible effects on climate of increased atmospheric concentrations of carbon dioxide and other radiatively active substances was expressed in the 1950s, but served less to bring about better observations of, say longwave radiation, than to justify computer-assisted models of global circulation. While these models portrayed zonal averages better than regional climates, where water resources and food production are most likely to be affected by fluctuations, they are expected to help study the climates of the past and foreshadow those of the future.

Summary

Seven strands were identified by Leighly (1949a) throughout the development of climatology since 1800: empirical formulation, classification, physical explanation, synoptics, cartographic analysis, description, and variability. Empirical formulations have nearly disappeared as an important activity of climatologists, as has classification of climates. They were compensated for by a strengthening of physical science, especially energetics and hydrology, which were compatible with the newer concerns of chemical and ecological climatology and with more sophisticated applications. Interface exchanges and tropospheric synoptics shape climate, and both increased with advances in meteorology after about 1920. Climatic, water, and agricultural atlases shifted to portray the elements specific to the needs of particular applications of climatology, and as new physical relations became known the relevant observations (e.g. solar energy) were made, duly mapped, and given verbal description. Many descriptions were written to explain applications in water management, food production, and construction, both in design and planning, and in operation. Climatic fluctuations became better defined with the lengthening of the instrumental record, more accurate deductions from information in the preinstrumental period, and from geology; this knowledge has gained importance with concern over the frequencies of severe winters and multiyear droughts, as well as the possibility of permanent shifts resulting from human activity.

A cloud is an assemblage of liquid water particles and/or ice particles in the atmosphere. Almost all clouds form when moist air is cooled until it becomes supersaturated, i.e. the relative humidity is above 100%. If the temperature is above freezing, supersaturated water vapor then condenses onto cloud condensation nuclei to produce liquid particles. If the temperature is

below freezing, the supersaturated water vapor deposits on ice nuclei to form ice particles. If there are not enough ice nuclei present, supercooled liquid particles will form even though the temperature is below 0°C. When the temperature is below -40°C, ice particles will form without ice nuclei and supercooled liquid particles will spontaneously freeze. Under certain conditions cloud particles will combine and/or grow large enough to fall as precipitation.

Clouds play a key role in the climate system. They are intimately connected to precipitation and have a large influence on the transfer of energy within the atmosphere. Latent heat is released when water vapor is converted to liquid water or ice and when liquid water is converted to ice. This added heat increases the temperature, and hence buoyancy, of the air in which a cloud forms. Correspondingly, the temperature of the air decreases due to conversion into latent heat when cloud or precipitation particles melt or evaporate. Latent heating and cooling associated with clouds and precipitation drive atmospheric motions, especially in the tropics. Clouds also have a strong influence on the transfer of solar and terrestrial radiation within the atmosphere. Because they are generally brighter than the surface of the Earth, clouds reflect more solar radiation back to space. This decreases the amount of energy absorbed by the Earth, thus causing it to be cooler than would be the case were it cloudless. On the other hand, clouds are generally colder than the surface and consequently emit less thermal infrared radiation than does the surface. This decreases the amount of energy emitted to space, thus causing the Earth to be warmer than would be the case were it cloudless. The greatest reduction in emitted thermal radiation occurs for clouds high in the atmosphere, because they are coldest. Globally, the reduction in absorbed solar radiation by the Earth caused by clouds outweighs the reduction in emitted thermal radiation by the Earth caused by clouds. This result is a net cloud cooling effect.

Cloud types

The most basic categorization of clouds is by the altitude range in which they occur. Low-level clouds have bases less than 2 km above the surface. Mid-level clouds occur between approximately 2 km and 6 km above the surface. High-level clouds typically occur more than 6 km above the surface. Each altitude range is further divided into genera, or types of clouds, according to their morphology. Low-level genera are stratus, cumulus, and stratocumulus. A stratus cloud exists as a uniform grayish layer with little apparent structure. Cumulus clouds develop vertically as mounds or towers separated from one another. Stratocumulus cloudiness occurs as a layer with distinct clumps. Mid-level genera are altostratus and altocumulus. Both altostratus and altocumulus clouds occur in layers, but differ in that altocumulus has distinct cloud elements and altostratus has a more uniform appearance. High-level genera are cirrus, cirrostratus, and cirrocumulus. Cirrus clouds are detached from one another and appear white and often feathery. A cirrostratus cloud occurs in a whitish and transparent layer. Cirrocumulus cloudiness exists as a whitish layer composed of very small but distinct cloud elements. Two cloud types that produce rain or snow are cumulonimbus and nimbostratus. A cumulonimbus cloud, typical of thunderstorms, resembles a cumulus cloud and may grow very high, but is nevertheless classified as a low-level cloud type. Cumulonimbus clouds sometimes have tops shaped like anvils and occur with thunder and lightning. Nimbostratus cloudiness exists as a gray and

Table C18 Cloud types

Altitude range	Genera (cloud type)	Abbreviation
Low	Stratus	St
	Cumulus	Cu
	Stratocumulus	Sc
	Cumulonimbus	Cb
Middle	Altostratus	As
	Altocumulus	Ac
	Nimbostratus	Ns
High	Cirrus	Ci
	Cirrostratus	Cs
	Cirrocumulus	Cc

frequently dark layer and is distinguished from stratus cloudiness by the occurrence of rain or snow. Although nimbostratus clouds are thick, and can occupy a large range of altitude, they are often classified as a midlevel cloud. Table C18 lists these 10 basic cloud types. Fog, essentially a cloud that touches the ground, can be identified as an additional cloud type. Because specific meteorological processes produce different types of clouds, cloud morphology qualitatively describes the local atmospheric environment. The global distributions of different types of clouds are closely related to the locations of various climate zones of the Earth.

Cloud observations

The primary sources of cloud data are visual observations made by people at the surface of the Earth and satellite observations made from orbit. Human observers report cloud fraction, the fraction of sky-dome covered by clouds, and what cloud types are present. They have a clear view of low-level clouds but often cannot see higher clouds because lower clouds obscure them. Satellites have an unobscured view of high clouds but not lower clouds. Since human observers view the hemispheric sky-dome and include cloud sides as part of cloud cover, the cloud fraction they report is generally not identical to the cloud fraction reported by satellite. The difference is usually greatest for cumuliform clouds (cumulus and cumulonimbus) and least for stratiform clouds (stratus, stratocumulus, and fog). People have made regular visual observations of clouds for many decades in connection with weather forecasting, and it is possible to use these data to study past changes in cloud fraction and cloud type. Unfortunately human observers are not everywhere at all times on the Earth, and there are large regions of the globe, especially over the ocean, where no surface observations of clouds are available. However, a small number of satellites can observe clouds over every part of the globe several times a day. The International Satellite Cloud Climatology Project (ISCCP) (Rossow and Schiffer, 1999) provides cloud fraction and other information from July 1983 onwards. Unlike human visual observations, satellite observations cannot unambiguously identify morphological cloud type. Satellites instead report the reflectivity of clouds and the amount of emitted thermal radiation. This information is useful for determining how clouds affect the transfer of visible and infrared radiation within the atmosphere.

Satellites directly measure radiances, the amounts of visible, infrared, or microwave radiation upwelling in the direction of

the satellite from various locations on the Earth. Meteorological satellites typically cannot resolve, i.e. distinguish, features less than several kilometers in size. The minimum area resolved by a satellite is called a pixel. Clouds smaller than the size of a pixel cannot be distinguished; the pixel is assumed either to be completely clear or completely cloud-filled. A common method for identifying clouds by satellite makes use of the fact that clouds are generally brighter and colder than the underlying surface. Consequently more visible radiation will be reflected and less thermal infrared radiation will be emitted by a cloudy pixel than by a cloud-free pixel. The threshold method used by ISCCP identifies pixels as cloudy if their visible radiance is greater by some threshold, and/or if their thermal infrared radiance is less by some threshold, than the expected visible and thermal infrared radiances of a cloud-free pixel at that location. Increasing the threshold will cause some true cloudy pixels to be identified as cloud-free, and decreasing the threshold will cause some true cloud-free pixels to be identified as cloudy. Clouds are also difficult to identify over snow and ice using the threshold method since the surface can be brighter and colder than the clouds. Satellite cloud fraction within a particular area is defined as the number of cloudy pixels divided by the number of all pixels. Cloud reflectivity is obtained from visible radiances using additional information about surface and other atmospheric properties at the location of the cloudy pixel. Because the amount of thermal infrared radiation emitted by a cloud is quantitatively related to its temperature, cloud top temperature is obtained from thermal infrared radiances, also using additional information about surface and atmospheric properties. Matching cloud top temperature to a profile of atmospheric temperature as a function of altitude provides cloud top height. Unlike the case for clouds observed from the surface, clouds detected by satellite are classified into altitude ranges according

to the height of cloud top. ISCCP arbitrarily defines middle-level clouds as those with tops between approximately 3.2 km and 6.5 km above sea level and high-level clouds as those with tops more than 6.5 km above sea level.

Geographical distributions of cloud types

Figure C33 shows annual mean cloud fraction of all clouds over the entire globe, as reported by ISCCP. There is more cloudiness at middle latitudes than at low latitudes, except near the equator. The geographical variations in cloud fraction are largely related to the large-scale circulation of the atmosphere. Oceanic low-level trade winds flowing from the northern and southern hemispheres come together near the equator in the Intertropical Convergence Zone (ITCZ). Conservation of mass requires upward motion to balance the converging trade winds, and the upward motion causes air to cool and produce substantial cloudiness and precipitation. Latent heat release provides buoyancy that strengthens the upward motion. The climatological ITCZ can be identified by the relatively large fraction of middle- and high-level cloud near the equator, as seen in Figure C34. The ITCZ is broad over the Indian Ocean and western Pacific Ocean and is narrow and slightly north of the equator over the Atlantic Ocean and eastern Pacific Ocean. Over continents, the area of equatorial precipitation and middle- and high-level cloudiness is very widespread. Enhanced cloudiness marks tropical rainforests in South America and Africa. Air moving upwards in the ITCZ diverges and flows out toward the subtropical latitudes of the northern and southern hemispheres and then downward to complete the circuit of the trade winds, also called the Hadley circulation. The downward-moving air warms, thus decreasing its relative humidity. Figure C34 shows that very little middle- and high-level cloudiness exists over most regions between 10°

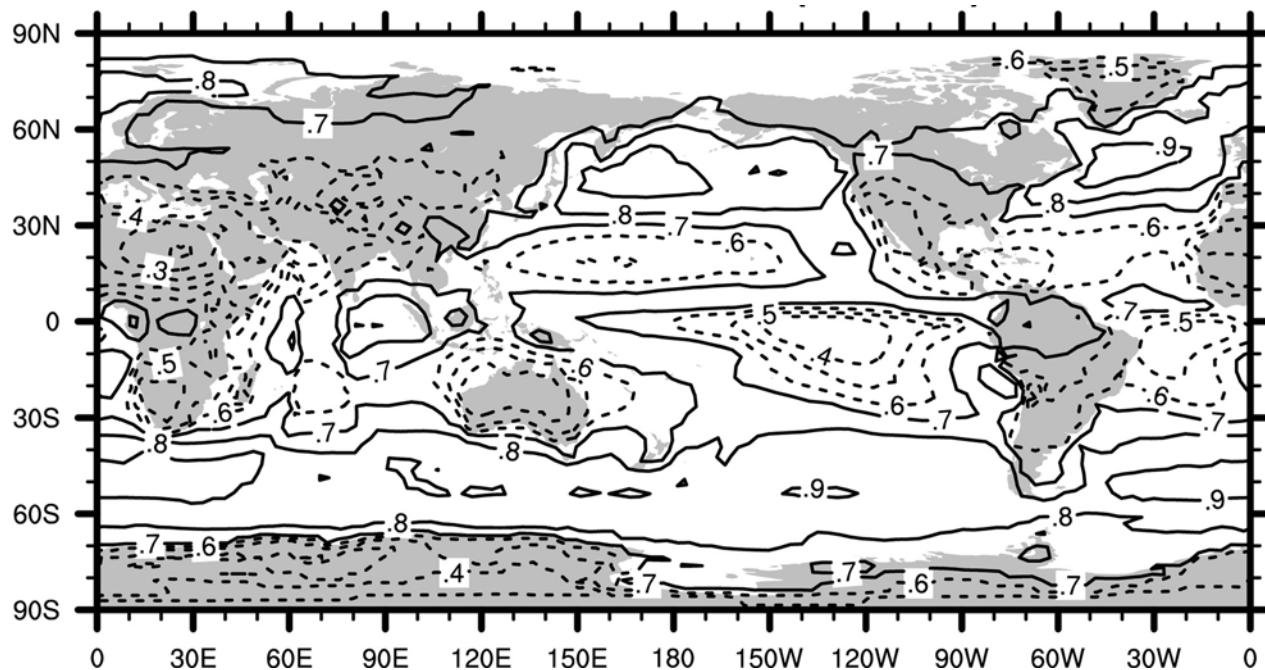

Figure C33 Annual mean cloud fraction of all (total) cloudiness obtained from the International Satellite Cloud Climatology Project and averaged from the years 1984–1999. Contour interval is 0.1, and values equal to 0.6 and lower are dashed.

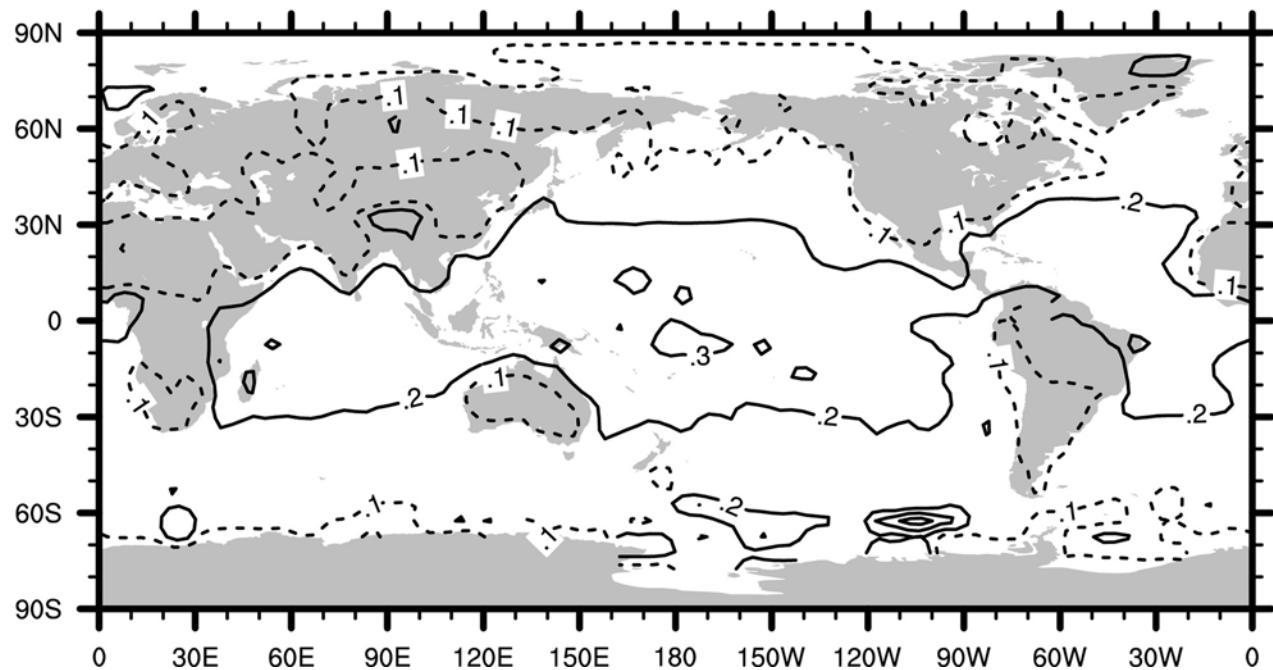

Figure C35 Annual mean cloud fraction of low-level cumulus and cumulonimbus cloudiness obtained from surface observations in the Extended Edited Cloud Report Archive and averaged from the years 1971–1996. Contour interval is 0.1, and the value equal to 0.1 is dashed.

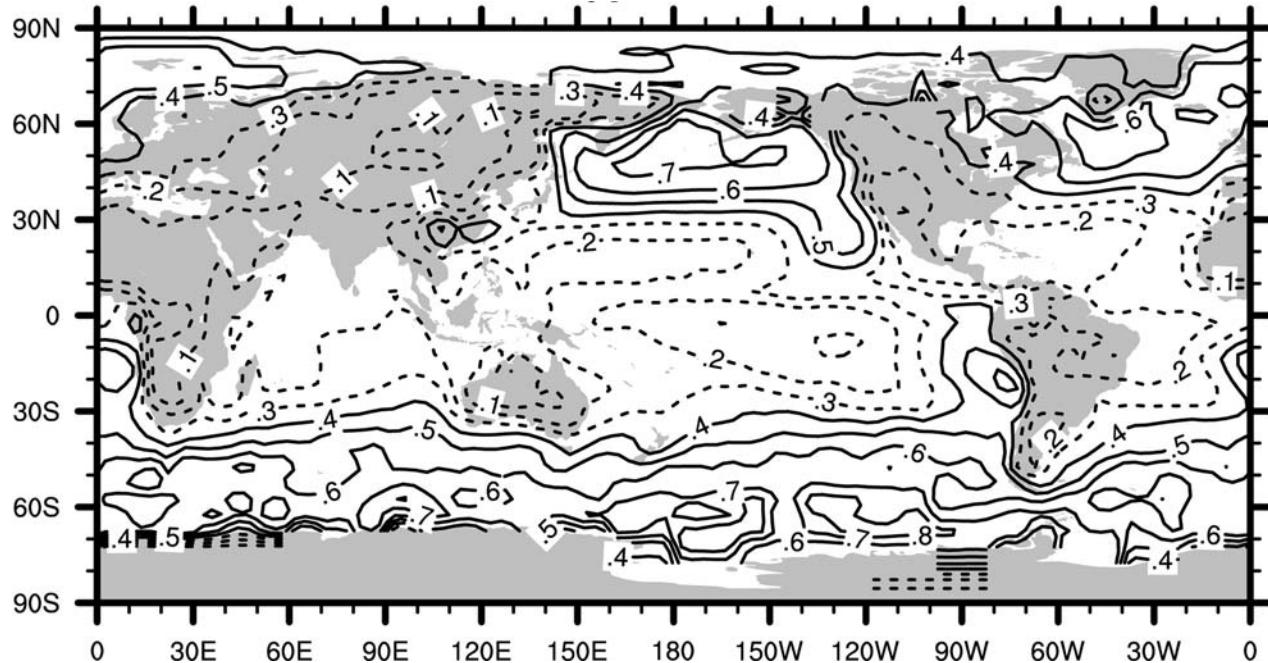

Figure C36 Annual mean cloud fraction of low-level stratus and stratocumulus cloudiness and fog obtained from surface observations in the Extended Edited Cloud Report Archive and averaged from the years 1971–1996. Contour interval is 0.1, and values equal to 0.3 and lower are dashed.

and 35° latitude. Middle- and high-level cloud fraction is greater poleward of 35°, especially over oceans. This is the latitude zone of the storm tracks, which are stronger over ocean than over land. Upward motion associated with extratropical cyclones passing through the storm track produces large amounts of cloudiness at middle and high levels.

Figures C35 and C36 show global distributions of low-level cumulus-type cloud fraction and low-level stratus-type cloud fraction, respectively. The source of cloud data for these plots was the Extended Edited Cloud Report Archive (Hahn and Warren, 1999), a collection of visual observations made by humans on ships or at land meteorological stations. Due to greater moisture availability, more low-level clouds occur over oceans than over continents. Cumulus-type clouds primarily occur equatorward and stratiform clouds primarily occur poleward of 30° latitude. A notable exception to this rule is the presence of large amounts of persistent stratocumulus clouds over eastern subtropical oceans, particularly off the coasts of California, Namibia, and Peru. In these regions the downward motion of the Hadley circulation is stronger, and the sea surface temperature is colder, than elsewhere in the subtropics. The marine boundary layer, the layer of the atmosphere directly affected by the ocean, is kept shallow by the strength of the descending branch of the Hadley circulation and kept cool and moist by the relatively cold underlying water. These conditions are conducive for the production of horizontally extensive layer clouds. Outside of stratocumulus regions, the tropical and subtropical ocean is warm and generates plumes of buoyant moist air that intermittently rise up from the surface. The plumes cool as they rise and form cumulus or cumulonimbus clouds when

saturation is reached. Stratiform clouds occasionally occur over the tropical ocean in association with large cumulonimbus cloud systems. The cold oceans at middle and high latitudes are favorable for the production of stratiform clouds. Widespread uplift associated with storms also produces many stratiform clouds. Cumulus clouds sometimes occur during winter over middle-latitude oceans when cold continental air flows offshore over relatively warmer water and generates many buoyant plumes.

COASTAL CLIMATE

For some distance on both sides of the 450 000-km-long world shoreline, meteorological processes and resulting climates differ from those farther seaward and landward. The coast is in essence a transitional zone between marine on one side and terrestrial on the other, a transitional zone or band that varies in total width as well as in the relative width of its two parts, land and water. The distinctiveness of this band varies with the amount and rate of meteorologic and climatic change across it. Although most of its characteristics are a blend of marine and terrestrial phenomena, there are a few characteristics, such as land and sea breezes and coastal fogs, that can be truly labeled coastal.

The climatic characteristics of the coastal zone most often have been considered a landward invasion of adjacent sea air and have been referred to as oceanic, marine, maritime, littoral, and coastal. The first three designations have been loosely used, and the last two appear only rarely in the literature. Maritime is the term that comes closest to our usage here of coastal (see Fairbridge, 1967). With the rapid evolution of the concept of the coastal zone, and especially because of the recent tendency to include the seaward segment of the coastal zone as one of its integral parts, the terms coastal meteorology and coastal climatology are now more appropriate than any of the others.

Climatic controls

Three of the most important climatic controls on Earth are variation of insolation with latitude, distribution of land and water, and surface configuration. Coastlines cross virtually every parallel on Earth except those immediately surrounding the two poles. Although coasts do not occur south of 78°S latitude because of the presence of Antarctica and its ice shelves, nor are they present north of 82°N latitude because of the presence of the Arctic Ocean, they nonetheless have a wide range of latitudinally influenced characteristics.

Whereas the juxtaposition of any two environments (e.g. forest/grassland, mountain/plain, and city/country) give rise to climatic modification, the land/water combination is the most distinctive on a worldwide basis. There are marked variations in the heat and moisture budgets of these two surfaces because of contrasts in albedo, evaporation rate, transparency, surface mobility, heat capacity, and sensible heat flux. Moreover, there are important modifications in circulation patterns because of variations in surface irregularities across the interface, including variations in the actual relief as well as in the mobility and spatial characteristics of roughness forms. Possibly the two most important differences are in wetness and roughness – the sea is almost always wetter and smoother than the land.

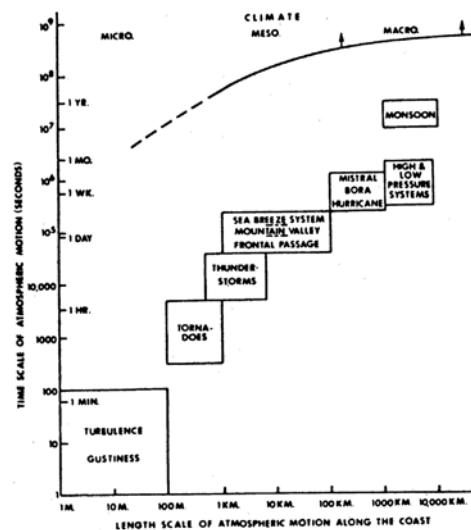

Figure C37 Time-length scales of atmospheric motions.

These controls are especially important in affecting atmospheric motion in the coastal zone. Pertinent motions have a great range in scale both spatially and temporally (Figure C37), and although all of these phenomena have some coastal expression, only a few have actually been considered from that standpoint. Studies to date most often have dealt with the impact of these levels of atmospheric motion (especially turbulence, sea breezes, and hurricanes) on the coastal environment rather than with the motion itself as a coastal phenomenon. Such an emphasis reflects the fact that coastal meteorology and climatology are integral parts of the total systems approach to the study of coastal environments.

Boundary-layer meteorology (microscale and mesoscale meteorology)

The boundary layer is the region of the atmosphere that is directly affected by friction caused by interaction with the Earth's surface. Transport in this layer in nearshore and estuarine environments is important from several points of view. For example, the wind stress or momentum flux is one of the most essential driving forces in shallow-water circulation. Heat and convection are the origins of some localized coastal weather systems. Sensible heat and water vapor fluxes are necessary elements in radiation and heat budget considerations, including the computation of salt flux for a given estuarine system. Experiments in these environments ranging from the tropics to the Arctic have produced a large number of conflicting drag and bulk transfer coefficients for both deep and shallow waters. There are several reasons for the discrepancies, but the most important is that early methods did not take into account the simultaneous contribution of wind, dominant waves, and atmospheric stability. This difficulty was removed by the development of a wind/wave interaction method of determining wind stress from commonly available wind and wave parameters (Hsu, 1976).

Aerosol transport

Atmospheric particles, particularly sea salts, have become an increasingly important subject for investigation in recent years.

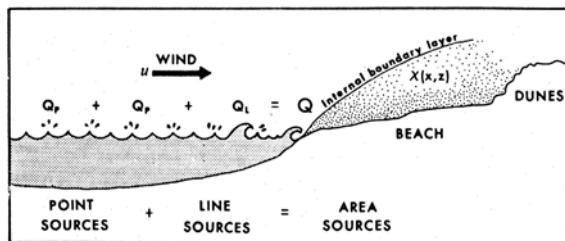

Figure C38 Schematic representation of point and line sources for sea salt and the effect of the internal boundary layer (from Hsu, 1977).

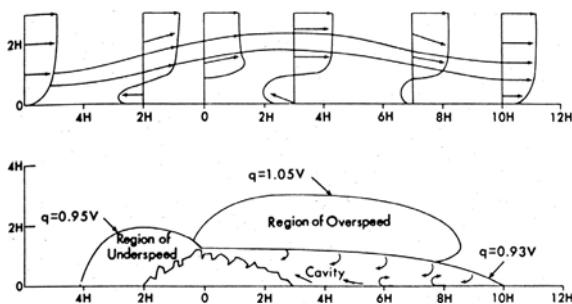

Figure C39 A basic flow model and a similarly shaped ice ridge. q is the local resultant mean velocity and V is the reference velocity in the uniform stream (from Hsu, 1977).

Sea-salt aerosols are a significant source of condensation nuclei. The quantity and quality of sea-salt particles deposited on land may be important in determining the physical and chemical characteristics of coastal soils and plants. The generation of aerosols depends on many meteorological and oceanographic factors. Among those in the coastal region are wind speed, direction, duration, fetch (which govern sea state and whitecap distribution), and subaqueous bathymetry (which controls the breaking wave condition in the surf zone). Aerosol contribution from these point sources (whitecaps) and line sources (surf zone) can be considered as originating from an area source (Figure C38). Experiments measuring the vertical distribution of sea salt in the atmospheric boundary layer over beaches have shown that on a coast influenced by synoptic onshore winds, such as a beach-dune complex, mixing depths are less thick than they are under sea breeze conditions (Hsu, 1977).

Sand dune and ice ridge air flow

When air passes over an obstacle it must adjust to a new set of boundary conditions. Major characteristics associated with this adjustment are the displacement zone, the wake, and the cavity. Measurements of the wind field in the region of coastal sand dunes in the tropics and ice ridges in the Arctic were combined with data from laboratory experiments in the preparation of a basic flow model. This model (Figure C39) is aiding the study of the modification of the structure of airflow over selected coastal topographies and is furthering the understanding of low-altitude atmospheric dispersion characteristics in the coastal zone.

Sea breeze

The sea breeze, a coastal local wind that blows from sea to land, occurs when the temperature of the sea surface is lower than that of the adjacent land (Defant, 1951; Hsu, 1970). It usually blows on relatively calm, sunny, summer days, and alternates with an oppositely directed, usually weaker, nighttime land breeze. As a sea breeze regime progresses, coriolis deflection causes the development of a wind component parallel to the coast. Coastal air circulations of this kind have been known and recorded since the time of Aristotle, about 350 BC, and have been studied more or less scientifically since the seventeenth century. Of all coastal meteorological phenomena, these have received by far the greatest amount of attention and are continuing to do so. For example, during the First Conference on Coastal Meteorology in 1976 about 40% of the papers dealt in some way with the sea breeze.

Synoptic meteorology and its coastal impact (macrometeorology)

Associated with the readjustment of airflow at the sea/land interface are other parameters such as temperature and humidity. As considered above at the microscale and mesoscale, these are quite distinctive. Although their effect is less obvious at the larger scale, they nonetheless have a significant impact on synoptic and planetary circulation systems.

Data support for the conduct of studies at this scale is scarce. Few meteorological data are routinely obtained at coastline stations; the major exception is at the all too few US Coast Guard stations where observations of temperature, precipitation, and wind are made. The most useful data, however, come from coastal airports, even though these are usually located several kilometers inland.

Such data have been used in the analysis of the weather input and environmental response in the coastal zone in Louisiana (Muller, 1977). This approach classified Louisiana coastal weather into eight inclusive synoptic types: Pacific High (PH), Continental High (CH), Frontal Overrunning (FOR), Coastal Return (CR), Gulf Return (GR), Frontal Gulf Return (FGR), Gulf Tropical Disturbance (GTD), and Gulf High (GH). Because each type can be identified on weather maps, climatic calendars were devised that are useful in the analysis of mean properties by months and seasons, climatic variation from year to year, and geographical comparisons of one coastal region with another (Muller and Wax, 1977).

Synoptic weather type changes have been found to be related to water level and salinity changes in the coastal marshes and estuaries of Louisiana (Borengasser et al., 1978). When the effects of astronomical tides were "filtered" from water-level data, it was found that water levels tended to drop during the 24-hour periods associated with a progression from the Frontal Gulf Return type to the Pacific High, Continental High, or Frontal Overrunning types. In contrast, water levels were shown to rise during other types of progression. Such analyses are only beginning but appear to hold promise for other non-tropical coastal areas as well.

In recent years there has been increasing focus on coastal storms, classification (Dolan and Davis, 1992), synoptic patterns (Davis et al., 1993), and some of the environmental and economic impacts (Davis and Dolan, 1993). Very important environmental issues still not well resolved focus on questions about increasing or decreasing frequencies and magnitudes of

^a Each pair of numerals in the body of the table refers to data from climatic stations at the 25th and 75th percentiles of the frequency distribution appropriate to the climatic type and element. As only long-period means have been entered into the frequency distributions, the data in the table above show the spread in average conditions of climate in the most representative parts of the several climatic regions. Because approximately equal spacing was employed in the station network, it is also true that the data illustrate, for a given climatic type, conditions in about 50% of the aggregate length of coastline affected by that climatic type.

^b The winter concentration of precipitation is defined as the percentage of the mean annual total that falls in the winter half-year. October through March in the northern hemisphere, April through September in the southern hemisphere. The computation was not carried out for those places where the difference between the mean monthly temperatures of the warmest and coldest month was less than 3°C.

severe and extreme events in terms of global change. For tropical storms and hurricanes there is clear evidence that regional frequencies of events vary significantly along the Atlantic coast of the United States and appear to be associated with ENSO and North Atlantic Oscillation indices (Muller and Stone, 2001).

Coastal climates

Whereas the atmospheric processes thus far considered are measured in intervals of seconds to weeks, there remain longer time periods to be considered – periods representative of climate (Figure C39). Climate, as a synthesis of atmospheric events, is unique for each location on Earth. Yet vast areas have climates that are sufficiently similar to justify consideration together. In most classifications continental types are extended directly to the shore, so that their coastal ramifications are indistinguishable (Wilson, 1967).

The major exception to date is the work of Bailey (1960, 1976), who developed a classification of coastal regions through the utilization of data from coastal stations. Defining his climatic types so that they closely approximated the distribution of coastal vegetation, Bailey (1976) arrived at 14 types (Table C19). The relative length of coastline represented by each type varies from 1% and 2% for five types to 20% and 25% for rainy tropical and polar climates, respectively. Only about one-fourth of the coastline of the world has a temperate climate.

The longitudinal gradients of the 14 coastal climates in Bailey's classification are generally weak. In contrast, the climatic gradients across the coastal zone are frequently steep. That there is a distinction between oceanic, coastal, and

continental conditions has been demonstrated by Bailey (1976) through comparison of the data in Table C19 with that from non-coastal areas. When the mean annual range of temperature is related to mean annual temperature, the intermediate nature of the coastal zone is evident (Figure C40). There are decided interhemispheric contrasts in the curves, contrasts that are especially evident in the seasonal swings (A of Figure C40) of temperature.

Bailey's classification of coastal climates, like most climatic classifications, is based on temperature and precipitation. Dolan et al. (1972), however, used airmass climatology as their basis for separating the coastal climates of the Americas. The airmass characteristics they considered significant are: airmass seasonality, airmass source region, nature of the surface over which the airmass moves, and the confluence of airstreams at the coast. Further conditions strengthening this approach are: each airmass possesses a set of secondary characteristics, including the traditionally utilized meteorological elements; the airmass is modified upon crossing the coast; and the boundary between airmasses (i.e. a front) is distinct and separates natural climatic complexes. Although the two approaches are different, the mapped distributions of coastal climates are nonetheless similar in both.

The future

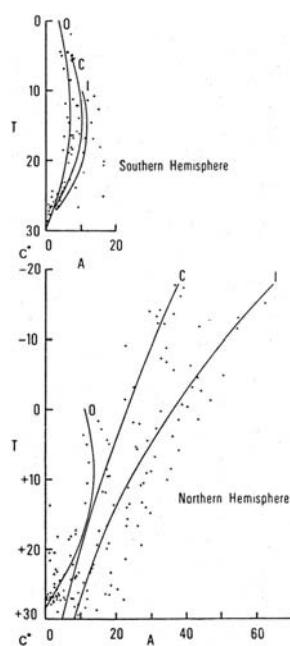

Coastal meteorology and coastal climatology are in their infancy as research disciplines, but the future for both looks bright. Many research organizations are beginning to place greater emphasis on the meteorology and climatology of coasts, albeit an emphasis that is still related mostly to the demand for data by other coastal sciences. In addition to the topics briefly discussed here, research is under way on storm surges, upwelling, tidal stirring, coastal fog, coastal dunes, and coastal frontogenesis, among others.

COMMERCE AND CLIMATE

The saying that “everyone talks about the weather but no one can seem to do anything about it” may seem like an appropriate statement for the vast majority of people even today. In many sectors of the nation’s economy the effect of weather and climate variations are well known yet the “weather” variable is the least understood in terms of all factors involved in weather-sensitive decisions (Maunder, 1970). Enhanced use of climate information has come about in recent years through improved understanding of the weather and climate, enhanced technology, and an interdependent global community that is ever more reliant on decisions impacted by weather and climate issues.

The “value” associated with the use of climate information in aspects of “commerce” (herein related to retail sales, the commodities market, and insurance sector) has been difficult to determine over time due to the lack of available data and investigations by either climatologists or businesses. Since the 1970s atmospheric scientists in three sectors – government agencies, universities, and commercial meteorology firms – have become increasingly engaged in activities with business decision makers (Smith, 2002). What triggered this increased interest in knowing more about the benefits and costs associated with weather and climate? First, as climate data and information became more timely and accessible, users could easily incorporate them into timely weather-related decisions. Second, since the 1950s weather forecasts at all time scales, hours to seasons, have improved and become more accurate. Third,

weather-related losses in the United States and around the world have increased dramatically, forcing government officials and insurance risk managers to re-examine climate risks and adjust accordingly. Recent studies (Dutton, 2002; Murnane et al., 2002) have indicated that the value of weather and climate information has increased and will continue to do so in this highly urbanized, industrial, and interdependent world. These new challenges have created new areas of growth for atmospheric scientists.

For the United States, Dutton (2002) estimated that nearly one-third (approximately \$3.0 trillion in 2000) of all private industry activities were weather-sensitive. Commercial activities (retail trade) accounted for \$894 billion and he estimated that nearly 100% of those activities were weather-sensitive. Changnon (1999) noted that United States retail sales increased nearly \$5.6 billion as a result of warmer than average conditions across the northern tier of states during the El Niño winter of 1997–1998. There is uncertainty in the economic value of weather in commercial activities but it is clearly significant.

Increased understanding of oceanic/atmospheric interactions and their relationship to regional climate variability around the world is considered one of the major climate advances since the 1970s. As a result, monthly and seasonal climate outlooks, which provide users with probabilistic forecasts of temperature and precipitation anomalies, are now being integrated into financial strategies used to hedge weather risks in energy, retail, and other industries (Dutton, 2002).

Retail sector

When examining the influence of weather/climate on the retail sector two time scales have been considered. Many studies have examined whether short-term day-to-day sales of a specific item are influenced (and to what degree) by weather conditions (whether it rains or not). For example, Zeisel (1950) examined the relationship of summer hot periods to beer sales, while Linden (1959) analyzed the influence of precipitation events on umbrella sales. Longer-term seasonal sales have generally been related to seasonal climate (either temperature or precipitation) anomalies such as those associated with El Niño (Changnon, 1999).

In any retail assessment it is difficult to document non-weather factors such as whether a shopper has the resources (money) to make purchases. To minimize this uncertainty in order to draw a clearer picture of how retail sales associated with one item are related to specific weather events or climate anomalies, studies have examined the retail–weather relationship over a number of years. This approach provides a range of outcomes and allows one to examine sales during warm versus cold periods and wet versus dry periods (Linden, 1962).

When examining the weather influences on all retail sales it is also important to consider that regional differences in weather across a country as large as the United States may in fact balance out regional profits in one area and losses in another. For example, during the 1997–1998 El Niño winter retail sales for the United States were \$4 billion above average; however, the gains were not experienced nationwide. Warmer and drier winter conditions along the northern tier of the United States helped to enhance retail sales as people were more likely to venture out of their homes to shop, whereas retail sales from southern California eastward along the Gulf Coast and into Florida sagged due to cooler, cloudier, and wetter winter conditions (Changnon, 1999). Similar regional increases in retail sales were

experienced in the eastern two-thirds of the United States during the record warm winter of 2001–2002 (Changnon and Changnon, 2002). On the other end of the scale, the record cold and snowy winters of the late 1970s in the Midwest and Northeast United States had a largely negative impact on retail sales (exceptions being winter clothing) in these regions (Changnon and Changnon, 1978). In summary, when examining national retail sales, one must keep in mind that there will often be regional “winners” and “losers” as some aspects of the retail sector are enhanced by pleasant weather while others hurt by a specific weather event or climate anomaly.

Commodities sector

This sector has witnessed some of the most dramatic changes in how it values weather and climate information. The commodities market involves trading of futures commodities such as oil, grains, meat, etc. (purchase now for something expected at a later date). Agricultural commodities have always been directly impacted by two conditions: present and forecasted weather events (Dutton, 2002). Mitigative strategies, such as contracts between different parts of the decision chain (resource, producer, processor, distributor, consumer) and a third party, were developed as a type of insurance plan for traders (Figure C41). Any commodities trader knows that the “weather factor” is ever changing, and that because commodities are grown and traded worldwide, one must examine weather issues and impacts around the globe (Davis, 2002). In the United States the weather-sensitive sector dominating commodities trading in the mid-1980s was agriculture. However, due to the deregulation of oil, natural gas, and electricity industries in the early 1990s, the need for weather and climate information in the United States energy sector has since increased and is now equal to agricultural needs.

Many decision makers in weather-sensitive industries realize that in this interdependent world they must better manage the weather and climate “risk” to reduce profit volatility and deal with increased competition. These efforts are becoming more

comprehensive and require quantitative answers (Dutton, 2002). As part of the commodities sector, the weather risk market has generated considerable interest in new approaches to management of the financial aspects of weather and climate risk. The recent development of weather “derivatives”, as a financial instrument to deal with seasonal climate anomalies, requires the use of very accurate climate information (Dischel, 1999, 2002; Dutton, 2002).

How does a weather derivative (contract) work? For instance, you own a Chicago company that is negatively impacted by very cold winter temperatures and desire protection. Once the risk associated with a particular seasonal climate anomaly (e.g. average winter temperatures in Chicago at 6°F below average) is determined, a contract can be established between you and another party. That is, one party concerned about this weather risk purchases an insurance-type policy that will pay (cover losses) if the average winter temperature is $\geq 6^{\circ}\text{F}$ colder than average. According to the Weather Risk Management Association (WRMA, 2002) the total national value of seasonal weather derivatives executed between parties over-the-counter was about \$2 billion per year in 1998–2000 and \$4 billion in 2001. This climate-based tool has dramatically altered how those involved with the commodities markets manage weather and climate risks and, as a result, it has opened new and extremely important opportunities for atmospheric scientists (Dutton, 2002).

Insurance sector

Since the late 1950s insurance companies have asked atmospheric scientists to assist them with the difficult task of determining weather-related risks to both crops and property. Initially, crop-hail insurance companies, which had experienced severe and extremely variable losses during the 1950s, wanted to gain a greater knowledge of the hail risk they faced at the local and regional scale. Using a statewide index of annual hail frequency and the annual “loss cost” value calculated for each state by the insurance sector, the hail risk calculations were completed (Changnon and Stout, 1967). These initial analyses, which were updated in the late 1990s (Changnon and Changnon, 2000), showed that, except in the western Great Plains and northern Texas, the hail risk had generally decreased or not changed in most agricultural regions of the United States (Figure C42). The research conducted by these meteorologists has assisted insurance decision makers in establishing the degree of risk and hence the premiums to be levied. Importantly, atmospheric scientists can help explain the causes of weather-related losses.

When examining property and casualty-insured losses related to weather catastrophes since the 1950s, one is impressed with the steady increase in total losses (Figure C43) and may have initially associated this increase with global warming. However, when losses for each catastrophe were adjusted for changing conditions (changes in property values, cost of repairs, growth in the size of the fixed property market, and relative change over time in the share of the total property market that was insured against weather perils), the trend in losses looked very different (Figure C44). Years with high values occurred when a major tropical storm/hurricane hit the United States (e.g. estimated losses for Hurricane Andrew in 1992 adjusted to 1996 dollars were \$30.5 billion).

Assessment of climate extreme data (hail, tornadoes, thunderstorms, floods, hurricanes, etc.) and insurance data led to important findings. Although annual insurance losses have

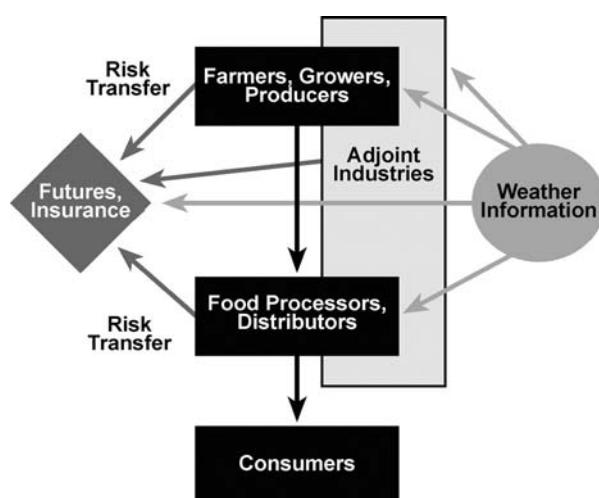

Figure C41 Flows of agricultural products, weather information, and transfers of financial risk (Dutton, 2002).

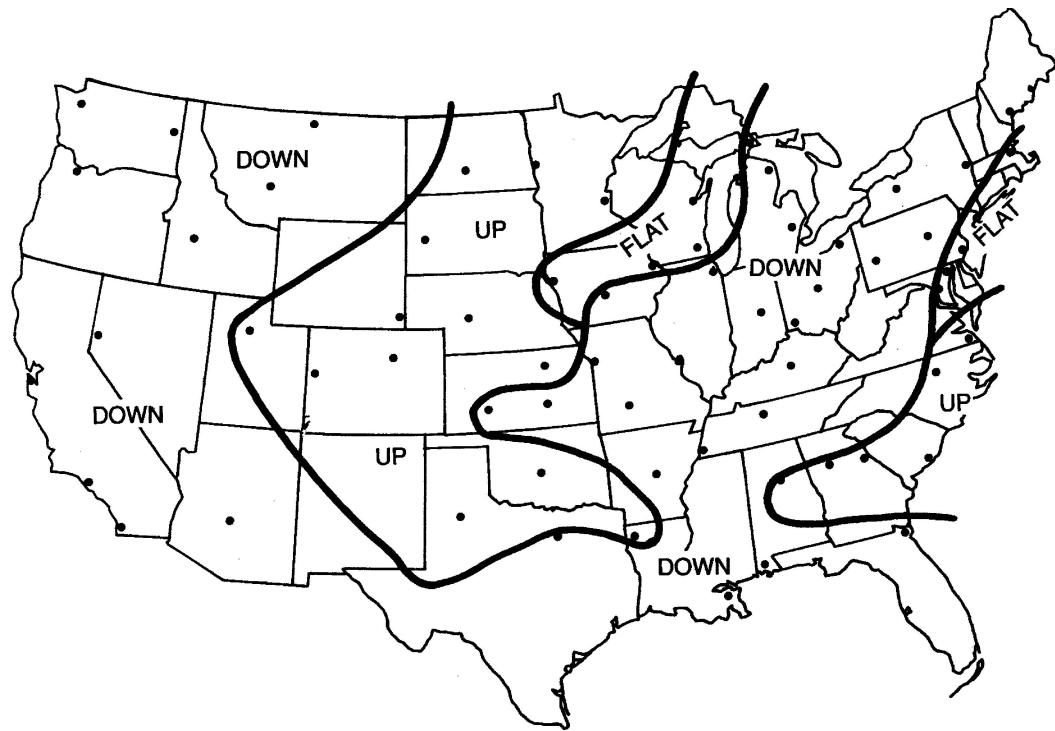

Figure C42 Regions defined based on linear trends of the 100-year hail-day values. Up is for increasing trends significant at the 5% level, flat is essentially no trend up or down, and down is for decreasing trends significant at the 5% level (Changnon and Changnon, 2000).

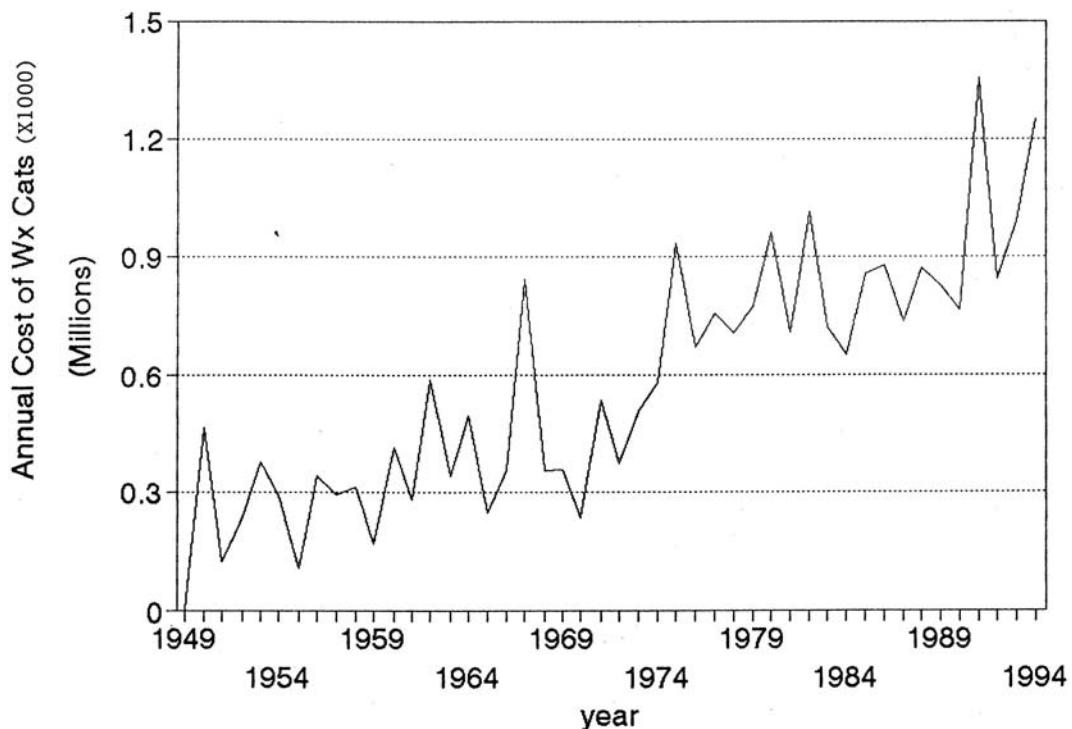

Figure C43 Annual losses produced by \$10 million to \$100 million catastrophes during 1949–1994 (Changnon and Changnon, 1998).

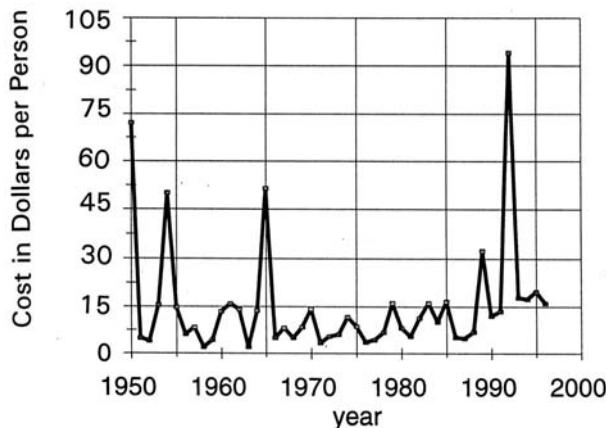

Figure C44 Annual losses caused by catastrophes causing <\$10 million in insured losses normalized by dividing annual losses by the annual US population during the 1950–1996 period. Values are dollars per person (Changnon and Changnon, 1999).

increased, and will continue to do so into the future, the changes during the past 50 years appear to be more closely related to societal changes than to changes in weather extremes (Changnon et al., 1999). Most climate extremes in the United States do not exhibit steady, multidecadal increases over time, as found in the insurance losses. Societal (demographic) changes – moving to coastlines, cities, and mountains) – explain some of the loss, along with growth of population and wealth. These societal shifts suggest that the “targets” for damaging weather have changed and have become more vulnerable to huge financial losses (Changnon and Changnon, 1999). Furthermore, more climate “impact” data are needed if climatologists working with insurers are to continue to understand and forecast insured losses.

Summary

There are a number of messages that need to be learned by climatologists if they are to become more effective in relating weather and climate information to commercial activities described herein. Many of the fundamental points listed below have been identified earlier by other atmospheric scientists (Maurer, 1970, 1973). However, given increased knowledge of the atmospheric sciences, enhanced technology, and increased loss amounts related to weather catastrophes, a number of these fundamental points have been modified to reflect current issues. The overall theme of this list is that interactions and research conducted with and for commercial business decision makers (Figure C45) should be “user-centered” (Changnon, 1998). The concept that atmospheric scientists totally understand (without user interaction) and solve the weather-related issues facing the commercial sector must be tossed aside. It is time climatologists and business decision makers got together. Following are five lessons to enhance commerce in the future.

1. Climatologists must work closely with the user in this changing world.
2. Climatologists should understand the value of climate information and develop relevant tools for commercial decision makers.

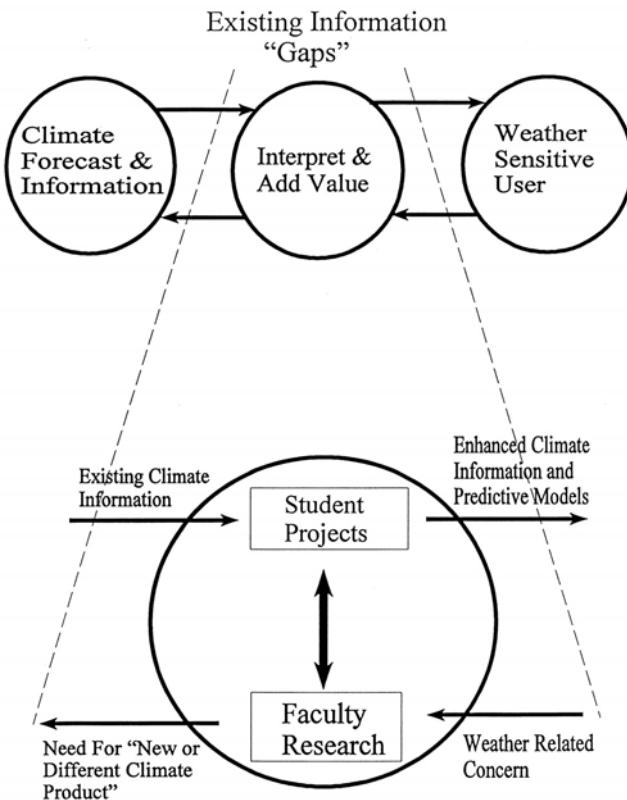

Figure C45 Bridging the information “gap” between climatologists and users (Changnon, 1998).

3. Climatologists need to separate climate variations from those of nonclimate factors involved in decision models.
4. Climatologists need to understand that uncertainty exists in any climate-related decision and this must be explained to users.
5. Climatological products need to change as the commercial world evolves.

Increased resources (public and private) for maintaining important climate databases and information are necessary if long-term benefits are to occur. Due to the dynamic nature of both the atmosphere and commerce, true benefits will be found only through long-term relationships. Basic reference unbiased climate datasets need to be maintained by the government to help users determine and minimize weather risks (Murnane et al., 2002).

CONDENSATION

Condensation is the phase change of water from its vapor to liquid. When moist air is cooled sufficiently, it attains a temperature at which saturation occurs – the dewpoint. Further cooling produces supersaturation, a condition in which relative humidity exceeds 100%. Supersaturation seldom occurs in the atmosphere, therefore condensation is the result of cooling. The condensed water may appear as dew or frost on the ground or as a suspension of water droplets in the air, fog or cloud.

Table C20 Heat transfers associated with phase changes of water

Phase change	Heat transfer	Type of heat
Liquid water to water vapor	540–590 cal absorbed	Latent heat of vaporization
Ice to liquid water	80 cal absorbed	Latent heat of fusion
Ice to water vapor	680 cal absorbed	Latent heat of sublimation
Water vapor to liquid water	540–590 cal released	Latent heat of condensation
Liquid water to ice	80 cal released	Latent heat of fusion
Water vapor to ice	680 cal released	Latent heat of sublimation

Condensation is brought about in three ways: (1) adiabatic expansion, which occurs when air rises to progressively lower pressure levels; (2) contact with a cold surface, for example, if the temperature of the surface is below the dew point, condensation may occur on that surface; and (3) mixing, for example, when two moist airmasses of very different temperatures are mixed, condensation may result.

If the air were perfectly clean, supersaturation of several hundred percent could occur. Air, however, contains impurities that act as nuclei on which condensation can occur. These condensation nuclei can be conveniently considered in three categories:

1. Aitkin nuclei with radii between 5×10^{-3} and 2×10^{-1} μm .
2. Large nuclei with radii between 0.2 and 1 μm .
3. Giant nuclei with radii greater than 1 μm .

The sizes and concentration of the condensation nuclei influence such factors as visibility and the precipitation process.

The condensation process, as a phase change, is responsible for the transfer of heat energy in the atmosphere. When water melts or is vaporized heat is absorbed. When the reverse process – condensation – occurs heat is released. Table C20 provides a summary of the energy exchanges that occur.

CONTINENTAL CLIMATE AND CONTINENTALITY

A continental climate has characteristics associated with areas within a continental interior as opposed to coastal locations under the moderating influence of water. Among the most significant of these climatic properties are large annual temperature ranges, which can be attributed to the distinctive thermal differences between land and water. Heat capacity is the ratio of the amount of heat energy absorbed by a substance to its corresponding temperature increase. Specific heat refers to the amount of energy necessary to raise the temperature of an exact mass of a substance by a certain quantity. It takes the energy of 4190 joules to increase the temperature of pure water by one degree Celsius. Thus, water has a high specific heat causing it to cool and heat slowly. Conversely, land has a low specific heat (five to six times less than that of water) causing it to cool and heat faster than water. Additionally, land surfaces lack the evaporative cooling effect of water and, unlike water bodies that distribute heat energy both horizontally and vertically, the solar radiation received by land heats only a shallow surface layer. As a result of these characteristics, continental locations tend to have cold winters and warm to hot summers.

Climatic characteristics

Continental climates also have large diurnal temperature ranges. Because these regions tend to be located in the interior of a continent, they are far removed from sources of moisture, reducing the availability of water vapor and subsequent cloud development. Clear skies allow insolation to quickly heat the land surface by day, causing temperatures to rise, while at night the absence of clouds enhances radiational cooling as temperatures rapidly decrease. Reno, Nevada, is an example of a continental location with a large diurnal temperature range. The mean maximum temperature in July is 92°F; however, the average minimum temperature during the same month is 47°F, yielding a daily range of 45°F.

A lack of significant moisture sources also causes continental climates to have relatively low annual precipitation amounts. Maritime airmasses that originate over distant water bodies typically lose much of their moisture before arriving at a continental

interior. However, higher temperatures during summer increase potential evapotranspiration, thus contributing water vapor to the regime and improving the possibility of precipitation. Table C21 lists the mean annual temperature, annual temperature range, and annual precipitation of selected continental stations.

Continentiality

Continentiality refers to the degree to which a place on the planet is affected by the temperature and moisture characteristics of a large, interior landmass. With the exception of latitude and its effect on solar radiation receipt, continentality is the most meaningful climatic control, and it is practical, for certain purposes, to separate every climate into a maritime or continental category (Driscoll and Fong, 1992). Further, Kopec (1965) asserts that it is possible to characterize a location based on its proportion of continentality, that is, its rank between perfect continentality and the total lack of continentality. D’Ooge (1955) notes that continentality quantifies the degree to which a region is influenced by continental characteristics. In the classical sense of the term, Stamp defines continentality simply as a climate with a wide range of diurnal and annual temperatures, as in the geographical center of a continent (Oliver, 1970).

The degree of continentality at a particular location is typically measured through the use of a derived climatic index. For example, the index of continentality at Prairie du Chien, Wisconsin, is 50%, which implies that the effect of continentality on the local climate is 50% greater at Prairie du Chien than on the island statio of Pago Pago (Samoa) where the index of continentality is 0%. The converse of continentality is “oceanicity.” A value of 0 represents the climate on an Earth completely covered with water (Kopec, 1965).

Continentality indices

Several climatic indices that account for the daily or annual range of temperature and which include some allowance for latitude have been derived. One of the earliest attempts to assign a numerical value based on geographic location and temperature came from Forbes (1859), who correlated the dependent variable, temperature, with the independent variable, latitude, in a formula expressed as:

$$T = -17.8^\circ + 44.9^\circ \cos^2(\phi - 6^\circ 30')^\circ \text{C}$$

where T represents temperature and ϕ represents latitude.

Table C21 Temperature, precipitation, and continentality of selected stations

Station	January mean temperature (°C)	July mean temperature (°C)	Annual range (°C)	Continentality value (%)	Annual precipitation (cm)
Beijing, China	-04.4	26.1	30.5	54	62.23
Calgary, Canada	-10.6	16.8	27.4	39	42.42
Fargo, North Dakota	-13.9	21.7	35.6	58	47.45
Fort Simpson, Canada	-27.2	17.2	44.4	65	33.27
Irkutsk, Russia	-21.1	15.6	36.7	57	37.59
Moscow, Russia	-10.0	18.9	28.9	40	62.99
Sverdlovsk, Ukraine	-17.8	16.8	34.6	50	42.41
Verkhoyansk, Siberia	-50.0	13.3	63.3	96	13.46

In 1905 Kerner developed a measure of the maritime influence on a location, or oceanicity, which he referred to as the thermoisodromic ratio. Kerner's formula is expressed as:

$$O = 100[(T_o - T_a)/A]$$

where O represents oceanicity, T_o represents the monthly mean temperature for October, T_a represents the monthly mean temperature for April, and A is equal to the average annual temperature range (Oliver and Fairbridge, 1987).

Among the earliest indices specific to continentality is that of Gorczynski (1920), whose formula is expressed as:

$$K = 1.7(A/\sin \phi) - 14$$

where K represents continentality, A is the average annual temperature range, and ϕ is latitude.

Conrad (1946) later amended Gorczynski's equation, suggesting that the sine of the latitude plus a constant of 10 would allow for use of the index at low latitudes. Conrad's index represents a reliable formula, which is widely accepted and expressed as:

$$K = 1.7[A/\sin(\phi + 10)] - 14$$

where K represents continentality, A is the difference between the mean temperature of the warmest and coldest month in degrees Celsius, and ϕ is station latitude in degrees.

Conrad's formula is perhaps the most frequently used of all continentality indices. Based on temperature records published in *Climatological Data* for 1952, Fobes (1954) applied Conrad's index in an assessment of the continentality of New England. Conrad personally assisted in the study, and the researchers concluded that northern stations in Maine possess the highest continental index values in the region with the effect

of continentality diminishing as one approaches the coasts. Index values for New England range from 30% along the coasts to 50% in the north.

D'Ooge (1955) examined the western United States using Conrad's index of continentality and temperature data from 1952. He found the maritime influence to be much greater than in New England with the 40% continentality values extending approximately 500 miles inland. The highest values are in eastern Montana and North Dakota (60%). However, the values are still less than the 100% calculated by Conrad (1946) for Verkhoyansk, Siberia, which represents the maximum continentality value on the planet.

Trewartha (1961) applied Conrad's index to an analysis of North America and found continentality to be much weaker on the West Coast than on the East Coast, with continentality values of 5–10% for the Pacific Coast, 25–30% along the Gulf Coast, and 30–40% along the Atlantic Seaboard. The core area of maximum continentality (60%) is located west of Hudson Bay in central Canada. Figure C46 depicts continentality values of North America as derived by Conrad's index.

Mapping continentality

Using data from the United States Weather Bureau for the period from 1931 through 1952, and Canadian data for the period from 1921 through 1950, Kopec (1965) analyzed continentality around the Great Lakes. Conrad's index reveals that the highest values for the region (60%) can be found northeast of the Great Lakes. As expected, the Great Lakes act as a moderating influence on the surrounding region with the lowest continentality values located along the shores. Kopec (1965) explains that the Great Lakes delineate a zone of reduced

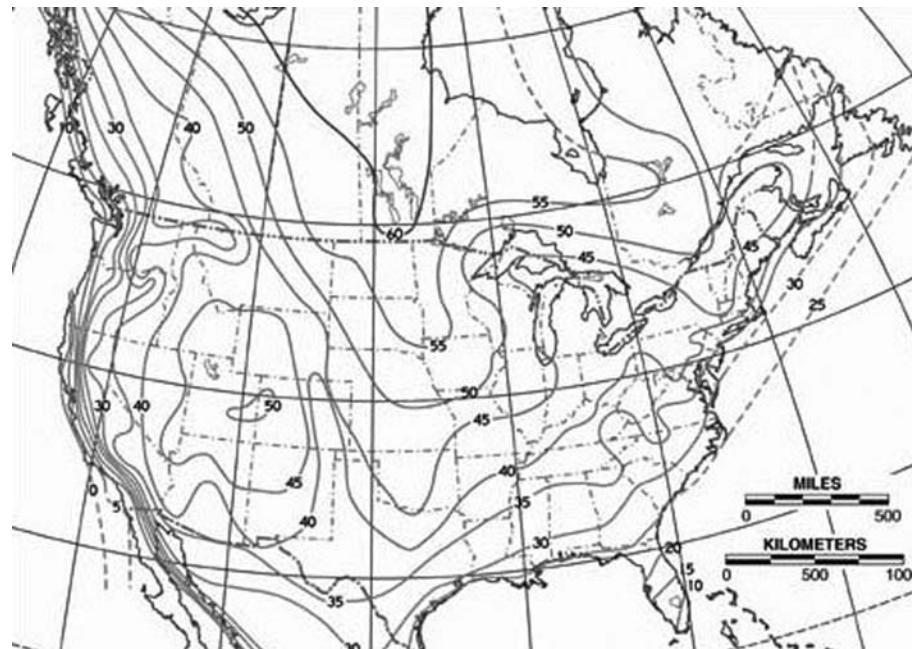

Figure C46 Continentality values of North America (after Trewartha, 1961).

continentiality values situated within a region that would otherwise represent the core of continentality for North America. In Siberia a comparable role is played by Lake Baikal. Even small lakes, as in Switzerland, a mild effect is noticeable.

More recently, Conrad's continentality index is among the formulas selected for a major study conducted by the Climate Criteria Examination Team (CET). The CET acts under the auspices of the Atmospheric Radiation Measurement Program (ARM), a multi-laboratory, interagency program created in 1989 with funding from the US Department of Energy (DOE). The CET is tasked with identifying and characterizing the geographic regions of the world based on the climatic attributes of latitude, seasonality, and continentality.

Despite its widespread use, the inclusion of the sine of latitude in continentality indices has been criticized because it assumes that contrasts in seasonal radiation receipts are approximately distributed such that dividing by the sine of the latitude negates the influence. This leaves aridity and continentality as the only remaining controls over annual temperature range. However, Driscoll and Fong (1992) insist the technique is flawed since seasonal radiation does not increase monotonically and have derived their own formula based on residuals from the regression line of annual temperature range on latitude. Their index yields a scale for North America that ranges from -10 along the coasts to +10 in the heart of the continent. However, the researchers acknowledge that, for regional studies in which the latitudinal area is limited, the use of $\sin \phi$ is essentially correct, and the results are not necessarily invalid (Driscoll and Fong, 1992).

Others have attempted to quantify continentality without including the sine of the latitude in the formula. Oliver (1970) applied an airmass evaluation to the concept of continentality using the formula:

$$K = L \cos A$$

where K is continentality, L is the length of the long axis (in millimeters), and A is the angular deviation away from the vertical on a climograph. Oliver concluded that a continental climate is one that experiences a large daily and annual range of temperature due to the proportionate preeminence of continental airmasses. Despite the ambiguity often associated with the classification of climatic regimes, continentality remains a viable concept that has inspired a wealth of research.

CORAL REEFS AND CLIMATE

Coral reef ecosystems are found in tropical marine environments, and extend between about 30° north and south of the equator. Optimal reef development occurs in clear, nutrient-poor waters where winter temperatures remain above 18°C. Coral reefs are unique in having a strong geological component (calcium carbonate, or limestone) as well as an ecological one (the coral reef ecosystem). Coral reef structures are built by the coral reef ecosystems themselves. Corals, calcareous algae, and many other organisms secrete limestone skeletons that progressively accumulate into complex three-dimensional structures that can attain tens of meters in thickness over a period of several thousand years. The coral reef ecosystem exists as a living veneer over these structures.

Although corals are animals, their success in reef-building is largely founded on their strong symbiotic relationship with microscopic algae, called zooxanthellae. Almost all reef-building corals require this symbiosis to survive. The zooxanthellae grow directly within the otherwise transparent coral tissue, fueled by photosynthesis and benefiting from nutrients provided from the coral animal. The coral animal in turn benefits from the carbohydrates produced by the zooxanthellae. This internal recycling allows corals to thrive in an otherwise nutrient- and food-poor environment. Corals which have these symbiotic algae grow and secrete calcium carbonate much faster than those that do not.

Early predictions of how climate change would affect coral reefs were optimistic. Because coral reefs thrive in warm waters, an expansion of the tropics during global warming was considered a probable boon for coral reefs, allowing them to migrate poleward with the 18°C isotherm. Over the last few decades the negative effects of climate change on coral reefs have dwarfed this optimism.

The most immediate problem facing coral reefs in a high-CO₂ world is global warming, which has so far proved to be damaging to corals and many other reef dwellers. The phenomenon of temperature-induced coral bleaching is the most serious climatic threat to coral reefs. Bleaching is a natural stress response of corals and other organisms that host zooxanthellae, whereby the host organism expels the algae and becomes colorless. A rule of thumb is that corals and many other organisms bleach once temperatures exceed the normal maximum temperature by 1–2°C. Many corals can and do recover from bleaching if the offending conditions are short-lived and of moderate intensity. Until the 1980s, bleaching events were rare and isolated events. In

1982–1983, mass coral bleaching was observed in the eastern Pacific, which resulted in nearly total coral mortality on Galápagos reefs. Mass bleaching events have become increasingly common and widespread during the past two decades, and nearly all have been associated with elevated temperatures. Secondary climate factors in coral bleaching and mortality include water circulation and light. Increased light penetration, particularly of ultra-violet radiation, intensifies bleaching. Vigorous mixing by winds, tides, and currents tends to keep sea surface temperatures in check, and to reduce light penetration. Bleaching in many areas has often been associated with several climatic patterns that occur during El Niño events: decreased cloud cover and increased insolation; increased sea surface warming; reduced winds; and reduced upwelling. In 1997–1998 an estimated 16% of the world's coral reefs were destroyed by bleaching.

Global warming also leads to other changes in the climate system that can affect reefs. Cyclones (hurricanes, typhoons) can destroy coral reefs, and although there is little evidence of an increase in storm frequency, there is some evidence that maximum winds will intensify. Increased precipitation on land can lead to greater sedimentation on many reefs, particularly those near deforested areas. Sea level rise is a consequence of climate change that can benefit some reefs and harm others. Because of the prolific production of calcium carbonate by coral reef organisms, many of the coral reefs that we see today were able to keep pace with the sea level rise of 100 m or more that occurred between about 18 000 and 3000 years ago. Sea level rise is predicted to be less than 1 m over the course of the twenty-first century. This relatively small rise could affect reefs near land if flooding of the coastal zone releases nutrients and sediments that degrade water quality. However, coral reefs that occur away from major landmasses are not considered threatened by a 1–2 m sea level rise.

An additional consequence of increasing atmospheric CO₂ concentration is ocean acidification. Ocean acidification in the tropics is a predictable process, driven directly by rising atmospheric CO₂ concentration rather than by climate change *per se*. The increase in partial pressure of atmospheric CO₂ drives more CO₂ into the ocean, some of which combines with water to form carbonic acid (H₂CO₃), which lowers the pH. Over this century, predicted decreases in surface ocean pH (about 0.25–0.33 pH units) are not likely to cause direct coral mortality, but constitute a creeping environmental problem that affects skeletal formation in corals and reef-building algae, and the overall calcium carbonate accumulation on a reef. Under increased acidity, corals secrete less calcium carbonate, and reef limestone dissolves more readily. It is likely that these effects will cause corals to secrete their skeletons more slowly, which would leave them less competitive for space; or less densely, which would leave them more fragile.

Predicting the effects of future climate on coral reefs depends on how well we can predict climate change, and on how well we can predict coral reef ecosystem response to this change. Corals may adapt to increases in temperature through a variety of mechanisms, including natural selection, and an interesting phenomenon whereby a bleached coral becomes repopulated with a more heat-tolerant variety of zooxanthellae. The recent increase in coral bleaching indicates that these mechanisms are not yet keeping pace with temperature rise. There is no evidence that coral calcification can adapt to changes in seawater chemistry. However, some coral species calcify more rapidly with temperature increase, and for those that survive the

negative effects of future warming, a decrease in calcification due to ocean acidification may be offset by increases in calcification due to warmer temperature. Projections of the state of coral reef ecosystems have ranged from moderate to total degradation; all predict significant disruption of ecosystem functioning. Current conservation efforts aim toward removing the controllable stresses on coral (e.g. overfishing, sedimentation, pollution), while encouraging a reduction in fossil fuel emissions.

CORIOLIS EFFECT

Any moving object above the Earth's surface tends to deflect from its course because of Earth's rotation. This deflection is known as the Coriolis force, named after a French engineer and mathematician Gaspard Gustave de Coriolis (1792–1843) in 1835. Given that this deflection is an apparent force, it is perhaps more correctly known as the Coriolis effect.

The Earth rotates eastward and has the same rotational velocity. However, places at different latitude have various linear velocities. A point near the equator goes around at 1000 miles an hour, while one near the pole moves only a few miles an hour. An object launched from the equator to the north will maintain the eastward component of velocity of other objects at the equator. When this object travels away from the equator it will be heading east faster than the ground beneath it. Similarly, an object moving to the equator from the north will be moving more slowly than the ground beneath it, and deflects to the right of its true path (apparently deflects to the west).

In fact there is no actual force involved in these displacements, and the ground is simply moving at a different speed than its original ground speed. Therefore this deflection (the Coriolis force) will only affect the direction and not the speed of the moving body. An object moving a north–south path on Earth will deflect to the right in the northern hemisphere and left in the southern hemisphere.

The magnitude of Coriolis deflection is directly related to the velocity of the object and its latitude, and can be expressed as:

$$F_c = 2(\Omega \sin \phi)v,$$

where: F_c is magnitude of Coriolis force per unit volume,
 Ω is Earth's angular velocity,
 ϕ is latitude and
 v is velocity of the object.

The Coriolis effect is zero at the Equator and maximum at the poles.

The Coriolis effect is significant in the dynamics of atmosphere, in which it affects large-scale atmospheric circulation and development of storms. Global scale winds blow in the paths commanded by the Coriolis effect. Wind deflects to the right in the northern hemisphere and left in the southern hemisphere. Stronger winds will have a greater amount of deflection than weaker winds. Wind blowing near the poles will deflect more than that with the same speed near the equator.

CRIME AND CLIMATE

Scientific inquiries into the relationship between climate and crime began during the early nineteenth century. Usually climate has referred to the monthly or seasonal mean temperatures and crime has been classified into two types: crimes against the person (or violent crimes such as homicide, rape, assault, and robbery); and crimes against property (such as burglary, larceny—theft, and motor vehicle theft).

During the nineteenth century A.M. Guerry in France and A. Quetelet in Belgium, in two independent studies, observed the coincidence of higher frequencies of crimes against persons in warmer areas and during warmer months. Moreover, crimes against property increased in winter months and in cooler areas. Quetelet conceptualized these observations into the *Thermic Law of Delinquency* (Cohen, 1941; Harries, 1980). Neither Guerry nor Quetelet felt that climatic conditions were the principal causes of delinquency. Both criminologists are credited with starting the geographic school of criminology where the ecological facts of crime are pursued – namely, the relationship between crime and social conditions (Gibbons, 1978).

Other European scholars, during the late nineteenth and early twentieth centuries, corroborated Guerry's and Quetelet's findings and agreed that climate was not the principal cause of crime (Cohen, 1941). Yet studies asserting a direct causal link-age emerged and persisted.

E.G. Dexter, studying 40 000 assault cases in New York City between 1891 and 1897, suggested that temperature was the most significant condition aggravating the emotions and erupting into fighting (Cohen, 1941; Harries, 1980). A stronger and more enduring endorsement of the causal relationship came from Ellsworth Huntington (1945) who claimed physiological and psychological conditions vary with climate and weather, hence the propensity for riots and assaults to increase with temperature. Huntington's vehement advocacy of climatic determinism as the cause of crime overshadowed the works of others including Cohen, whose work in 1941 contradicted climatic determinism.

During 1941, using the Federal Bureau of Investigation's Uniform Crime Reports, Cohen observed the expected highs for violence during the midsummer and property crimes during the midwinter. However, the most important finding was that regional variations of frequencies and types of crimes were more pronounced and significant than the seasonal variations. Cohen believed that the regional variations were the surrogates for significant social forces (1941). Despite findings like these the academic community's reaction to Huntington's environmental determinism was so strong and negative that inquiries into the relationship between climate and social phenomena in general, and climate and crime in particular, became almost taboo (Harries and Stadler, 1983).

Gradually, studies began emerging disproving the direct climate–crime linkage or including climatic variables with a host of other independent variables in causal analyses. An example of the former is a study by Lewis and Alford (1975) testing the *Thermic Law of Delinquency* by examining 3 years of monthly assault data across 56 US cities. Beginning with the winter months, the expectation was that the number of assaults would oscillate seasonally with the march of the sun on a south to north vector. Such an orderly progression was not found and, regardless of region, the transition from lower to higher levels of assaults was rather abrupt (Lewis and Alford, 1975). An example of the latter is a study by Van de Vliert et al. (1999) associating riots and armed attacks in 136 countries between 1948 and 1977 with temperature, population size and density, degree of democratic government, socioeconomic development, and a cultural masculinity dimension. They conclude that the culture mediates the effect between temperature and collective violence.

The fast pace of changes in computing and information systems technology since the mid-1980s has decreased the number of inquiries into the climate–crime relationship. Easy access to weather and crime information of varying temporal and spatial scales has spawned numerous studies on the relationship between crime or police activity with weather elements or events (see LeBeau and Corcoran, 1990; Rotton and Cohn, 2000). Despite the changes in focus the *Thermic Law of Delinquency* remains an integral guide for these and other studies.

The relationship between climate and crime is more suggestive than definitive, but climate is viewed as indirectly providing enhanced opportunities for the commission of different crimes. Finally, regardless of the empirical evidence, the public may feel there is a definitive relationship between the two; especially since many residential real-estate companies on their Internet websites list a range of factors describing the quality of life in a place and on the list climate is followed by crime.

CULTURAL CLIMATOLOGY

Climate and life are intimately linked. Without life the composition of the Earth's atmosphere today would be totally different and the climate of the Earth would be more like that of Venus – the Earth's atmosphere would be 98% CO₂ (Morrison and Owen, 1996). This intimate link between life and the atmosphere on Earth has led to claims that the atmosphere is effectively managed by the biosphere, leading to the "Gaia hypothesis" (Lovelock, 1979). No-one is sure how life developed on Earth about 3850 million years ago, but after continuous evolution humans emerged about 5 million years ago, and civilization and society as we know it began about 5000 years ago. Hence it is impossible to study climate in isolation from the biosphere and society, and any changes to the Earth's atmosphere caused directly or indirectly by society should be firmly within the remit of climatology. Since the industrial revolution of the nineteenth century society has threatened to change our climate, ironically to increase CO₂ concentrations and other so-called greenhouse gases, the need for effective climate management has never been greater.

Today the links between climate and society are explored under the headings of applied climatology where the climate is seen as both a resource and a hazard that needs to be effectively managed by society. Climate change cannot be managed under the heading of applied climatology as the issue has global consequences and climatologists do not have the social science skills to effectively manage climate change and social scientists do not understand the vagaries of climate sufficiently. Hence it is time that climatologists were trained to understand how to manage the climate effectively, otherwise it will be left to politicians and economists to decide the future of our climate. This has never been a more important issue than in the assessment

and management of climate change. Hence the need for cultural climatology to emphasize this requirement for climatologists who understand how society works, as well as the climate.

Cultural climatology is a new branch of climatology concerned with the study of physical and dynamical processes in the atmosphere at various space and time scales in conjunction with evaluating and understanding climate–society interactions and feedbacks. Climate is considered to be an integral part of culture and conversely culture is an integral part of climate. This climate–culture dialectic gives meaning and value to the study of climatology that has been missing in the past. Given that the ultimate goal of climatology is to apply the field's knowledge to the solution of both environmental and socioeconomic problems, a cultural turn is taking place as climatologists enter the post-normal phase of their science. The nature of this cultural turn, and what constitutes cultural climatology, is discussed in detail elsewhere, together with a consideration of climate and society relationships as these are at the heart of cultural climatology (Thornes and McGregor, 2003).

Culture is a complex and overused word, and is used to encapsulate everything from the "total way of life" of a people (language, dress, religion, music, values, etc.) through to works of art and advertising. Mitchell (2000, p. 14) gives six possible definitions of culture, but the simplest definition of all is: "Culture is all that is not nature". Although the definition of nature is not as simple as it might seem (Macnaghten and Ury, 1998) we can fruitfully examine the relationship between climate, as part of nature, and culture.

The summons to cultural climatology should not be misconstrued as a call for climatologists to abandon the research mainstays of synoptic, dynamic and physical climatology. On the contrary we expect cultural climatologists to be concerned with issues such as global climate system change, establishing what the principal drivers of the climate system are, assessing how the climate system will respond to natural and human-induced changes, answering how society might respond to the opportunities and threats posed by climate change, and evaluating to what extent the changes expected in the climate system can be predicted. This call to cultural climatology should be seen more as a signal to climatologists that opportunities await us at the interface between science and society, an area which climatologists on the whole have felt great apprehension with in the past.

Cultural climatology is just the ticket for catching the climate and society boat of opportunity. A passage on this boat will bring climatologists closer to understanding the physical and societal mechanisms underlying the complex interactions between components of the climate–human system. All students and purveyors of climatology courses need to look beyond the learning and teaching of straight climate processes by considering the multitude of ways in which climate and society may interact. Such a broadening of horizons into the realms of cultural climatology will not only will provide us with learning and research opportunities, but, will provide society with a better understanding of the meaning of climate.

CYCLES AND PERIODICITIES

Throughout recorded history people have been aware of periodic meteorological events that have influenced their well-being. Because so much of our lives is governed by seasonal rhythms, it is natural that there has been a search for long-term order in the physical world. Today the study of cycles, which may be defined as a series of recurring events that repeat with some sense of periodicity, is a well-defined area of research.

The search for cycles

The search for cycles in weather records has been a constant endeavor of a lot of meteorologists for many years. Whether the

product of natural variability of the climate system or the result of interactions between the Earth's atmosphere and oceans and external agencies, including periodic variations of solar activity and the astronomical motions of the Moon and the planets, there has been a long and largely fruitless search for clear evidence of predictable cycles.

Interest in weather cycles has fluctuated over time, but has recently experienced an upsurge in activity for two principal reasons. First, the record-breaking El Niño of 1982/1983 stimulated huge interest in the possibility of events in the tropical Pacific Ocean having an impact on the weather around the globe (Diaz and Markgraf, 2000). The realization that the El Niño was part of atmosphere–ocean interactions that can set up quasi-cyclic behavior in the climate has led to a burgeoning study of such “oscillations”. Second, satellite measurements since 1980 have shown that solar irradiance varies in phase with the 11-year cycle in the number of sunspots on the sun (Figure C47). This has led to renewed interest as to how changes in solar activity might affect the climate (Haigh, 2000).

The quasi-biennial oscillation (QBO)

Prior to the 1980s the one oscillation that had established as being a real feature of the climate was the periodic reversal of the equatorial winds in the stratosphere (Baldwin et al., 2001). On average the cycles in these winds have a period of around 27 months, hence the name quasi-biennial oscillation (QBO). First observed in the 1950s, their period has varied from over 3 years to well under 2 years (Figure C48). The QBO shows well-defined characteristics. The wind regime propagates downward as time progresses. The amplitude is greatest at an

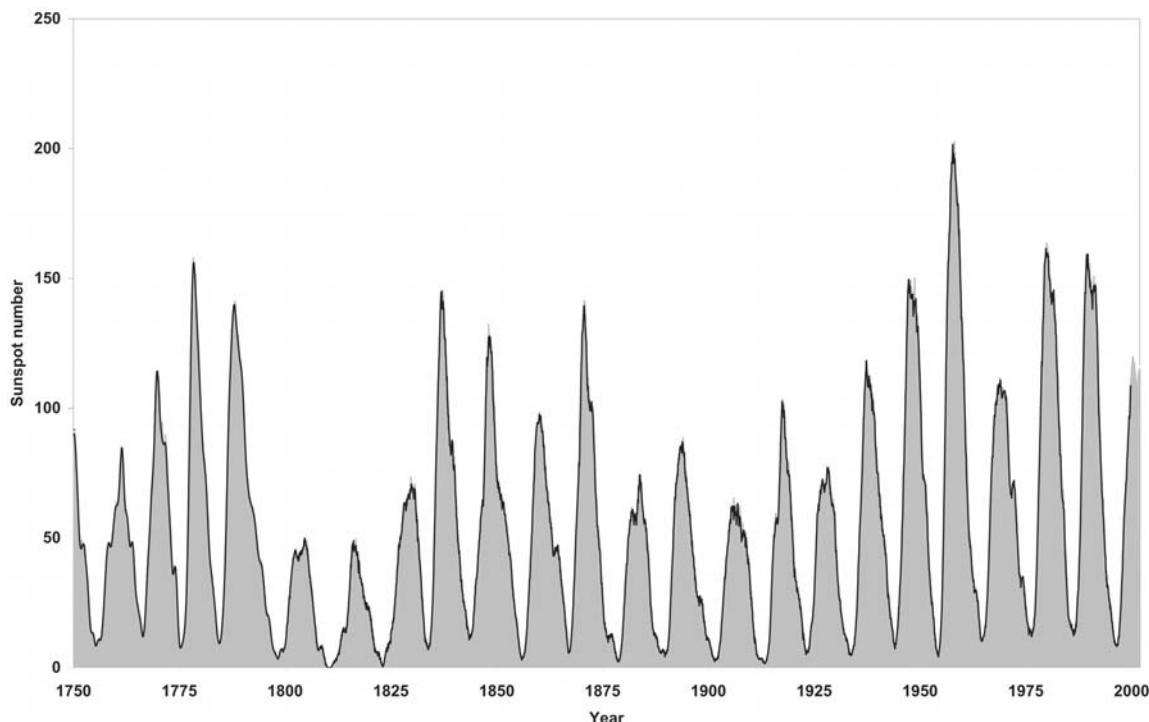

Figure C47 The observed variations in the number of sunspots since 1750, showing the 13-month running mean of monthly numbers. (Data from National Geophysical Data Center, NOAA.)

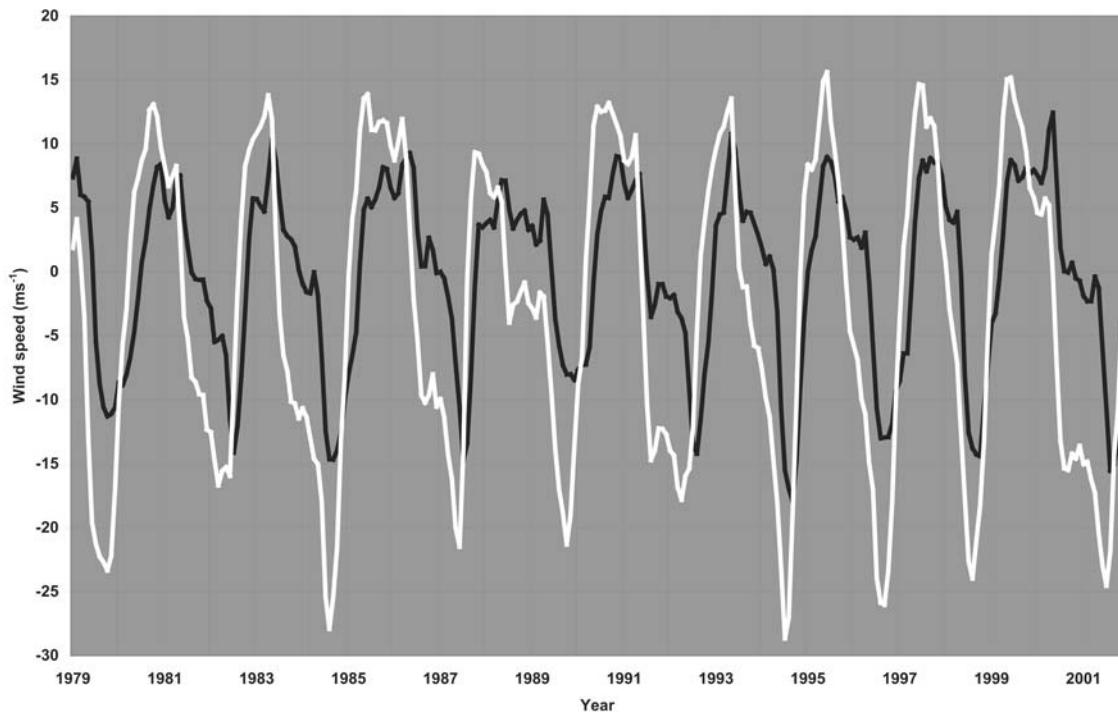

Figure C48 The quasi-biennial oscillation of the winds in the stratosphere over the equator shows a pronounced periodic reversal. The scale of this oscillation is greatest at around 30 hPa (white line) and reduces at lower levels, as shown by the values at 50 hPa (black line) as the periodic feature migrates downward over time, so that the peaks occur first at high levels. (Data from NOAA, available on websites: <ftp://ftp.ncep.noaa.gov/pub/cpc/wd52dg/data/indices/qbo.u30.index> and <ftp://ftp.ncep.noaa.gov/pub/cpc/wd52dg/data/indices/qbo.u50.index>.)

altitude of 30 km (a pressure of 30 hPa). The easterly phase of the QBO is stronger than the westerly phase.

The accepted explanation for reversal of the winds in the equatorial stratosphere involves the dissipation of upward-propagating Kelvin and Rossby waves in the stratosphere. These waves originate in the troposphere and lose momentum in the stratosphere by the process of radiative damping. This involves rising air cooling and radiating less than the air that is warmed in the descending part of the wave pattern. Westerly momentum is imparted by decaying Kelvin waves. Rossby waves perform a similar function in respect of the easterly phase. These two sets of waves combine to produce a regular reversal of the upper atmosphere winds.

The tropospheric biennial oscillation (QBO)

The tropospheric biennial oscillation (TBO) is the less well-defined cousin of the QBO. The TBO appears in many meteorological series, but it is nowhere near as distinct as the QBO. Moreover, both within individual series and between different series, its period varies from around 2.1 to 2.6 years in a manner that cannot be directly linked to the QBO. In part this disconnection may be related to the dominant role of the annual cycle in many meteorological series, and especially to the extremes of winter and summer. Because the QBO and TBO move in and out of phase with the annual cycle there is possibility that the weaker oscillation will tend to “phase lock” with the annual cycle and then skip a beat every third year or so. This potentially chaotic behavior has compounded the difficulty of

establishing whether the QBO and TBO are manifestations of a common meteorological phenomenon or reflect separate physical processes.

El Niño Southern Oscillation (ENSO)

The El Niño Southern Oscillation (ENSO) is a major contributor to interannual fluctuations in the tropical climate. It is best known for its warm (El Niño) episodes, when much of the eastern tropical Pacific has well above normal sea surface temperatures (SST). These are interspersed with either more normal conditions or cool (La Niña) episodes. This coupling between the atmosphere and the ocean across the equatorial Pacific shows a quasi-cyclic periodicity centered around 3–5 years with the strength of both warm and cool events varying appreciably over time. Detailed analysis of SST for the central equatorial Pacific since 1950 shows that much of the variance is made up of two periodicities: the first being the TBO (period 26 months) and a quasi-quadrennial oscillation (QQO) with a period of 53 months (Figure C49). Here again there is evidence of “phase locking” between ENSO and the annual cycle, as warm (El Niño) episodes tend to peak around the end of the calendar year, thereby making their spacing erratic and difficult to predict.

Other interannual oscillations

The insights provided by modeling ENSO have led to renewed interest in other forms of atmosphere–ocean oscillations around the world. In particular the North Atlantic Oscillation (NAO),

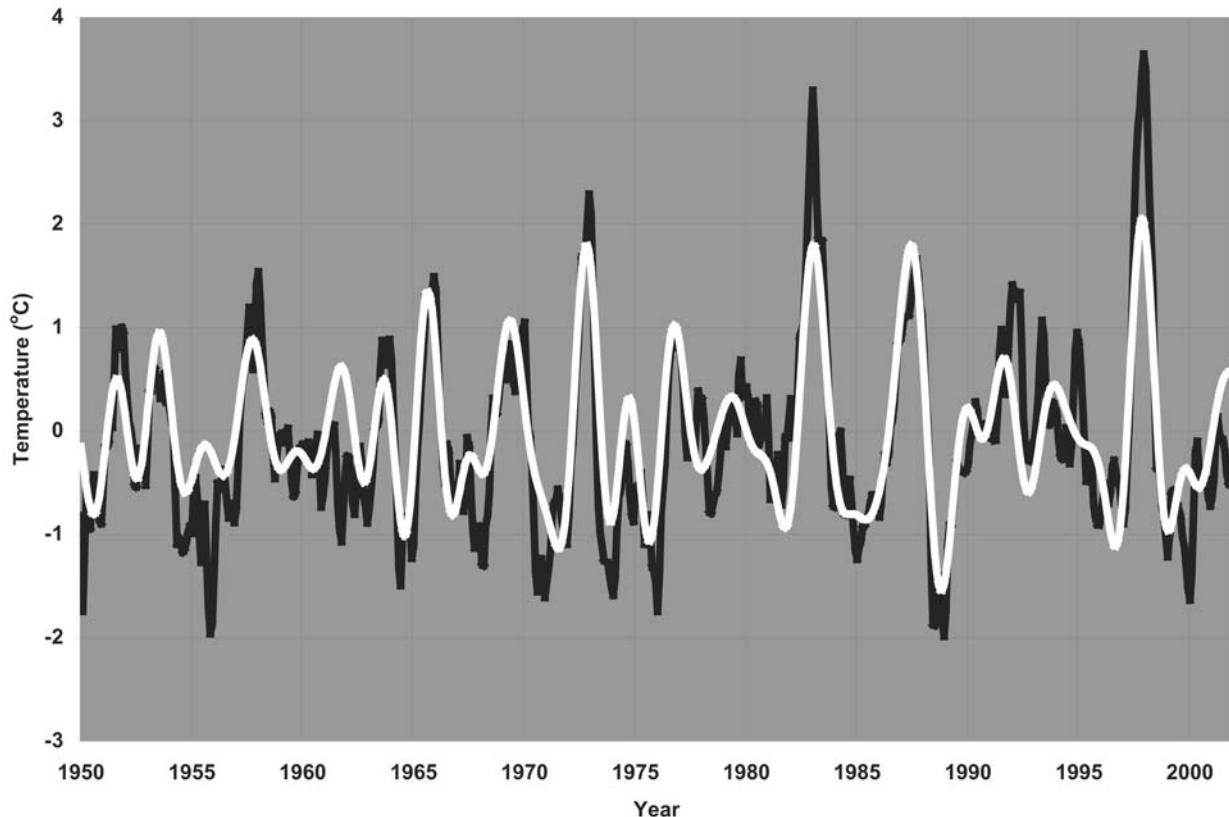

Figure C49 A comparison of the observed bimonthly temperature anomalies in the central equatorial Pacific Ocean (black line) and a reconstruction of this series using a combination of two filtered versions of the data (white line): one centered on 24 months and the other centered on 48 months. This result shows that the data can be largely represented by the combination of a tropical-biennial oscillation (TBO) and a quasi-quadrupennial oscillation (QQO) that is effectively “phase locked” to the warm events peaking at around the end of the calendar year.

the Pacific Decadal Oscillation (PDO) and Antarctic Oscillation have attracted most interest. In certain cases these oscillations were first identified in interannual fluctuations in the pressure difference patterns between mid- and high latitudes. So the NAO is usually measured in terms of the pressure difference between Iceland and the Azores during the months of December to March and is a measure of the strength of the winter circulation of the midlatitudes of the northern hemisphere. Although the NAO shows some evidence of periodicities in the region of 7–9 years and around 20 years, these do not show real statistical significance. The PDO tends to occur with a periodicity of around 20 years.

Decadal oscillation

Many meteorological records show evidence of periodicities around 10–12 years. Often these have been linked with solar activity, (see section on Solar activity), but the case for the link is not always convincing as they are inclined to shift in phase with respect to the 11-year sunspot cycle. So, although seen in both large-scale temperature patterns across the northern hemisphere, notable over North America, and in the oscillations in the Pacific Ocean, including ENSO, these various manifestations do not show any particular coherence.

Bidecadal oscillation

A cycle with around 20 years frequently appears in meteorological records, and in some instances is closely linked with the double-sunspot cycle (known as the Hale cycle). One of the most convincing associations is with the incidence of drought in the western United States. An alternative hypothesis however, is that the 18.6-year lunar tidal cycle may be the cause of this variation. Other impressive examples of bidecadal oscillations are found in Greenland ice-core data, central England temperature records and extratropical Pacific SST, where it is part of the case for the PDO.

Multidecadal oscillations

There is considerable evidence of 65–90-year oscillation in both temperature records and tree-ring data. In particular, for the North Atlantic and its bounding continents, there is a basin-wide pattern of sea surface temperature anomalies. This is probably related to the NAO, but it has now become known as the Atlantic Multidecadal Oscillation (AMO). This periodicity has also shown up in tree-ring data in northern Eurasia, sea level measurements in northern Europe and rainfall observations in the United States. It appears also to be part of a wider phenomenon, as there is evidence of an oscillation in the global

climate system of period 65–70 years, although in a record of only 135 years this is the subject of some doubt.

Longer-term cycles

The best-established cycles in the climate are associated with the waxing and waning of the ice ages over the last million years or so. These have periodicities centered on 100 000, 41 000 and 23 000 years (100, 41 and 23 kyr). These cycles appear to be the result of variations in the Earth's orbital parameters, which lead to the amount of solar radiation falling at different latitudes at different times of the year varying in a cyclic manner. These variations result in the amount of snow and ice in polar regions rising and falling with a characteristic 100-kyr sawtooth pattern, which is modulated by the 41- and 23-kyr cycles (Figure C50).

In addition, within the last ice-age cycle there is evidence of a roughly 1500-year cycle that has been linked with variations of the ocean circulation in the North Atlantic. While the most striking evidence of this cycle is during the last ice age, it appears to have played a part in less dramatic climatic changes during the last 10 kyr.

Ocean–atmosphere coupling

The most obvious explanation for the many oscillations observed in the global climate is that they are the product of feedback processes between the atmosphere and the oceans. Because the atmosphere and the oceans respond to various

physical stimuli on different timescales, it is possible for them to interact nonlinearly to produce quasiperiodic behaviour. Indeed, it is possible to produce nonlinear models of the atmosphere alone that are capable of producing substantial interannual variability. When combined with the fact that the oceans are more likely to exhibit longer-term fluctuations, it is possible for coupled atmosphere–ocean computer models to produce periodic fluctuations on every timescale from the interannual to the millennial.

Physical explanations of ENSO involve large-scale atmosphere–ocean interactions. During warm (El Niño) episodes the combination of the warming of the ocean off the coast of South America, the associated strong convection and the reduced trade winds all contrive to maintain the abnormal conditions. Similarly, during cool (La Niña) episodes the strong convection in the western Pacific and the strong trade winds should maintain the below-normal SST in the eastern equatorial Pacific. So, in principle, the system should stay in one or other state indefinitely. The reason this does not happen is because of changes in the depth of the thermocline in the ocean due to Kelvin and Rossby waves in the ocean.

Close to the equator downwelling and upwelling Kelvin waves in the depth of the thermocline move rapidly eastwards across the Pacific basin every 2 months or so. Farther from the equator wind fields generate Rossby waves moving westward whose speed depends on the latitude. These speeds are much slower than those of the equatorial Kelvin waves. Near the equator they cross the Pacific basin in about 9 months. Toward the poles the time increases rapidly, to be about 4 years at 12°N

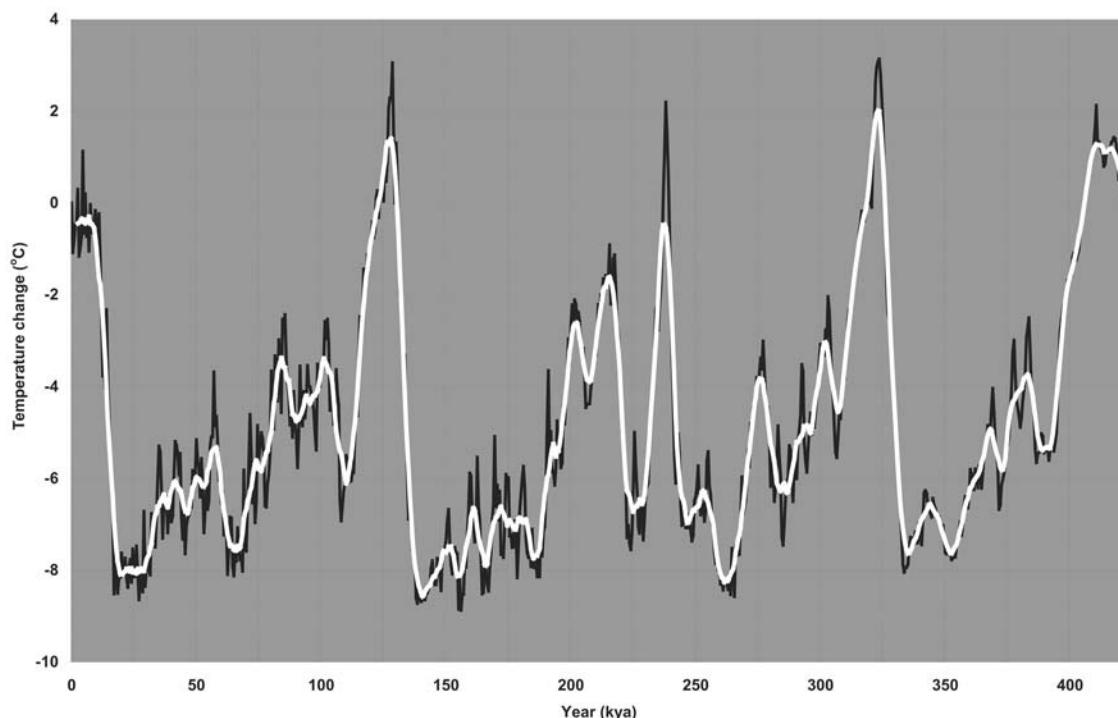

Figure C50 The estimate of the temperature change over Antarctica using measurements of the hydrogen isotope ratio (H/D) in an ice core drilled at the Vostok research station, going back to over 400 000 years ago (400 kya). This shows how the record is dominated by a 100-kyr periodicity over the last four ice ages, while during the glacial periods there is evidence of shorter periodicities of around 20 and 40 kyr. (Data archived at the World Data Center for Paleoclimatology, Boulder, Colorado, USA.)

and S. The combination of these effects leads to the quasiperiodic appearance of warm water in the eastern Pacific (El Niño) every 3–5 years, interspersed with cool (La Niña) episodes.

The unresolved question about atmosphere–ocean coupling is whether the atmosphere or the ocean is the driving force behind interannual periodicities. In principle, the greater thermal inertia of the oceans should exert a dominant influence, and hence make the prediction of behavior months and years ahead a practical proposition. In practice, both the models and experimental forecasting suggest that, with both ENSO and the NAO, the chaotic influence of the atmosphere exerts an overriding influence.

In the longer term changes in the thermohaline circulation of the world's ocean currents may play a part in the 1500-year periodicity seen within the ice age cycle. In particular the pattern of currents in the North Atlantic appears to be especially sensitive to shifts in temperature and salinity of the surface water up around Iceland. Computer models of the oceans show that changes in evaporation, precipitation and freshwater runoff from the surrounding continents can produce sudden switches in circulation patterns. It is proposed that, during the last ice age, such changes, combined with surges of icebergs from the northern ice sheet, led to dramatic swings in temperatures around the northern hemisphere.

Solar activity

Since the seventeenth century, observations on the sun's photosphere have revealed sunspots whose number, size and duration vary over time in a more or less regular manner with a period of about 11 years (Figure C49). The variation in number during each cycle is more than two orders of magnitude greater than for any shorter period. It ranges from virtually no spots during the minimum of solar activity to just over 200 in the most active cycle that peaked in 1957. The instrumental record has now accumulated reliable data since around 1750, and is now in its twenty-third cycle of activity, which peaked at around 120 spots in 2000.

Another measure of solar activity is the number of faculae, which is closely associated with sunspots: they brighten as the number of dark sunspots increases. Their increased brightness is the dominant factor in changing solar output rather than sunspot darkening. A series of satellites have made measurements that provide unequivocal observations of how the sun's output varies with the 11-year cycle in solar activity (Figure C47). These results show that the level of total solar irradiance (TSI) is greatest around the solar maxima and the amplitude of the solar cycle variation is slightly less than 0.1%.

Models of the TSI that combine changes in sunspot number and faculae brightness produce a good fit with satellite observations of the TSI. These models explain not only the observed changes in solar output since 1980, but also the longstanding hypothesis that the cold period known as the Little Ice Age may be related to changes in solar activity. In particular, the colder weather of the seventeenth century appears to have been the result of an almost complete absence of sunspots during this period, known as the "Maunder Minimum".

The small change in the TSI during the last two solar cycles is, however, on its own, an order of magnitude too small to explain observed correlation between solar activity and global temperature trends since the late nineteenth century. Predicted changes in TSI since the seventeenth century, which include the sun's magnetic, solar cycle length, solar cycle decay rate, solar rotation rate and various empirical combinations of all of these, suggest greater changes in the TSI (Haigh, 2000). These

models produce widely different estimates of changes since the Maunder Minimum, ranging between 1 and 15 W m⁻² although most estimates lie in the range 2.5 to 5 W m⁻². Even so, this may be sufficient to explain much of the observed correlation between global climate change and solar variability during the last three to four centuries.

The TSI also varies with wavelength. The greatest changes are in the ultraviolet (UV) region. These wavelengths are largely absorbed in the atmosphere and this could enhance the impact on the weather. In particular, the amount of UV affects the amount of ozone formed in the stratosphere. This, in turn, alters the radiative balance of both the stratosphere and lower levels of the atmosphere. Computer models, which include realistic changes in UV and ozone, show a significant effect on simulated climate. Solar cycle variability may therefore play a significant role in regional surface temperatures, even though its influence on the global mean surface temperature is small. So it is possible, by both radiative and dynamical means, that variations in solar UV output can produce disproportionate changes in the atmosphere.

Possible links between the sun's magnetic field, solar activity and the Earth's weather involve a complex set of mechanisms. The magnetic polarity of sunspots alternates between successive cycles. Known as the Hale magnetic cycle, this 22-year cycle could be the key to the amplification process. Furthermore, the sun's magnetic flux at the Earth rose by 130% between 1901 and around 1990. While it exhibits periodic fluctuations apparently linked to 11-year sunspot cycle, these are not precisely in phase with it and are less regular.

The direct effect of fluctuations of the sun's magnetic field on the weather may relate to the quantity of energetic particles emitted from the sun. Second, the overall strength of the sun's magnetic field alters the Earth's magnetic field, and with it the amount of cosmic rays (energetic particles from both the sun and from elsewhere in the universe) that are funneled down into the atmosphere.

The impact of variations in the solar magnetic field depends on the energy of the cosmic rays as they enter the Earth's atmosphere. Cosmic rays of low energy have their origin in the sun and are absorbed high in the atmosphere. Galactic cosmic rays (GCR) are of much higher energy and have an appreciable impact on the troposphere. When the sun is more active GCR are less able to reach the Earth and so their impact on the lower atmosphere is inversely related to solar activity.

Cosmic rays produce various chemical species, which alter the concentrations of radiatively active molecules such as ozone (O₃), nitrogen dioxide (NO₂), nitrous oxide (N₂O) and methane (CH₄). These species are most likely to be seen in the stratosphere where their impact will be similar, but less significant to the changes caused by solar UV variations. In addition, the formation of ions will affect the behavior of aerosols and cirrus clouds that have a direct radiative impact and also alter the amount of water vapor throughout the atmosphere. These changes could lead to shifts in the radiative balance of both the stratosphere and troposphere and so produce long-term fluctuations in the temperature.

There is also a question of whether GCR alter cloud cover at lower levels. An analysis of satellite observations of global total cloud cover, between 1984 and 1991, suggested a correlation with cosmic ray flux. Increased GCR flux appears to cause total cloud amounts to rise, and this cools the climate. The interannual variations in cloudiness are, however, difficult to distinguish from parallel changes caused by warm and cold ENSO events.

There is, however, a possibility that charged particles are more efficient than uncharged ones in acting as cloud condensation nuclei (CCN), even though only a small proportion of aerosol particles are capable of acting as ice nuclei, depending on chemical composition or shape. Recent work has provided the first observational evidence of cosmic ray-induced aerosol formation in the upper troposphere. In theory, the higher level of charge carried by such aerosols can enhance the formation of ice nuclei. By changing precipitation rates or radiative balance, the changes in the clouds then affect atmospheric dynamics and temperature.

Tidal forces

The other obvious periodic influences on the weather tidal forces, which can have a direct effect on the movement of the atmosphere, the oceans and even the Earth's crust, are the Earth's tides. The nature of these links varies in complexity. Tidal effects in the atmosphere are relatively predictable and measurable, but tiny compared with normal atmospheric fluctuations. In the oceans the broad effects can be calculated, but estimating changes in the major currents is much more difficult. In particular, recent satellite altimetry studies have come up with some interesting results that may shed new light on the climatic implications of the dissipation of tidal energy. Prior to this work it was widely assumed that this energy, representing the effect the moon receding from the Earth at a rate of some four centimeters a year, was dissipated in the shallow waters of the continental shelves around the world. It is now reckoned that about half this energy is fed into deeper water where it exerts a significant effect on the strength of the major ocean currents and hence the transport of energy from the tropics to polar regions. So the 18.61-year lunar cycle affects the strength of the principal ocean currents.

As for movements of the Earth's crust, the problems are compounded by possible links with solar activity. The direct influence of the tides could influence the release of tectonic energy in the form of volcanism. Since there is considerable evidence that major volcanic eruptions have triggered periods of climatic cooling, this would enable small extraterrestrial effects to be amplified to produce more significant climatic fluctuations. In addition, there is evidence that intense bursts of solar activity interact with the Earth's magnetic field to produce measurable changes in the length of the day. Such sudden tiny changes in the rate of rotation of the Earth could also trigger volcanic activity. It should be noted that, while there is no evidence that their occurrence was in any way related to this effect, the three climatically important volcanoes in the second half of the twentieth century (Agung in 1963, El Chichon in 1982 and Pinatubo in 1991) were spaced in such a way as to have a confusing impact on the interpretation of any solar or tidal effects.

The Earth's orbital parameters

The explanation of the periodicities in the ice ages relies on the Earth's orbital parameters producing latitudinal and seasonal variations in incident solar radiation. In particular, the variations in the amount of sunlight falling in summer at high latitudes in the northern hemisphere appear to affect the amount of build-up of ice sheets over the continental landmasses. These changes are controlled by the precession of the equinoxes (the 19- and 23-kyr periodicities) and the variations of the tilt of the Earth's axis (the 41-kyr periodicity) and the 100-kyr periodicity due to the eccentricity of the Earth's orbit. There is, however, a problem

with this proposal. While the first two periodicities are probably sufficient to trigger significant climatic changes, the 100-kyr eccentricity periodicity is the weakest of the orbital effects. Nevertheless, the 100-kyr ice age cycle is the strongest feature of the climatic record in the last 800 000 years.

A solution to this problem is to use a differential model in which the rate of change of the climate is a function of both the orbital forcing and the current state of the climate (Imbrie et al., 1992, 1993). Not only is this a more realistic representation of climatic behavior, but it also contains a nonlinear relationship between the input and the output that has important physical consequences. For instance, if the model is sensitive to changes in ice volume that are reflected in the time constants for the growth and decay of the ice sheets and the lag between the changes in solar radiation falling in summer at high latitudes of the northern hemisphere, it can be shown to achieve a reasonable representation of the observed long-term behavior. Various models have tuned the parameters to achieve the best fit between the calculated ice-volume changes and the oxygen-isotope record to give a reasonable match with past changes. The dependence on empirically derived time constants, which are broadly linked to the physical behaviour of the ice sheets, is a measure of the nonlinear response of the global climate to changes in the orbital parameters.

A more sophisticated approach is to draw on the fact that there is evidence that the North Atlantic appears to have exhibited three different modes of circulation during the last ice age (Paillard, 1998). As a result of this behavior it appears that the global climate is capable of switching between three distinct regimes (e.g. interglacial, mild glacial and full glacial). Switches between these regimes could well be controlled by a combination of changes in insolation, resulting from the Earth's orbital parameters, combined with changes in ice sheet volume. By defining the conditions for the transition between the three regimes a model has been produced that is capable of reproducing with remarkable accuracy the changes in ice sheet volume over the last million years.

DEGREE DAYS

The degree-day is an index number originally developed by heating, ventilation, and air conditioning engineers (Houghton, 1985). The heating degree-day was developed to assess energy needs necessary to heat business buildings and private homes. The heating degree-day index assumes that people will begin to use their furnaces when the mean daily temperature drops below 65°F. It is computed by subtracting the mean temperature for a day from 65°F to determine the total number of heating degree-days for a given day. When the mean daily temperature is above 65°F there are no heating degree-days. The greater the range in a mean daily temperature from 65, the greater the number of heating degree-days; hence, more fuel must be expended (Ahrens, 2001).

The cooling degree-day is used to assess energy needs required to cool buildings and homes. When the mean daily temperature exceeds 65°F people will begin to employ measures to cool their environment by switching on their air-conditioners and cooling pumps. The cooling degree-day index is computed by subtracting 65°F from the mean daily temperature. If the two temperatures are the same, there are no cooling degree-days. The greater the range in a mean daily temperature from 65, the greater the number of cooling degree-days; hence, more power must be expended to maintain a comfortable environment. Cooling degree-days provide a guide for builders when planning the size and type of cooling units to install in structures. Power companies may use these data to predict energy demands throughout a summer season. When combined, the heating and cooling degree-day indices provide a practical way of assessing energy requirements for a region throughout the year.

The freezing or thawing degree-day is a measure of the combined duration and magnitude of below or above freezing temperatures during a freezing season. It is designated as an air freezing/thawing index when taken for air temperatures 4.5 ft above the ground, and surface freezing/thawing index for temperatures immediately below the surface. The freezing/thawing degree-day (FDD) is used to assess conditions related to problems with highway construction, soil disturbance

Table D1 Base temperatures for selected crops and insects.
By reviewing the climate data for a region and comparing mean daily temperatures, growing degree-days can be computed for a crop

Crops and insects	Base temperatures
Wheat, barley, rye, oats, flaxseed, lettuce, asparagus	40°F
Sunflower, potato	45°F
Sweet corn, corn, sorghum, rice, soybeans, tomato	50°F
Corn rootworm	44°F
Alfalfa weevil	48°F
Black cutworm, European corn borer	50°F
Green cloverworm	52°F

involving mass movements, and foundation assessment due to groundwater through flow and sapping processes resulting from freeze/thaw conditions.

The growing degree-day is used by farmers as a guide for planting and estimating when a crop will be ready for harvest; and closely associated with crop production, the peak time of a season in which crop-destroying insects occur. The growing rate or biological development in plants and insects is based in part upon the amount of heat absorbed during a growing season of a plant or the life cycle of an insect. Each species, whether crop, weed, insect, or disease organism, is adapted to grow over a certain minimum (base) temperature, and decline in growth at a maximum temperature. The quantity of heat absorbed as a requirement of sustained growth and development is often referred to as a heat unit or degree-day. By subtracting the base temperature (Table D1) for a given crop from the daily mean temperature, the number of growing degree-days may be computed. When growing degree-days are totaled, farmers can establish an estimate of the minimum number of days of growth required for a crop until it is ready for harvest. While this index provides a quick guide for crop development, soil moisture properties, precipitation amounts, and other climatic variables are not considered in this general format.

Discussion

The *Handbook of Applied Meteorology* (Houghton, 1985) discusses the degree-day on the basis of heating or cooling requirements, growing degree-days, or freezing/thawing

degree-days. Degree-days are generally quantified from a threshold or base temperature determined for each condition, i.e. cooling, heating, growing, or freezing/thawing degree-days. Threshold temperatures include:

1. 65°F (18°C) for cooling energy requirements generating cooling degree-days (CDD), and expressed as, $CDD = \sum(\bar{T}_i - A)$ where, \bar{T}_i is the mean daily temperature for a day i , A is a threshold temperature, and \sum is the summation over a period of days, such as a week, month, or season. If \bar{T}_i is < 65°F, CDD is 0.
2. 65°F (18°C) for heating energy requirements generating heating degree-days (HDD) with the equation written as, $HDD = \sum(65 - \bar{T}_i)$. If \bar{T}_i is > 65°F, HDD is 0.
3. Variable base temperatures (B) for growing degree-days (GDD) dependent upon crop type where, $GDD = \sum(\bar{T}_i - B)$, and B is a base temperature for a given crop type. If $\bar{T}_i < B$, GDD is 0. Growing degree-days are similar to cooling degree-days, only the base temperature can vary with different plant types in computing growing degree-days, while the threshold temperature for cooling degree-days generally remains constant at 65°F.
4. 32°F (0°C) for freezing degree-days (FDD) where, $FDD = \sum(32 - \bar{T}_i)$. If \bar{T}_i is > 32°F, HDD is 0. By extension, thawing degree-days (TDD) are computed as, $TDD = \sum(\bar{T}_i - 32)$. If \bar{T}_i is < 32°F, TDD is 0.

Degree-day values have been used to show that climate change models may not adequately explain the energy expenditures that would be expected with reported increases in mean temperatures, increases in extreme high temperatures, and increases in the frequency, duration, and magnitude of summer heat waves. Hansen et al. (1998) developed a common-sense climate index using degree-days and reported that parts of North America are showing changes consistent with climate model predictions given increasing levels of greenhouse gases. A graph for New York City's LaGuardia airport shows a decrease in heating and cooling degree-days for the past few decades. Balling (1999) analyzed temperature data derived from NOAA's Daily Historical Climatology Network for the conterminous United States from 1950 to 1995. He computed and plotted the heating, cooling, and total degree-days for this time period. His graph paradoxically shows no statistically significant trends throughout this time. He reports a 0.2% decrease in heating degree-days, 5.7% decrease in cooling degree-days, and a 1.0% decrease in total degree-days. When considering climate change and energy needs, this slight decrease in cooling degree-days would indicate a reduction in the energy needs to cool buildings, and is contrary to what would be expected with warming trends. The period of time reviewed in this study was one of substantial buildup of greenhouse gases throughout the Earth's atmosphere. Numerous climate models for global warming suggest that a decrease in heating degree-days and increase in cooling degree-days would follow rises in these greenhouse gases, yet the analysis of degree-day patterns from the historical climate record for this 35-year period does not provide empirical evidence to support these climate model simulations.

A climatic classification using degree-days has also been reported. The somewhat generalized nature of this classification does not appear to provide a significant contribution toward the enhancement of the more widely accepted climate classification systems since it only addresses degree-days with respect to

ordinal-scaled (e.g. very severe, severe, moderate, mild, warm, or hot) seasonal characteristics. Figure D1 (Houghton, 1985) illustrates this classification for the eastern United States.

Phenology models

The degree-day concept is fundamentally simple in design, but it has limits when used to determine growing degree-days for agricultural use. Phenology models predict time of growth events for organisms (insects and plants). Plants and insects require a minimal amount of heat to develop throughout their life cycles. An accumulation of heat units is called physiological time, and it is measured in degree-days (°D). Degree-day methods provide scientists with quantitative methods used to assess the physiological time of organisms. Estimating heat units or accumulated degree-days provides a more biologically accurate snapshot of an organism's stages of development than using calendar days based upon variations in yearly climate records.

Organisms (plant and insect) develop faster when temperatures are higher, although this does not imply there is a yield or quality benefit in warm seasons. While organisms will grow faster in warmer temperatures, and they are exposed to greater heat for fewer days, the net accumulation of heat units (degree-days) required for development is about the same as for organisms developing under cooler conditions for more days. Since temperatures fluctuate from cool to hot during a growing season, it is the total heat accumulation derived between the lower and upper threshold temperatures for each plant species that determines the time to complete development. Plant development ceases when a temperature falls below a lower threshold, and also begins to decline and ultimately stop development when the temperature exceeds an upper threshold. In some cases the maximum temperature can exceed the base temperature for a plant, thus 0 growing degree-days are accumulated, e.g. if a maximum temperature is 60°F, a minimum temperature is 35°F, then the average daily temperature is $(60 - 35)/2 = 47.5^{\circ}\text{F}$. If the base temperature for this plant = 50, then $47.5 - 50 = -2.5 = 0$ degree-days. This example results in 0 growing degree-days (an underestimation), although the average temperature used in the calculations is above the lower threshold for the plant.

When temperatures become excessively hot, the degree-day system will give heavy weighting to these temperature extremes that can actually be detrimental to the plant. A modified growing degree-day provides an adjustment for high temperature extremes. If a temperature exceeds a threshold high (Figure D2) for a given plant, it is adjusted back to the threshold. Alternatively, if the lowest temperature is below the threshold low (Figure D2) for a plant, it is adjusted up to the threshold. Once the temperatures have been adjusted, the average daily temperature is computed and used to compute growing degree-days. Threshold temperatures are used for certain crops (e.g. corn) and based on the assumption that development is limited once a threshold low or high is exceeded.

While degree-days are generally based upon a mean daily temperature (maximum daily temperature – minimum daily temperature/2), the influence of diurnal patterns is lost when only considering these temperature extremes. Computing growing degree-hours (GDH) may provide a more representative way of assessing variability in the daily temperatures. Mimoun and DeJong (1999) have documented that accumulated

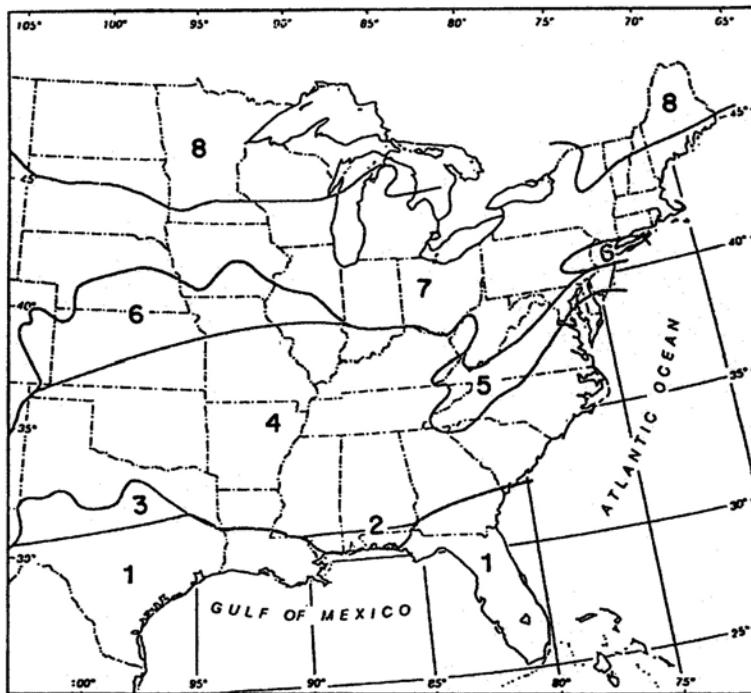

Figure D1 A climatic classification of the United States using heating (HDD) and cooling (CDD) degree days. Key:

	Winter	HDD	Summer	CDD
1	Mild	<2000	Hot	>2000
2	Mild		Warm	1000–2500
3	Moderate	2000–4000	Hot	
4	Moderate		Warm	
5	Moderate		Mild	<1000
6	Severe	4000–8000	Warm	
7	Severe		Mild	
8	Very severe	>8000	Mild	

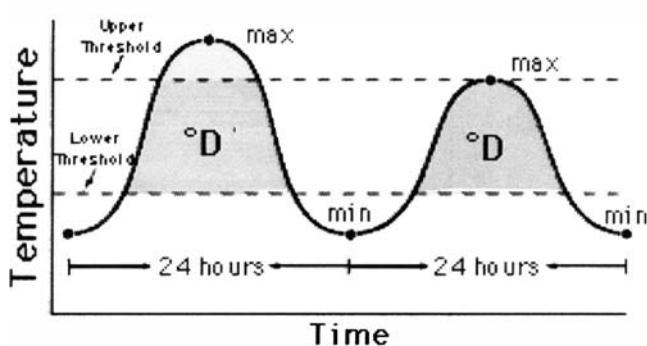

Figure D2 Thresholds (dashed lines) and area representing degree-days (shaded) for 24-hour time periods (from the University of California, Pet Management Program, 1990).

temperatures (in growing degree-hours) for 30 days after bloom are highly correlated with yearly differences in harvest date for peaches, plums, and nectarine cultivar. A general use would be to compare records of bloom dates (when 50% of the flowers on a tree or orchard are fully open) and harvest dates for previous years, look for a year with a comparable GDH accumulation (at 30 days after bloom), and expect the number of days from bloom to harvest will be similar to that year.

Seasonal variances and climatic region can also impact how accurately a degree-day method represents actual degree-days. Several refinements in computing degree-days have been reported (Allen, 1976; Wilson and Barnett, 1983; Zalom et al., 1983). These methods include (from the simplest to the most mathematically complex): single triangle, double triangle, single sine, double sine, and Huber's method (a modification of the single sine method). Each has been applied to determine heat units required for insect development, and by extension to agricultural development since insects can have a pronounced and detrimental affect

on annual crop yield. These methods are based on the area under a diurnal temperature curve and between critical threshold temperatures.

The degree-day computational techniques including the cut-off methods that establish parameters for the upper and lower threshold temperatures are discussed in University of California, 1990, Zalom et al. (1983), and at the web site for University of California, Davis, (<http://www.ipm.ucdavis.edu/WEATHER/ddconcepts.html>).

Summary

The degree-day was initially designed by heating and cooling engineers to assess the cooling and heating needs of business buildings and homes. A number of procedures for computing degree-days have been presented in this discussion. The more robust mathematical models (triangle and sine methods) tend to provide more credible results than those models that only use the mean daily temperature. Growing degree-days have been used to study pest management and further applied in agricultural studies. An ordinal climatic classification has also been proposed, although it does not provide any significant contribution to the more widely accepted climate classification systems.

DESERTIFICATION

The prolonged multiyear drought in the early 1970s in the Sahelian zone, stretching from West Africa to the Horn of Africa, precipitated a sharp increase in death and morbidity of humans and livestock, as well as widespread environmental deterioration. Stark satellite images capturing the degradation of the land surface throughout the region were backed up by ground-truth photographs of the landscape and human suffering.

Although many articles, papers, and reports from various countries begin with comments on the role of the Sahelian drought in the growing interest in desertification (e.g. Glantz, 1977; UN Secretariat of the Conference on Desertification, 1977; Quintanilla, 1981; Zonn, 1981), that drought was neither the first manifestation of the desertification phenomenon nor the only reason for scientific interest in it. In fact, Aubreville (1949), a French scientist, was the first to use the term “desertification” in his report, and others (e.g. Le Houérou, 1962) have discussed the phenomenon since the late 1950s. Desertification received immediate and widespread public attention ever since the early 1970s, as witnessed by the creation of the United Nations Conference on Desertification (UNCOD) in Nairobi in 1977. It was clear that the conference was convened mainly as a result of the devastating impacts of drought in the West African Sahel earlier in the decade.

This conference brought the concept of desertification and its demographic aspects into the spotlight (UN Secretariat of the Conference on Desertification, 1977). The conference report described desertification in the following way:

The diminution or destruction of the biological potential of the land...can lead ultimately to desert-like conditions. It is an aspect of the widespread deterioration of ecosystems, and has diminished or destroyed the biological potential, i.e., plant and animal production, for multiple use purposes at a time when increased productivity is needed to support growing populations in quest of development. Important factors in contemporary society – the struggle for development and the effort to increase food production, and to adapt and apply modern technologies, set against a background of population growth and demographic change – interlock in a network of cause and effect. Progress in development, planned population growth and improvements in all types of biological production and relevant technologies must therefore be integrated. The deterioration of productive ecosystems is an obvious and serious threat to human progress. In general, the quest for ever greater productivity has intensified exploitation and has carried disturbance by man into less productive and more fragile lands.

Overexploitation gives rise to degradation of vegetation, soil and water, the three elements which serve as the natural foundation for human existence. In exceptionally fragile ecosystems, such as those on the desert margins, the loss of biological productivity through the degradation of plant, animal, soil and water resources can easily become irreversible, and permanently reduce their capacity to support human life. Desertification is a self-accelerating process, feeding on itself, and as it advances, rehabilitation costs rise exponentially. Action to combat desertification is required

urgently before the costs of rehabilitation rise beyond practical possibility or before the opportunity to act is lost forever (Reining, 1978, p. 3).

The 1977 Nairobi conference also served to bring together representatives of countries whose arid and semiarid landscapes had been directly or indirectly affected by desertification processes. More than a score of governments produced and shared their national case studies about desertification processes within their borders. The actual usefulness of this conference varied from country to country. It became quite clear that desertification was a local to national-level problem with transboundary impacts. It is listed among major global problems because of its occurrence and interest worldwide.

For some countries, such as the People's Republic of China, the conference drew the attention of national policy makers toward arid lands research and helped to elevate such research to a sustained national priority. It remains a high priority more than 25 years after UNCOD. The former Soviet Union's State Committee for Science and Technology (GKNT) established, with the United Nations Environment Program (UNEP) support, international training courses on various aspects of desertification (e.g. overgrazing, salinization, woodcutting) and on ways to identify and combat them (Plit et al., 1995; Zonn, 1981). Today, almost all of the arid parts of the former Soviet Union are within independent countries of Central Asia. Nevertheless, the Russian Federation contains in its Kalmykia Republic the only desert in Europe (Saiko and Zonn, 1997).

In the United States the attention of national policy makers was directed at the time toward environmental degradation in arid areas, and a plan of action was drawn up to assess desertification in a national context (Sabadell et al., 1982). However, the US government refused to admit that desertification processes were taking place on its soil. It believed that desertification was a Third World problem, even though the US rangelands were being overgrazed, dust storms were occurring, and salinization and waterlogging of the soils could be witnessed.

Desertification is a complex multifaceted phenomenon, requiring the expertise of researchers in disciplines such as climatology, soil science, meteorology, hydrology, range science, agronomy, ecology, veterinary medicine, as well as geography, political science, economics, and anthropology. It has been defined in different ways by researchers in these and other disciplines, as well as from national and bureaucratic (institutional) perspectives, with each perspective emphasizing different aspects of desertification of concern to it. Scores of definitions exist for the concept, so it is important to know what one is referring to when discussing desertification processes.

At one time desertification as a process was of particular interest to climatologists in their attempts to understand climate variation and change on both short and long time scales (e.g. Charney, 1975; Hare, 1976). With increasing pressure on government decision makers to allow populations to move into climatically marginal areas, the implications of natural variations in climate have become even more important in decisions relating to the use by society of its land in desertification-prone regions. There will always be climatic deserts on the Earth, although their locations can shift. Human-induced expansion of these desertlike conditions can take place in areas where they had not previously existed.

Desertification literature shows a great diversity (and confusion) among definitions (e.g. Carder, 1981). The wide range of

meanings attributed to the concept leads to misunderstandings among physical and social science researchers and policy makers, as well as between researchers and policy makers (see International Geophysical Union Working Group on Desertification, 1975, *passim*). An analysis of the definitions of desertification helps to improve understanding of the phenomenon, of how it is viewed from different disciplines, countries, and bureaucratic units, and whether progress in combating it has in fact been as slow as many observers suggest (e.g. Glantz and Orlovsky, 1986; UN General Assembly, 1981). Scientific interest in desertification remains high, because, as Reynolds and Smith (2002) noted,

There is disagreement concerning the causes and processes of land degradation and its importance; the extent to which land changes are natural (climate-driven) versus anthropogenic; the role of "grass roots" abatement efforts versus scientific and technological ones; how to determine the amount of land affected or at risk; and whether or not desertification is reversible.

Various reviews of the progress to combat desertification processes worldwide exposed limited successes in isolated situations. Some of the scientists who in the 1970s and early 1980s had written about those adverse conditions were, by the end of the 1980s, suggesting that natural causes of desertification in the West African Sahel were dominant. Thus, scientific papers were beginning to challenge the hypotheses about the irreversibility of desertification and about the dominance of influence on the fragile environment of human activities in the region. In other words, desertification is, under certain conditions, reversible in spite of human pressures on fragile arid, semiarid, and dry subhumid ecosystems.

According to the UNCCD (UN Convention to Combat Desertification) website, at the Earth Summit (the UN Conference of Environment and Development, or UNCED) in Rio de Janeiro in 1992, delegates supported a

new, integrated approach to the problem, emphasizing action to promote sustainable development at the community level. It also called on the UN General Assembly to establish an Intergovernmental Negotiating Committee to prepare, by June 1994, a convention to combat desertification, particularly in Africa. In December 1992, the General Assembly agreed and adopted Resolution 47/188 (www.unccd.int).

The UNCCD entered into force in December 1996, after the fiftieth ratification by a government was received. The Conference of Parties, the Convention's supreme governing body, held its first session in October 1997 in Rome, Italy. The UNCCD also noted that

The Convention aims to promote effective action through innovative local programs and supportive international partnerships. The treaty acknowledges that the struggle to protect drylands will be a long one – there will be no quick fix. This is because the causes of desertification are many and complex, ranging from international trade patterns to unsustainable land management practices. Difficult changes will have to be made, both at the international and the local levels (www.unccd.int).

In the following sections these definitions are used as the basis for discussion, as they are often what is seen and used by decision makers. In the last section it is argued that the concept

of desertification also applies to higher rainfall regions than those cited by contemporary arid lands researchers.

Desertification: a process or an event?

Some people consider desertification to be a *process* of change (degradation), whereas others view it as the *end result* of a process of change (a desertlike landscape). This distinction underlies one of the main disagreements on what constitutes desertification. Desertification-as-process has generally been viewed as a series of incremental (sometimes stepwise) cumulative adverse changes in biological productivity in arid, semiarid, and dry subhumid ecosystems. It can encompass decline in yield of the same crop or, more drastically, the replacement of one (maybe equally productive or equally useful) vegetative species by another, or as a decrease in the density of the existing vegetative cover. Desertification-as-event is the creation of desertlike conditions, where perhaps none had existed in the recent past, as the end result of a long-term process of cumulative adverse changes. Many find it difficult to accept incremental changes, whether natural or human-induced, as a manifestation of desertification processes.

In fact, both perspectives represent different aspects of a broader overarching concept of desertification. Thus, seemingly different statements such as “the creation of desertlike conditions in areas once green”, “the encroachment of desertlike conditions”, or “the intensification of a desertlike landscape”, as well as less drastic projections such as “changes in soil structure or in climate” or “the land is becoming less fit for range and crops”, can be encompassed by the concept of desertification.

Form of change

Within the dozens of existing definitions of desertification, many words are used to describe the phenomenon. Some of them complement each other, whereas others appear to be contradictory. A point on which they all agree, however, is that desertification is an adverse environmental process. The negative descriptors used in these definitions of desertification include: deterioration of ecosystems (e.g. Reining, 1978), degradation of various forms of vegetation (e.g. Le Houérou, 1975), destruction of biological potential (e.g. UN Conference on Desertification, 1978), decay of a productive ecosystem (e.g. Hare, 1977), reduction of productivity (e.g. Kassas, 1977), decrease of biological productivity (e.g. Kovda, 1980), alteration in the biomass (e.g. UN Secretariat of the Conference on Desertification, 1977), intensification of desert conditions (e.g. Mecklein, 1980; World Meteorological Organization, 1980), and impoverishment of ecosystems (e.g. Dregne, 1976). More recent definitions continue to fall into one or another of the above categories.

Each of these terms suggests a change in landscape from a favored or preferred state (with respect to quality, societal value, or ecological stability) to a less preferred one. Depending on the particular definition, each has been used to describe the condition of vegetation, soils, moisture availability, or atmospheric phenomena. Other descriptors used in these definitions connote an expansive movement or a transfer of characteristics of a desertlike landscape into an area where such characteristics had not previously existed: extension, encroachment, acceleration, spread, and transformation. If one combined each of

these negative and transfer descriptors with all the other factors cited in the existing definitions, desertification would encompass most kinds of environmental changes related to biological productivity (see Rozanov, 1981). UNEP (1992) produced the *World Atlas of Desertification*, which identified the location as well as threats of desertification processes around the globe (Figure D3).

What is being changed?

Different definitions have focused on changes either in soil (e.g. salinization), vegetation (e.g. reduced density of biomass), water (e.g. waterlogging), air (e.g. increased aridity), or land surface (e.g. increased albedo). Most of them, regardless of primary emphasis, also describe changes in biological productivity, with comments related to the type, density, and even socially determined value of vegetation.

Type-of-vegetation comments center on changes from desired (or accepted) species to less desired (or less accepted) ones. Such comments include a reduction in the proportion of preferred species having an economic or societal value, the lowering of yields of an existing preferred species, or a major ecological change such as species replacement.

Change in the density of the vegetative cover is an important factor acknowledged in many definitions of desertification. As density decreases, for example, the risks of wind erosion, water erosion, and the adverse effect of increased solar radiation on bare soils are increased dramatically. Surface albedo (reflectivity), also enhanced by a reduction in the vegetative cover, is a major contributor to desertification processes.

With respect to the value of vegetation, researchers have also referred to “lower useful productivity” (Johnson, 1977, p. 317), “reduced productivity of desirable plants” (Dregne, 1976, p. 12), “sustained decline in the yield of useful crops” (UN Secretariat of the Conference on Desertification, 1977, p. 17), and “loss of primary species” (Rapp et al., 1976, p. 8). However, the concern with the value of vegetation in desertification processes is not shared by all researchers. Some researchers have dismissed the value concern, suggesting that any type of vegetation that holds the soil in place is of value in the combat against desertification, whether or not it has an economic benefit for a given society.

As a final comment on what desertification is, it is important to note that disciplinary and institutional biases might appear in any given definition of desertification. For example, a meteorological bias might require that a change take place in the meteorological parameters of a given region, so that they become similar to those for a desert region (e.g. high evaporation rates, aridity, increased rainfall intensity, etc.). As another example, Mecklein (1976), cited in Kharin and Petrov (1977), alluded to the disciplinary bases for desertification when he wrote that desertification could be characterized by the following components: *climate*: increasing aridity (diminishing water supply); *hydrological processes*: runoff becoming more irregular; *morphodynamic processes*: intensification of distinct geomorphological processes (accelerated soil erosion by wind and water); *soil dynamics*: desiccation of soils and accumulation of salt; *vegetation dynamics*: decline of vegetation. It is important to note that, while one aspect of desertification processes could be arrested, others may appear (Prince, 2002).

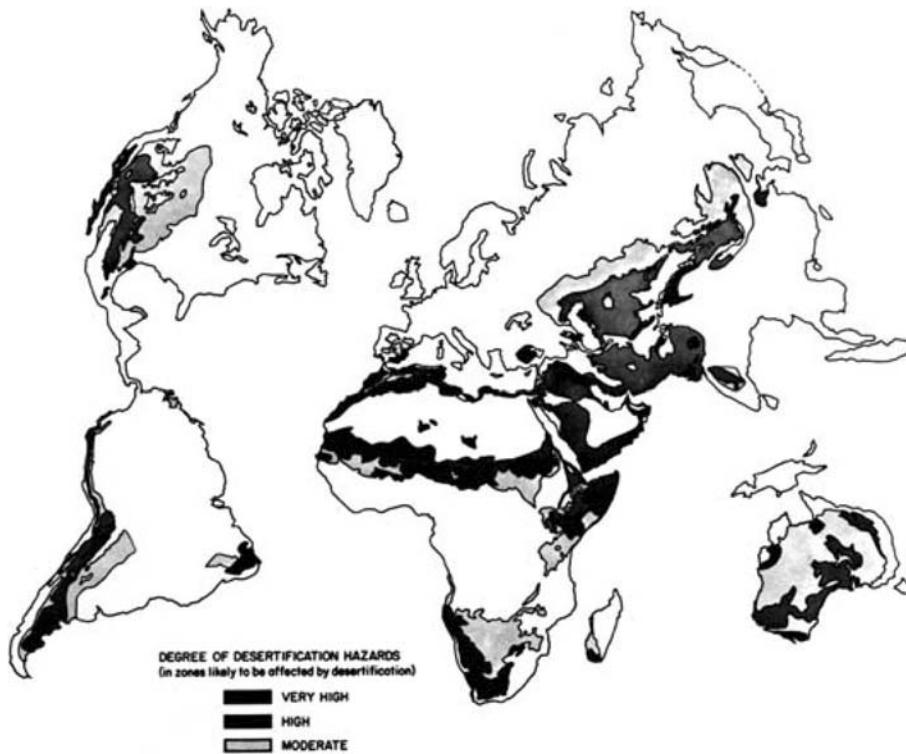

Figure D3 Degree of desertification hazards (in zones likely to be affected by desertification) (after *United Nations Map of World Desertification*, 1977; see also for comparison UNEP's *World Atlas of Desertification*, 1997).

Location of change

There is no agreement on where desertification can take place. Many researchers identify arid, semiarid, and sometimes dry subhumid regions as the areas in which desertification can occur or where the risks of desertification are highest. Others imply that the areas prone to desertification might not be restricted to arid, semiarid, or subhumid regions, by using such descriptive words as extension, encroachment, and spread of desert characteristics into nondesert regions. Still others (e.g. Mabbutt and Wilson, 1980) refer to the intensification of desertlike conditions, suggesting that desertification can occur in desertlike areas. Many oppose this view, however, contending that desertlike conditions cannot be created in a desert. They assert that desertification can only occur along the desert fringes. According to Le Houérou (1975), for example, desertification can occur only in the 50–300 mm isohyet zone.

Reversibility

Few definitions explicitly refer to whether or not desertification is permanent. Le Houérou (1975) briefly explained the conditions under which desertification (he called it “desertization”) might be reversible. Others have implied reversibility with reference to the higher costs of rehabilitation of desertified areas (as opposed to prevention). For example, Adams suggested that the “reversibility of desertification was a function of technology and the cost of rejuvenating an area....”

Irreversibility should refer to a situation in which the costs of reclamation were greater than the return from a known form of land use” (International Geophysical Union Working Group on Desertification, 1975, p. 138). Still others implied irreversibility by referring to the *end result* of desertification as the creation of desertlike conditions.

Two additional important considerations relating to the *in situ* permanence of desertification are: (1) when desertification (as a process or event) might be reversed (i.e. the “time” factor); and (2) under what conditions (i.e. the “how” factor).

With respect to the time factor, some observers consider desertification to be irreversible during periods of up to several seasons but reversible on the order of decades and, if not decades, perhaps centuries. Peel “saw great danger in the concept of irreversibility because it has no time limitations whatever” (International Geophysical Union Working Group on Desertification, 1975, p. 138). One author has drawn a distinction between temporary and permanent desertification (Kove, 1982). Is it possible to distinguish between temporary desertification and, for example, seasonal environmental changes? Some have addressed this question by defining desertification as a sustained (as opposed to temporary) decline in biological productivity (e.g. Sabadell et al., 1982; UN Secretariat of the Conference on Desertification, 1977). Le Houérou, commenting on “what is temporary?”, noted that, while temporary fluctuations may be interspersed with more favorable conditions, such a condition of successive crises does involve a progressively deteriorating situation, possibly past a

threshold of irreversibility (International Geophysical Union Working Group on Desertification, 1975, p. 27).

How can desertification be reversed? Reversal might occur naturally, once the natural contributing causes have been removed. Otherwise, human intervention would be required (e.g. Kassas, 1977) if there is a desire on the part of decision makers to reverse it in less time than might be required to do so naturally. Chinese scientists have actively pursued programs for the past few decades designed to reverse desertification in China. In a 1990 speech the Executive Secretary of the UN Convention to Combat Desertification used China as an example of the threats imposed by desertification. His comments echoed those made during the early 1970s and the prolonged drought in the West African Sahel, when he suggested that "the desert has moved to within 100 miles of Beijing, and in the long term this desertification will have serious effects on food scarcity and people's health and will force people to migrate" (D'Aleo, 2000). He also suggested that the desertlike condition was approaching Beijing at a rate of 1.2 miles per year.

The Chinese government has become increasingly concerned about another sign of desertification – the enhanced frequency and intensity of dust storms originating in its western provinces and blanketing the nation's capital, Beijing (Royston, 2001), as well as dust storms originating in northern China. The government is especially intent on arresting such dust storms in advance of the 2008 Olympics to which they are hosts.

Under specific circumstances, desertification is totally irreversible. For example, in mountainous areas of West Africa, once the higher elevations are denuded of soil (wind and water erosion), it will require millions of years to reform. Former sand dunes, now vegetated, if deprived of that protection, will be remobilized, and desert dune encroachment will result. Those desert sands cannot be easily stabilized, nor made fertile (Fairbridge, 1968, p. 1134 et seq.). Examples can be seen in Senegal, Maci, Niger, Sudan, as well as in India and Australia.

Desertification: why does it occur?

Ever since the mid-1970s, researchers have been divided over whether to blame the climate system or human activities for desertification. Some researchers consider climate to be the major contributor to desertification processes, with human factors playing a relatively minor supporting role. Other researchers reverse the significance of these two factors. For example, Le Houérou (1959) concluded that "on its edges the Sahara is mainly made by man; climate being only a supporting factor" (quoted in Rapp, 1974, p. 32). A third group blames climate and humans more or less equally. For example, Grove (1974, p. 137) has noted that "desertification or desert encroachment can result from a change in climate or from human action and it is often difficult to distinguish between the two". Each of these views can be shown to be valid, at least at the local level and on a case-by-case basis. Thus, there is a region-specific bias to perceptions about desertification, one that spills over to the definitions.

Climate

References to climate in these definitions relate either to inter-annual climate variability, climate fluctuations, climate change,

or drought. *Climate variability* (a term that is usually overlooked in these definitions) refers to the natural variations that appear in the atmospheric statistics for a designated period of time, usually on the order of months to years. Variations can occur in any or all of the atmospheric variables (such as precipitation, temperature, wind speed and direction, relative humidity, evaporation, etc.). Those variations could alter an ecosystem, which would eventually affect human activities in adverse ways, activities that had been designed to exploit the productivity of that ecosystem.

It is important to note that during the annual dry season the characteristics of the atmosphere in an arid or semiarid area are like that of a desertlike region (low precipitation, high evaporation, high solar radiation, etc.), and if the land is improperly used during this period, degradation results (Aubreville, 1949). Thus, short-term variations in climatic factors as well as seasonal dry periods, when combined with improper land-use practices, can give the appearance of the impact of a regional climate change (e.g. global warming) when none may have occurred at all. *Climate fluctuation* refers to variations in climate conditions that occur on the order of decades. Climate and hydrologic regimes are known to fluctuate between extended wet and dry periods that can last up to several decades. *Climate change* refers to the view that the statistics that represent the average state of the weather for a relatively longer period of time are changing, and that desertification is primarily the result of such natural climate change. For example, there has been an obvious multidecadal trend beginning in the late 1960s toward increased aridity in the West African Sahel; a natural desiccation of the region that humans can do nothing to stop. Usually cited as evidence for long-term climate changes in that area in the past are the fossil dune fields near the West African coast far from the active dunes close to the desert. The debate over the possible impacts of long-term global climate change on the climate conditions in the West African Sahel (and on other arid lands around the globe) continues.

Nevertheless, paleoclimatologists, point out that since the "Little Ice age", which reached its nadir in the 17th century, there has been a systematic global warming (of natural causes), associated with aridification of the Sahara and other high pressure belts.

Drought episodes are also considered to be a major cause of high-pressure desertification. Especially during multiyear meteorological droughts, desertification becomes relatively severe, widespread, as well as more visible, and its rate of development increases sharply (e.g. Grainger, 1984). As the probability of drought increases as one moves from the humid to the more arid regions under present-day global climate conditions, so too, does the likelihood of severe desertification. Land forms, soils, and vegetation are often transformed, sometimes irreversibly, during such extended drought periods.

Tree-ring analysis, lake sedimentation, Nile floods and other proxies prove conclusively that drought cycles have been recurrent for at least the last few thousand years. Man-made pollution (CO_2), however, has amplified the late 20th century and early 21st century intervals.

The view held by the general public of what constitutes climate change exposes a misunderstanding. It is not just a matter of a summer warmer than last year, or less snow in winter than in the preceding decade. Scientists are referring to a profound climate change (a global warming of a few degrees Celsius), the magnitude of which societies have not witnessed for millennia. For reasons of clarity for the public, this profound type of

change might be called “deep climate change”. Many countries are now concerned about the possible impacts of global warming of the atmosphere on the rate and irreversibility, as well as the location, of desertification processes in future decades (Ci et al., 2002).

Human activities

Cultivation, herding, and wood-gathering practices, as well as the use of technology and even the occurrence of conflict (Timberlake and Tinker, 1984), have been cited in the definitions as major causes of, or contributors to, the desertification process in arid, semiarid, and, subhumid areas (e.g. Swedish Red Cross, 1984). *Cultivation practices* that can lead to desertification include irrigation, land clearing, deforestation, cultivation of marginal climatic regions, cultivation of poor soils, woodcutting for firewood and construction, and inappropriate cultivation tactics such as reduced fallow time, improper tillage, drainage, and water use. Areas that might support agriculture on a short-term basis may be unable to do so on a long-term sustained basis. Even land surfaces that are considered suitable for cultivation of some sort may become degraded, if they are managed in a way that is inappropriate to their ecological and climatic setting.

Rangeland abuse leading to desertification includes excessively large herds in relation to existing range conditions (e.g. overgrazing and trampling) and herd concentration around human settlements and watering points. Government policies toward their pastoral populations can also indirectly lead to desertification by, for example, not pursuing payment policies that encourage herders to cull their herds, by arbitrarily putting a minimum sale price on grain and a ceiling on prices that pastoralists might receive for their livestock, and so forth.

Gathering firewood by itself or in combination with overgrazing or inappropriate cultivation practices can create conditions that expose the land to existing “otherwise benign” meteorological factors (such as wind, evaporation, precipitation runoff, solar radiation on bare soil, etc.), thereby contributing to desertification.

The *use of technology* in arid, semiarid, and subhumid environments is often a result of the policy-makers’ desire for economic growth and development. Thus, deep wells, irrigation and cash crop schemes, even the reduction of livestock diseases, each in its own way, increases the risks of desertification processes, if the technology is not properly applied. Desertification can result from road building, industrial construction, geological surveys, ore mining, settlement construction, irrigation facilities, and motor transport (Rozanov, 1977).

In sum, most researchers accept that both human intervention and climate are involved in the desertification process, with a few observers noting that the two factors are so entwined that to separate them as to primary and secondary contributors would be a fruitless endeavor.

Return to Aubreville

Aubreville discussed desertification at great length in his 1949 report entitled *Climats, Forêts et Desertification de l’Afrique Tropicale*. His work, when compared to the scores of contemporary definitions, raises the issue about where desertification can take place. Most of the contemporary definitions relate desertification to what broadly speaking might be viewed as the

desert fringes: the arid, semiarid, and dry subhumid areas. Aubreville explicitly referred to the dry tropical forest of Africa, noting that “these are real deserts that are being born today, under our eyes, in the regions where the annual rainfall is from 700 mm to 1500 mm” (1949, p. 332). Interestingly, Aubreville’s original view of desertification would likely have no place in desertification studies today because it fails to meet the criteria identified in most contemporary definitions.

Aubreville viewed desertification primarily as a process but also referred to it as an event. He described how forested regions were transformed into savanna and savanna into desertlike regions. One of Aubreville’s central concerns was the rate of destruction, resulting from human activities, of Africa’s dry tropical forests. He noted that cultivation, deforestation, and erosion were so entwined as to lead to the destruction of the vegetative cover and soils in the forested regions of tropical Africa where “the desert always menaces, more or less evident, but it is always present in the embryonic state, during the dry and hot season” (Aubreville, 1949, p. 331). Savanna would result. Continued disregard for the fragility of the savanna would result in the creation of desertlike conditions.

Aubreville’s original research findings and observations are still relevant to contemporary efforts to identify, understand, and combat desertification processes. The resurrection of his research on desertification is not a call to discard other definitions, but a call to broaden thinking about what constitutes desertification as a process and where on Earth that process might occur. If desertification can be identified by some of its component subprocesses, such as soil erosion, deforestation, overgrazing, or cultivation in marginal areas as defined, for example, by soil characteristics or by the amount of rainfall, then there is a great deal of research activity under way that relates directly as well as indirectly to desertification, even though the word desertification does not appear in its title (e.g. Riquer, 1982).

A broad view of desertification would shed a different light on progress in the understanding and combating of desertification. There is much research under way on soil erosion, range management, deforestation, increasing biological productivity in arid and semiarid lands. Only in this broader conceptualization of desertification can we develop a more accurate assessment of how nations are really doing in their national “war” against desertification.

DESERTS

The world's deserts are some of its most extreme and spectacular environments. The incredible dune systems of the Sahara or the Namib are but two examples; the bountiful succulents fields of the American southwest are another. Desert environments globally are highly diverse, a result of the complexity of the climatic conditions that can produce aridity and the underlying surface materials. However, all deserts share one essential commonality: a relatively scarcity of precipitation.

The definition of a desert depends on the aspect of environment of principal concern, such as vegetation, terrain, culture, climate or resources; hence there is no simple way to define or delineate desert environments. Even climatic boundaries of deserts, and therefore geographic boundaries, are hard to establish because there is a gradual and continual transition between arid and semiarid environments.

In basic climatic terms a desert can be defined as an area which receives little or no rainfall and experiences no season of the year in which rain regularly occurs. However, rainfall alone insufficiently defines climatic boundaries of deserts because it varies dramatically from year to year and because aridity is not determined solely by rainfall. What distinguishes deserts from non-deserts is the amount of moisture available to the ecosystem, or the difference between the rainfall a region receives and that lost through evaporation. According to estimates based on this concept, true deserts make up roughly 20% of the Earth's land surface and another 15% is semiarid.

Deserts are concentrated in Asia, Africa, and Australia. The largest expanse of arid land lies in an almost continuous area stretching nearly half a hemisphere across northern Africa and Asia, an inhospitable barrier separating most of Europe from southeastern Asia. Africa and Asia respectively contain 37% and 34% of the world's arid lands. The principal deserts of the world include (see Figure D4) the Kalahari–Namib, Somali–Chalbi and Sahara on the African continent; the Arabian, Iranian and Turkestan Deserts of the Middle East; the Thar, Takla-Makan and Gobi Deserts of Asia; the Monte–Patagonian and Atacama–Peruvian Deserts of South America; the Australian Desert; and the North American Desert, including the Great Basin and the Sonoran, Mojave and Chihuahuan Deserts. Vast tracts of semiarid land, such as the American Great Plains and the African Sahel, border each of these.

The deserts shown in Figure D4 tend to be situated in subtropical latitudes or in the lee of major mountain ranges, as the factors which promote aridity are common to these locations. Deserts are also found at high altitudes and high latitudes, but

these differ in two basic respects: the low rainfall is primarily a result of cold conditions and evapotranspiration is inherently low and of minor importance in determining water availability.

Classification of deserts

Although sparse or negligible rainfall is a common characteristic of all deserts, aridity is better defined by moisture availability. This is a residual in the balance between water availability through precipitation and water loss via evapotranspiration. The latter quantity represents the maximum amount of water that could be evaporated by solar energy or transpired by plants under conditions of constant moisture supply. Potential evapotranspiration can be as high as 3000 mm in some regions. In deserts, however, water is limited and hence this maximum is never achieved. Nevertheless, this parameter can be considered as "water demand" and climatic characteristics such as temperature or incoming radiation are used to approximate this demand. Rainfall, in turn, represents water availability.

Water demand, whether assessed by net radiation, temperature or potential evapotranspiration, varies greatly from one region to another. It tends to decrease with increasing latitude and it is higher in summer than winter. Therefore the amount of rainfall at the desert margin tends to decrease with increasing latitude, and it is higher for deserts with summer rainfall. Within a geographical region, water demand is more constant and desert boundaries are often delineated regionally on the basis of mean annual rainfall. In Australia, for example, the generally accepted limit for the desert is 400–500 mm of rainfall in the north and 250 mm in the more temperate climate of the southern border.

A comparison between supply and demand forms the basis of most definitions of deserts. All systems of assessments are in reasonable agreement on global space scales, but show significant differences along the margins at regional scale. The best-known

classification scheme for arid lands, that of Peveril Meigs, assesses "demand" by way of potential evapotranspiration. An example of Meigs' classification for Africa is shown in Figure D4. The classification scheme of the Russian climatologist Budyko represents it by the net radiation received at some location, i.e. the difference between the net heat gain from the sun and the net heat loss by radiation from the ground (Figure D5).

The Budyko classification has some advantages, in that it allows for a simple quantitative comparison of the degree of aridity of various deserts and its aridity index is readily interpreted

physically. The index is a parameter termed the "dryness ratio". To produce it, net radiation is converted to energy units and the index is defined as the ratio of mean annual rainfall to the amount of rainfall which this energy suffices to evaporate. In Budyko's classification the boundary between deserts and semiarid regions is where the ratio is 3 (Figure D6). This ratio is as high as 200 in the central Sahara, but is generally below 10 in the North American deserts.

Causes of aridity

The formation of rainfall requires moisture supply, unstable atmospheric conditions and ascending air. Ascent can be produced by extreme heating of the surface, by a convergent pattern of air flow, or orographically forced by mountain barriers. Aridity is promoted by the opposite conditions: a lack of atmospheric moisture, stable air, subsidence (i.e. descending air motion), and a divergent pattern of air flow (i.e. air streams spreading apart from each other). Another cause is distance from the main tracks of major weather systems.

Except in polar and high-altitude deserts, a lack of sufficient moisture is generally not the overriding cause of the arid climate. The case of the Sahara Desert clearly demonstrates this. In summer the atmosphere above the Sahara is enriched with about as much moisture as that over the wetter regions of the southeastern United States. Likewise, the Namib Desert of southwestern Africa is a very humid environment, although it is one of the driest (i.e. most rainless) deserts on Earth.

The other factors, stable and subsiding air and divergent flow, are common to two meteorological situations linked to the occurrence of dry climates: the semipermanent high-pressure systems which prevail in the subtropical latitudes and the rain-shadows on the leeward sides of mountain barriers. These are the most common locations of deserts.

Descending currents are particularly effective in promoting aridity. They originate at high altitudes, where the air is dry and, as they sink, they undergo intense compressional heating. Consequently, the air is very hot and dry when it reaches the surface. The warming also produces a temperature inversion (temperature increasing with elevation), which stabilizes the lower atmosphere and suppresses the uplift required to produce clouds and precipitation. Air descends in the core of high-pressure cells because of the pattern of surface air flow; it descends also in the lee of mountains.

Near the high-pressure cells, aridity is further enhanced by a temperature inversion produced by the descending air and by cold water on the eastern flanks of the highs. The occurrence of this unusually cold water is linked to the surface wind flow around the high, which produces the upwelling of cold water and advects cold polar water into relatively low latitudes. Along the coast of South America the upwelled water is as cold as 12°C, compared to over 20°C in the mid-ocean.

Both the subtropical highs and mountain barriers further promote aridity by blocking the passage of major weather systems. Mountain barriers also act as a barrier to the inland penetration of moist, maritime airmasses. The transformation of airmasses crossing the mountains produces a "rainshadow". Air approaching a mountain range is forced to rise, promoting cloud formation and rainfall on the windward side and the peaks. The air which reaches the leeward side has dropped its moisture at higher elevations and is relatively dry. As it sinks in the lee, compressional heating accentuates its dryness.

Most of the world's largest deserts are under the influence of the subtropical highs: the Australian Desert, the Peruvian-Atacama Desert of South America, the southwestern United States, the Namib Desert and Kalahari of southern Africa, and the Sahara. Aridity is strongest on the western sides of continents in these latitudes, where the influence of the highs is greatest and where the coastal deserts lie.

The deserts of the midlatitudes are generally located in the lee of major mountain ranges: the Patagonian Desert of South America, many of the deserts of the Middle East and Asia, and the intermontane region of the western United States. Topography also plays a role in the Somali-Chalbi Desert of Ethiopia and the Horn of Africa and, to some extent, the Thar desert of India.

In most cases, however, complementary factors also play a role in producing aridity. For example, the influence of the subtropical highs cannot suffice to explain the full extent of the Sahara and its continuation into Arabia and the Middle East. There, neither the cold-season temperate latitude weather systems to the north nor the warm-season tropical disturbances on its equatorward side penetrate to its interior. The deserts of Asia and the Middle East are far from prevailing storm tracks. The latter two regions are also quite distant from any moisture sources. In the Somali-Chalbi Desert, one factor is local patterns of wind flow, jet streams lying near the surface. A coastal, low-level jet stream enhances the aridity of the Peruvian Desert, the most latitudinally extensive desert in the world.

Thus, the causes of desert climates are quite complex and often regional influences must be taken into account. The complexity and the regionalization of these factors gives a nearly unique climatic identity to each of the Earth's major dryland regions, despite their many common climatic characteristics.

Surface environments of the desert

The vision of the sandy desert is applicable to only a portion of the world's arid lands. Other surface types include bedrock (often termed hammada), stone pavements (termed reg and serir), depositional flats, and desert crusts. Sand fields and dunes are common in the Sahara and in parts of the Australian Desert, but the Syrian and Gobi deserts are largely hammada and reg types. As the desert gives way to semiarid landscape, soils become more common and widespread.

Overall sand dunes occupy less than 20% of the surface area of the world's deserts. They cover about 28% of the Sahara but only 1% of the desert surface in North America. Classically, two types of dunes are distinguished: longitudinal (or linear) dunes, which are roughly parallel to the prevailing winds, and transverse dunes, which are aligned roughly normal to the wind. In reality, a great variety and complexity of dune forms exist. The simpler dune forms result from simple wind regimes, i.e. one or two prevailing directions. As the complexity of the prevailing winds increases, so does the complexity of dunes.

Many deserts sustain a rich vegetation cover, which can include grasses, trees and shrubs (although fewer in number than in the wetter environments). In the true deserts arboreal species (trees and tall shrubs) are rare, as are perennial grasses. The dominant vegetation in most deserts includes dwarf shrubs and low shrubs (such as *Artemisia* or sagebrush) and succulents (cacti and euphorbia). Annual grasses may be present in the years with abnormally high rainfall.

Desert vegetation consists of two general classes, based on the primary way to resist moisture stress: perennials which *avoid* drought, and annuals or ephemerals, which *evade* it. The latter grow profusely during periods of favorable precipitation and produce seeds which lie dormant during drier episodes, until wetter conditions return. The perennials are phreatophytes, which develop long taproots penetrating downward to the water table, or xerophytes, which adapt to low water supply and high salinity. The xerophytes include many dwarfed, woody species, with reduced water demand, and succulents, that resist drought by storing water in their leaves, roots and stems. The succulents include the cacti of the American deserts and the Old World euphorbia.

Diversity and extremes of desert climates

Most desert environments share several common climatic characteristics. These include meager rainfall which is highly variable in time and space, and often concentrated in very small, localized areas; low atmospheric relative humidity; an extreme thermal environment with large fluctuations of temperature between day and night and during the year; and generally low cloudiness and high insolation. Individual deserts differ markedly with respect to the amount of rainfall and the degree of aridity. The thermal characteristics, especially mean annual temperature and its seasonal variations, are determined to a large extent by latitude.

Consequently, several types of deserts are distinguished on the basis of climate: warm, cold-winter and foggy or coastal deserts (Figure D7). In the warm deserts of the lower latitudes, temperatures are high year-round and freezing is rare or absent. These may occasionally receive incursions of frigid air from higher latitudes, producing frost or even snow. The midlatitude deserts generally experience cold winters, often with seasonally occurring freezing temperatures. Both are characterized by low relative humidity year-round.

In contrast, coastal deserts are relatively humid and the temperatures relatively mild in both winter and summer, a consequence of the influence of the coastal waters. Compared to inland deserts, both the diurnal and annual temperature ranges are reduced. Also, they tend to be frequently cloud-covered and fog is a common occurrence.

The rainfall conditions in deserts are quite diverse. Some, such as the Sahara, have virtually rainless sectors with less than 10 mm of rainfall annually. Rainless stretches of 10 years have been recorded in parts of the Sahara and at locations such as Swakopmund (Namibia) and Lima (Peru) in the coastal deserts of Southern Africa and South America. Few deserts are this dry. In the Sonoran, Mojave, Iran and Arabian Deserts and in the Takla-Makan, mean annual rainfall is on the order of tens of millimeters in their driest cores. It exceeds 80–100 mm everywhere in the Thar, Gobi, Patagonian and Australian Deserts and in the Kalahari. In contrast, it scarcely falls below 200 mm in the Chihuahuan Desert and Great Basin of North America.

The temperature conditions are also diverse because they depend on several factors, including latitude, elevation, distance from coast and degree of aridity (Figure D8). Except in coastal deserts mean daily maximum temperatures during the summer months are generally on the order of 30–45°C. The mean daily winter minima are usually above –10°C, except in the interior of Asia, where they may be as low as –20 or –30°C. There is a general tendency for annual temperature

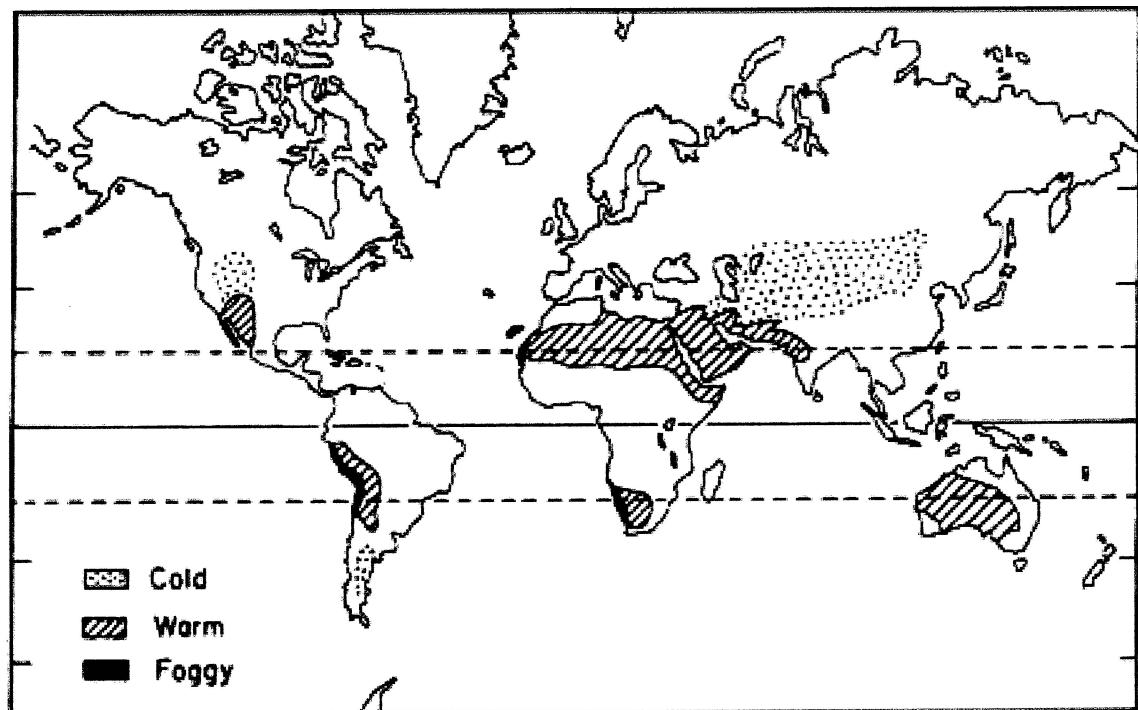

Figure D7 Classification of desert regions into cold, warm and foggy deserts (after Schmid).

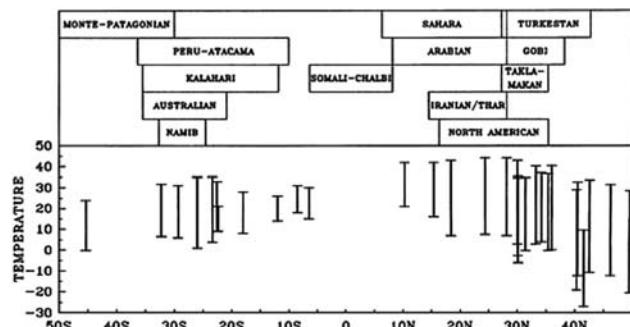

Figure D8 Annual temperature range vs. latitude for arid and semiarid regions. Bars extend from mean temperature of the warmest month to mean temperature of the coldest month. Note the smaller temperature range in the southern hemisphere, a consequence of the large ratio of water to land.

range to increase with latitude, varying from about 15°C in low-latitude deserts to 20–35°C in the cold-winter deserts. The mean diurnal range is likewise diverse, varying from about 4°C in coastal deserts to 22°C in high latitudes.

These mean conditions of rainfall and temperature do not fully illustrate the extreme range of thermal conditions experienced in deserts. In Australia and Asia the absolute maximum air temperatures are on the order of 48–50°C, but temperatures of 57°C and 58°C have been recorded in the Sahara, 57°C at Death Valley, California. Surface temperature commonly

fluctuates by over 30°C between day and night in the Kara Kum Desert of Asia and by over 40°C in the parts of the North American Deserts. Some deserts of the Soviet Union experience absolute temperature ranges in excess of over 100°C, with air temperatures as low as –58°C having been recorded.

Ground temperatures are even more extreme, with temperatures in excess of 70°C having been recorded at several locations. At Port Sudan on the Red Sea, a sand temperature of 83.5°C was recorded. The deserts also experience extreme cold: at Repetek, in the Kara Kum desert of Asia, where a sand temperature of 79.4°C was once recorded, the ground temperature can drop to about –40°C.

The precipitation regime is similarly extreme. In some areas many years pass without a drop of rain, but when rain does fall it is often torrential. Many times the mean annual rainfall can fall within hours or days. At Lima, where the mean annual rainfall is 46 mm, 1524 mm fell during one storm in 1925. In the Sahara at Nouakchott (Mauritania), over twice the annual mean, 249 mm, fell in 1 day; at Tamanrasset (Algeria), the mean annual rainfall of 48 mm once fell in hour.

Thermal regime

The subtropical location of many deserts and the scant cloud cover of most produce a regime of strong solar insolation and high surface temperatures. Temperature is enhanced by the dryness of the soil and the lack of a dense vegetation cover to absorb and redistribute the solar radiation near the ground. The heat is concentrated at the surface because the dry ground transports little heat to deeper layers of soils; temperature decreases rapidly with depth into the ground and with height above the

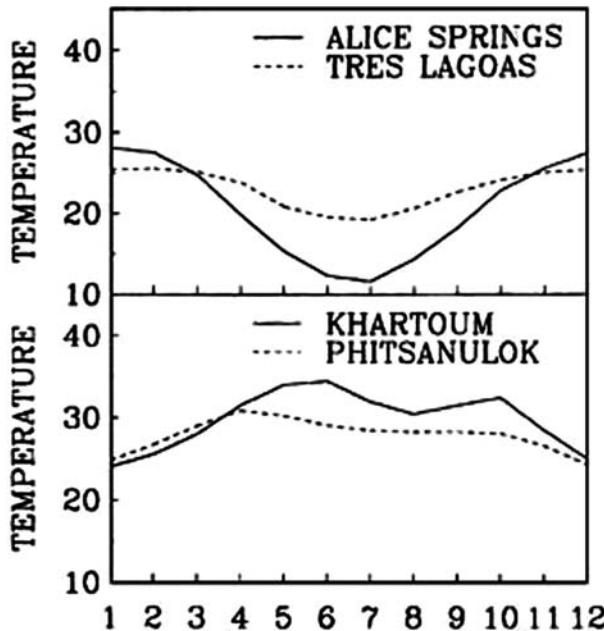

Figure D9 Mean monthly temperature at pairs of stations at comparable latitudes but differing precipitation regimes. Alice Springs and Khartoum are desert locations; Tres Lagoas and Phitsanulok are regions of tropical forests.

surface. In the Kara Kum Desert of Asia daytime temperature typically drops over 15°C within the first few centimeters and 20–30°C within the first 10 cm below the surface. Air temperature can drop by more than 10°C within the first 10 cm above the surface.

The concentration of heat at the surface means that there is no subsurface thermal reservoir. As a consequence of this, and the sparse vegetation cover, the surface cools extremely rapidly and efficiently at night. The generally clear skies and the dryness of the air near the ground allow most of the heat accumulated by day to escape to the upper atmosphere by night (90%, compared to 50% in humid regions). This accentuates the nighttime cooling.

The result is a large daily range of both ground and air temperature. At Khartoum, Sudan, at 15°N latitude in the eastern Sahara, the daily air temperature range is on the order of 18°C in the dry season and 11°C in the wet season. At Alice Springs, at 23°S in central Australia, the diurnal range is about 15°C. The daily fluctuations at humid stations of comparable latitude would be about half as great during the wet season. At a station in the Sahara, during the course of a day the air temperature fell from a daytime maximum exceeding 37°C to –1°C at night. At Death Valley, California, a daily range of 41°C was observed in August 1891; at Tucson, Arizona, the record is 56°C.

The lack of a surface heat reservoir in deserts tends to lead also to a high annual range of temperature. To a large extent the annual range is dependent on latitude, increasing with latitude as seasonal contrasts become important. Nevertheless, the annual temperature range at a desert location will tend to be greater than that at a humid location at a comparable latitude. The annual ranges for Alice Springs (24°S) and Khartoum (16°N) are

16°C and 10°C respectively, compared with approximately 6°C at Tres Lagoas (Brazil) and Phitsanulok (Thailand), at similar latitudes but with humid climates (Figure D9). In deserts near the equator the annual range is often much less, so that the daily temperature range is several times larger than the annual range.

Hydrologic regime

Much of the hydrologic character of a desert is dependent on its latitudinal location. Tropical rainfall prevails at low latitudes, such as in the southern Sahara or the northern sector of the Australian Desert. A midlatitude rainfall regime prevails at higher latitudes, such as the poleward sectors of these deserts or in the deserts of North America and much of Asia. The tropical and midlatitude regimes differ with respect to both the nature and seasonality of the precipitation and, consequentially, with respect to the loss of moisture through runoff and evapotranspiration.

Tropical rainfall is produced by convective processes (i.e. cloud formation related to localized surface heating and dynamic processes). In the midlatitudes most rainfall (especially that which occurs in winter) is linked to large-scale warm or cold fronts. Convective rainfall tends to be much more localized and intense than frontal rainfall. As a result, in areas where convective rainfall prevails, whether deserts or humid regions, rainfall is highly variable in space, confined to raincells on the order of 10–50 km, or less. The monthly rainfall at two locations a few kilometers apart might be quite different. For this reason rainfall in deserts was often thought to be a completely random and localized occurrence. Satellites have shown, however, that although this is true of individual raincells, these cells tend to occur in organized, large-scale, meteorological disturbances.

Convective rainfall tends to be of both short duration and high intensity. A typical rain might last for a few minutes or hours, compared to days for frontal rainfall. The high intensity of the convective rainfall also affects its effectiveness, since the ground quickly becomes saturated and much of the rainfall is lost to runoff. Because there are few drainage channels in deserts, the runoff may form a thin sheet of water, transforming the barren ground to an enormous lake within minutes. This runoff produces flashflooding in many deserts, especially when rain falls over barren rock at higher elevations. As little as a few millimeters of rain can produce flow in dry desert wadis; the flow may emerge suddenly, peak rapidly, but last only a few hours. Less than 100 mm can produce catastrophic floods. In the Tadmait Plateau of the Sahara a rain of approximately 16 mm generated a flood with peak discharge of about 1600 m³/s.

Not only the rainfall in individual storms, but also the mean distribution in a desert, can be a mosaic, particularly in the rain-shadow deserts. In the state of Washington, in the western United States, mean annual rainfall varies from 3000 mm on the peaks of the Cascades to less than 200 mm in the leeside valleys only 40 km away. Isolated mountains, such as Tibesti or the Hoggar in the Sahara, dramatically enhance rainfall. Peaks may routinely receive 100 mm or more per year, compared to a few millimeters in the surrounding regions.

Although by some definitions a true desert is a location without a regular rainy season, in most desert regions there is a preference for concentration in either the warm or cool season (Figure D10). The subtropical deserts represent a transition

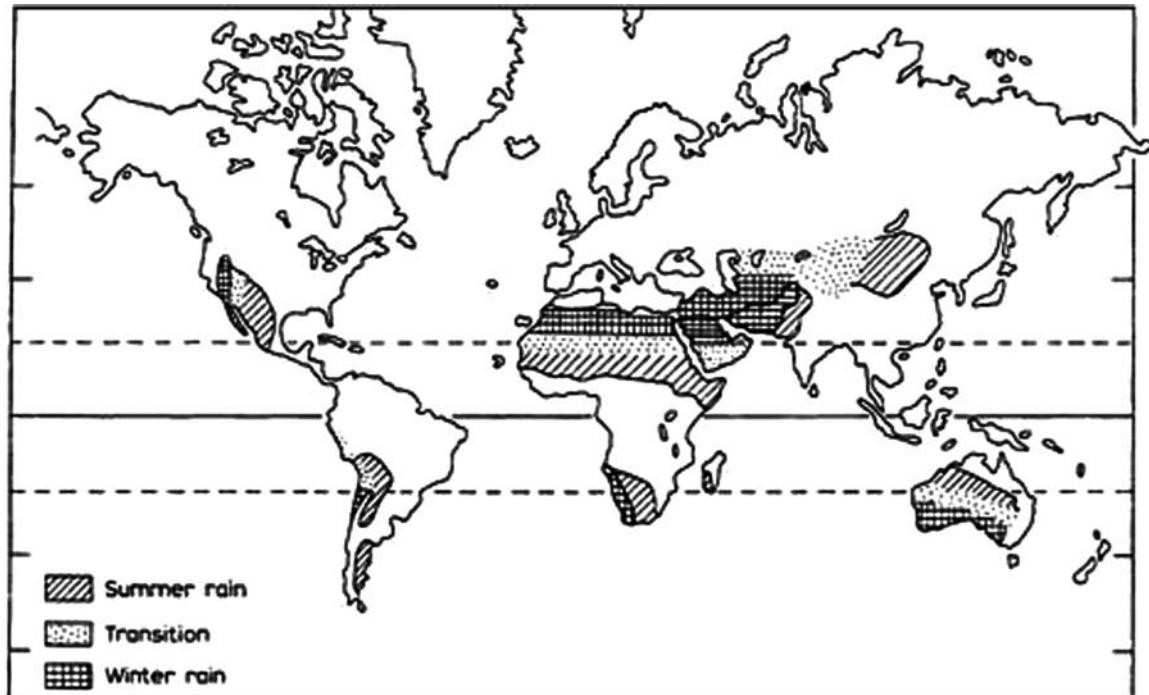

Figure D10 Areas of hot deserts with summer rain, winter rain and rainfall during the transition seasons (from Schmid).

Figure D11 Saguaro cactus in the Sonoran Desert of Arizona.

from tropical, summer rainfall, which prevails along their equatorward margins, to midlatitude, winter rainfall on their poleward borders. Both the seasonality and amount of rainfall decrease toward their center.

In the cold-winter deserts of the midlatitudes, fewer generalizations can be made about the seasonal occurrence of precipitation. For example, in the western Great Plains of the United States, precipitation is concentrated in summer, but the desert Southwest tends to receive both summer and winter rainfall, with greater aridity in the transition seasons. In some deserts of

the Middle East the maximum is in spring. In most midlatitude deserts summer rainfall has the characteristics of tropical rain, falling in intense but brief bursts which promote high runoff. Winter rainfall is usually linked to large frontal systems, of low to moderate intensity but persisting for long periods.

For these reasons, and because potential evapotranspiration is higher in summer than winter, summer precipitation is less effective for vegetation growth. The seasonality of the meager precipitation can produce vastly different surface conditions. The Mojave Desert of California is distinguished from the adjacent Sonoran Desert of Arizona and northern Mexico on the basis of the percent of precipitation fall during the winter season. The latter is characterized by succulent vegetation, such as the giant saguaro cactus (Figure D11); while the former features dwarf shrubs and the uniquely-formed Joshua tree.

Snow occasionally falls in the poleward margins of the subtropical deserts. At oases such as Ouarqha and Ghardaia in the northern Sahara, snow falls as often as 1 in 10 years. At Laghouat snow fell nearly every year toward the end of the nineteenth century and now occurs every 2–5 years. The traditional housing is not meant to withstand such occurrences, which may lead to the collapse of roofs. In the higher latitudes snow is much more common, especially in deserts where precipitation is concentrated in the winter months. These include the Takla-Makan and Iranian Deserts.

The distribution of rainfall in a desert is erratic in both space and time, especially in regions of tropical rainfall. The amount of rainfall varies tremendously from year to year; many years may pass without a drop. Usually rain occurs only a few days within the year and most of the rain which falls occurs within short periods, sometimes as briefly as a few hours. Several

times the mean annual rainfall may occur within one day. In Helwan (Egypt), where the mean annual rainfall is about 20 mm, seven storms produced a quarter of the rain that fell during an entire 20-year period. At Nouadibou (Mauritania), with mean annual rainfall of 32 mm, annual totals have ranged from 0 to 301 mm; on one day in 1909, 140 mm fell. At Biskra (Algeria) (mean annual rainfall of 140 mm), annual totals range from 32 to 638 mm, but 299 mm fell in September of 1969 (210 of it in 2 days). The same storm system brought nearly 800 mm to Sidi bou Zid (Tunisia) during September and October, months in which the mean rainfall is on the order of 10–20 mm.

Coastal deserts

Deserts are common along the western coasts of continents in the subtropical latitudes, where high pressure prevails. These deserts have certain climatic characteristics, such as a high frequency of fog, which distinguish them from other desert regions. Their origin lies in three main factors: the aridifying influence of the subtropical high-pressure cells over the oceans and adjacent coasts; the cold water which exists along these coasts; and a frictional effect of the shoreline on the coastal winds. Aridity is greatest at the coast, with rainfall increasing inland. Many local factors serve to accentuate the coastal aridity, such as near-surface jet streams constrained by coastal mountain chains.

The extent of the coastal deserts ranges from 25° of latitude for the Peruvian–Atacama Desert of western South America to less than 5° of latitude for western Australia. The latitude of their equatorward margin, with summer rainfall, is highly variant, but the poleward border with winter rainfall is in all cases at about 25°N or S of the equator. In those of Africa and South America, rainfall approaches zero in the arid core.

The climatic conditions of coastal deserts are less extreme than those of inland deserts. Many of the coastal deserts are relatively moist environments, with a high frequency of fog and relatively high atmospheric humidity. In some, more precipitation is received as fog-water than as rainfall. The temperature regime is generally quite moderate, as the water, with its high thermal capacity, dampens both diurnal and annual fluctuations. In the Namib, for example, the daily and annual range are about 6°C at the coast, compared to 15–20°C just 100 km inland.

These more moderate temperatures, together with the moisture provided by the fogs, create a more favorable environment for plants and animals than interior deserts. In the Peru–Atacama and Namib Deserts some plant and animal species have special adaptations which allow them to utilize fog-water. Certain plants can absorb water directly through the leaf surface. A species of beetle in the Namib builds trenches on the dunes to trap water as it condenses on the sand. Another “basks” on the dune with its head pointed downward and body to the wind, causing fog droplets to condense on its back and roll downward into its mouth.

Many coastal deserts are affected by a phenomenon called El Niño, a major change of temperature and wind patterns in the Pacific that has global climatic consequences. During El Niño years the cold water along the South America Desert coast disappears, establishing conditions which promote intense rainfall. In March and April of 1965 an El Niño brought 600 mm of rainfall to areas of coastal Peru, that receive on average about

80 mm during those months. The El Niño often renders similar changes along the coasts of Southern California, southwestern Africa and in other coastal deserts.

Winds, sand and dust

The desert surface conditions, barren ground and extreme heat, interact with the prevailing regional scale winds to produce a local wind regime which is strong and turbulent. The sparse vegetation cover means little surface friction to dissipate wind near the ground, so mean wind speeds are quite high in deserts. In the afternoon steady gale-force winds may prevail for hours, but at night, when the surface cools and the air becomes stable, winds are often calm. The desert winds are hot and dry and often blow from the desert to surrounding regions of more humid climate. Some, like the *Harmattan* of the Sahara, may provide welcome relief to stifling humidity.

The hot desert ground and rapid temperature drop above the ground produce unstable conditions which create gusty, turbulent winds. These are very effective in lifting particles from the surface. These winds are reflected in the patterns of sand dunes and surface erosion. They also produce sand and dust storms and smaller and shorter-lived dust devils. The heavy sand does not stay aloft very long, but the smaller dust particles do. The dust layer over the Sahara, for example, extends to over 5 km in altitude, producing vivid red colors in the clouds at this height.

When a dust storm occurs in a desert its effects can be instant and dramatic. Within minutes bright sunshine changes to an eerie, dusk-like ambience of red–brown haze and the temperature can drop more than 15°C. One particular type of dust storm, called a *haboob* in North Africa and the Southwestern United States, originates as a strong, turbulent downdraft in a thunderstorm. The dust is kicked up by what is called a density current, cold air which sinks to the ground from high altitude. As it hits the surface it spreads laterally, churning up dust in violent gusts that may exceed 60 mph. The visibility can rapidly approach zero, producing near darkness in mid-afternoon.

Microclimates in the desert

There are a number of microenvironments, or habitats, in deserts which offer shelter from the harsh conditions. It is here where life thrives. Some, such as parts of sand dunes and desert plants, modulate the thermal extremes. Others, such as oases and riverine environments, offer more favorable moisture conditions. Even dry riverbeds can support a virtual forest. Favorable habitats can also be dictated by topography or soils; the arid surface conditions are accentuated by stone pavements but moderated in lowlands near high relief. On the other hand, desert depressions, such as the Qattara depressions of Egypt or the Chott el Jerid of Tunisia, are the hottest places on Earth. The heat of the walls of the depression (Figure D12) creates a circulation cell of hot air that continues to heat up via conduction from the hot surfaces. At Tozeur, in the Chott el Jerid, the mean daily maximum temperature exceeds 42°C in June and July. In Death Valley, in the United States, the mean daily maximum exceeds 46°C in July.

Even an environment as small as a dune contains a number of microhabitats, as each part of the dune is affected differently by sun and wind. The side facing the morning sun will heat up first and by 8 a.m. may be 10°C warmer than elsewhere. In the afternoon the windy dune crest may be the

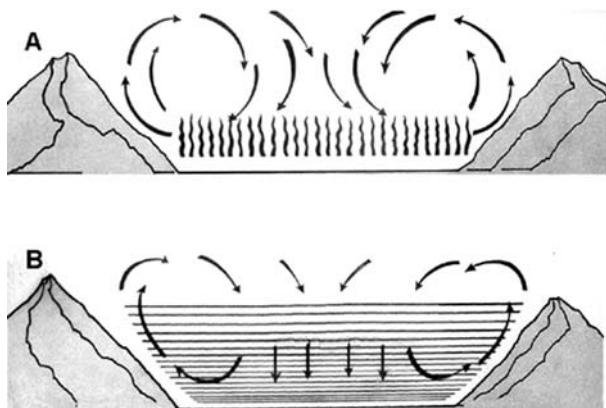

Figure D12 Heating of a desert depression.

Figure D13 The *Welwitschia*, an unusual plant of the Namib Desert, absorbs the fog water through its leaves. The long, flat, low surfaces of its leaves promote condensation.

coolest location by more than 10°C. Characteristic plant and animal communities reside at different parts of the dunes and in the interdune areas.

Water accumulates deep inside sand dunes, because the surface dries out first. This deep water reservoir helps to support plant life. Moisture also varies among the dune habitats. In coastal deserts, for example, where sea breezes bring fogs inland, moisture is most efficiently captured where wind is strongest.

Temperature and surface moisture are also moderated by plant cover. The temperature in litter underneath and within the leaves of a *Welwitschia* plant (Figures D13 and D14) may be as much as 20–30°C cooler than on the surrounding, exposed ground surface. The soil moisture content can be twice as high as in the exposed ground. Insects and small animals take refuge within the plant cover.

Climatic change

The Earth's deserts have undergone numerous climatic fluctuations on time scales of tens to tens of thousands of years. The fluctuations in these regions are roughly synchronous with major changes over the Earth as a whole. Those of higher latitudes have experienced fluctuations of both temperature and rainfall, but the major changes in the low-latitude deserts involve mainly rainfall. In recent times generally only the semiarid margins have been affected, but over the last 30 000 years the global extent of deserts has changed markedly.

During the last glacial maximum, about 18 000 years ago, the low-latitude deserts generally expanded, with the Sahara advancing nearly 10° toward the equator and its dunes overriding the lakes and rivers south of its previous border. The expansion of the arid zone into the tropics was so complete that the rainforests nearly vanished, their species taking refuge in a few highland habitats. At the same time "pluvial", or humid, conditions prevailed in many of the midlatitude deserts. Great lakes covered much of the current states of Utah, Nevada and California. Many dried up at the end of the Ice Age, about 10 000 years ago, and the left behind huge beds of fine sediments, like the Bonneville Salt Flats of Utah, where the ultra-smooth surface has permitted a vehicle to set a land-speed record of 622 mph.

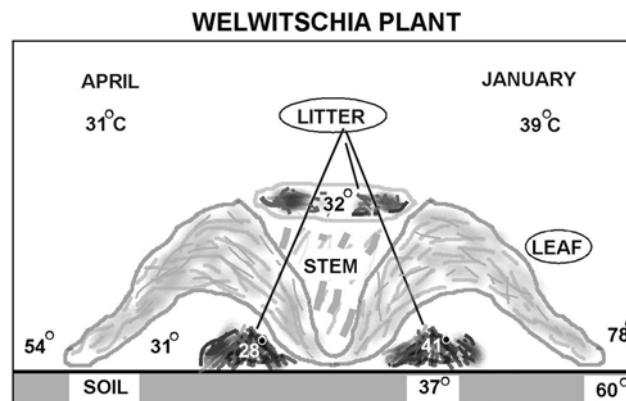

Figure D14 The relatively moderate microclimate of the *Welwitschia* plant provides a refuge for small animals and insects.

The conditions which commenced about 10 000 years ago are in stark contrast, with a low latitude "pluvial" period reaching a maximum some 5000 years ago. Then, the low-latitude deserts were generally reduced to their hyperarid cores. There is little evidence anywhere of active sand dunes at that time. In parts of the Sahara, Neolithic man herded cattle and animals grazed on savanna vegetation; fish hooks uncovered in archaeological sites attest to the presence of lakes in, and human occupation of, now-hyperarid regions.

A more recent period in which aridity has waxed and waned was around the Middle Ages, some 600–1200 years ago. Considered to be a global warm epoch, the core of this period was one of wetter conditions along the margins of many deserts. This was probably the case in the Peruvian Desert, the southwestern United States, Australia, the Mediterranean, the Middle East and the southern Sahara. Major civilizations, such as the Mali empire, thrived in presently semiarid regions of Africa. Caravan routes traversed now-waterless plains of the

Sahara and several towns flourished along these routes. On the other hand, drier conditions prevailed in some deserts and semi-desert regions of higher latitudes, such as the Great Plains of the central United States.

In recent centuries similar fluctuations of climate have affected desert regions, although less extreme. These are an inherent characteristic of the desert environment, and one to which life in the deserts has adapted. A quick look at the major deserts suggests no systematic change in recent decades, with one exception: throughout most of Africa there is a trend toward more arid conditions and expansion of the total area occupied by deserts. This is a significant percentage of the global arid environments and is cause for concern.

DETERMINISM, CLIMATIC

Determinism is the doctrine that all happenings and existences are the inevitable outcome of a set of preexisting conditions, and specifically that human actions are not based on free will, but are determined by environmental influences. In its widest context such a philosophy is encompassed within the framework of environmental determinism. Climatic determinism is a subset of environmental determinism, with climate considered the major influence or control.

Environmental determinism has its roots in classical antiquity but in its modern terms can be traced to the influence of Charles Darwin, whose ideas made it inevitable that social scientists should see natural laws operating in the different cultures and activities of people. The formal statements of such a relationship are often attributed to Friedrich Ratzel (1844–1904), although many of the ideas presented in his work *Anthropogeographie* are not as naive as sometimes suggested by those who have referred to it. In the United States, Ellen C. Semple, a student of Ratzel's, became the foremost proponent of environmental determinism. Despite the avoidance of the word "determinism" in her work, she expressed her basic thesis

in the declaration "man is a product of the earth's surface" (Semple, 1935).

Reaction to many of the simplifications of environmental determinism led other writers to proposed modifications of the role of environment in human endeavors. Thus "stop-and-go" determinism was proposed by Griffiths Taylor, who wrote:

Man is able to accelerate, slow or stop the progress of a country's development. But he should not, if he is wise, depart from the direction as indicated by the natural environment. He is like the traffic controller in a large city who alters the rate and not the direction of progress (Taylor, 1955).

Similarly, the ideas of environmental possibilism and probabilism reflect a spectrum of the role of environment in determining the possible and probable outcome of human endeavors.

Within this flow of ideas it was to be expected that the role of climate as a significant part of the human environment should be given special emphasis. Climatic determinism has a developmental history of its own.

The early concepts

Variations from climatic conditions that existed in the heart of their world caused classical Greek philosophers and writers to postulate many ideas concerning the role of climate in the nature of people. In his discussion *On Airs, Waters and Places*, Hippocrates (ca. 420 BC) contrasted easy-going Asiatics with penurious Europeans by suggesting that the latter had to be much more active to ameliorate their environment. A similar theme occurs in the work of Aristotle (ca. 350 BC), who commented "The inhabitants of colder countries in Europe are brave but deficient in thoughts and technical skills" (see Tatham, 1957).

Such concepts were also used by Roman writers. Strabo (ca. 64 BC–AD 20), for example, suggested that the rise and strength of Rome was due in part to the climate, physical makeup, and position of Italy. With the decline of Rome, however, explanations of the role of humans in their environment diminished, and in medieval times writers were not encouraged to deal with items that did not completely conform to biblical teachings.

While this was true in the Christian world, Arabic writers did contribute to the climate–human relationship. The great historian–geographer Ibn Khaldun (1332–1406) divided the hemisphere into seven climatic zones. The extremes were uninhabitable and only the middle zone provided the climate in which people could excel in wisdom and were neither too stolid nor excessively passionate. He said that

the human inhabitants of these zones are well proportioned in their bodies, color, character qualities and general conditions. The inhabitants of the zones that are far from temperate are also farther removed from being temperate in all their conditions. Thus the inhabitants of the middle zone have all the natural conditions necessary for a civilized life (Khaldun, 1958, vol. 1).

The sixteenth and seventeenth centuries produced writers who once again resurrected the classical ideas. Of particular note was the work of the French social writer Montesquieu (1689–1755). In his *The Spirit of Laws* he sought to determine the effects of climate and soils on the character of people and, in his opinion, climate was of particular importance.

Table D2 Selected concepts on climatic determinism

Author	Concepts
Hippocrates (ca. 420 BC)	Developed ideas on environmental influence on human behavior.
Aristotle (384–322 BC)	The varying habitability of the earth with differences of latitude: the inhabitants of extreme climate conditions are deficient in thought and technical skill, whereas living in the intermediate region combined the best quality of living.
Strabo (ca. 64 BC–AD 20)	Attempted to explain how climate affected the rise and strength of Rome.
Ibn Khaldun, A.R. (1332–1406)	Argued that environmental factors, such as climate, provide their due influence on such social factors as cohesion, occupation, and wealth.
Bodin, Jean (1530–1596)	Presented ideas of environmental influence on human life: the habitability of a place was a function of its latitude.
Carpenter, Nathanael (1589–1628)	Human character is determined by climate.
Montesquieu, Charles Louis de Secondat (1689–1755)	Presented ideas about the influence of climate on politics.
Kant, Immanuel (1724–1804)	Animals and men gradually change by their environment: effect of temperatures on nerves and veins, making the movements stiff and unsupple.
Von Humboldt, Alexander (1769–1859)	Developed the relations of latitude air, temperature, vegetation and agriculture in tropical mountains: made investigations with a view to seeking answers to questions about interconnections among the phenomena grouped together in rich diversity on the face of the Earth. He cautiously pointed out that atmospheric conditions merely favored that which had been called for by mental qualifications, and by the contact of highly gifted races with more civilized neighbors.
Ritter, Carl (1779–1859)	Some of his basic ideas concerning the influence of the Earth's major features on the course of history were developed. He sought to understand the interconnections, the causal interrelations, that make the areal associations cohesive. He was interested in the effect of the Earth on humans, the reciprocal action of humans on the Earth was to him equally significant.
Darwin, Charles (1809–1882)	Mechanism of natural selection of the cause of evolution, rather than need or use.
Spencer, Herbert (1820–1903)	Pointed out close resemblance of human societies to animal organisms.
Buckle, H.T. (1821–1862)	Physical agents have powerfully influenced the human race. These are climate, food, soil, and general aspects of nature. Contended that climate, generally working indirectly, is a major environmental influence.
Haeckel, E.H. (1834–1919)	Humans are only one of the organisms to be studied, and was equally in the grip of the surrounding forces; a proponent of Darwin's theory.
Ratzel, Friedrich (1844–1904)	The application of Darwin's biological concepts of human societies: human beings must struggle to survive in particular environments much as plant and animal organisms must do, known as Social Darwinism. He recognized climate as a chief environmental influence but pointed out that its effects are often indirect, affecting man by way of its influence on plants, animals, and soil.
Davis, William Morris (1850–1934)	Set forth his concept of geography as an explanatory description of the physical character of the Earth's surface, and of the human response to the physical surroundings. Began to seek cause and effect generalizations, usually between some elements of inorganic control and some elements of organic response. Attempted to bring cohesion to geography by introducing Spencer's ideas of Social Darwinism.
Demolins, Edmond (1852–1907)	Argued the role of climate produces grass vegetation; and the presence of grass determines a uniform mode of work – the art of pastoralism. Sought the "laws" which govern human actions.
Semple, Ellen Churchill (1863–1932)	Very careful to make the point that the environment does not control human activity: only that under certain circumstances there is a tendency for people to behave in predictable ways.
Dexter, E.G. (1868–1938)	Compared the daily temperature, atmospheric pressure, humidity, wind, sunshine, and precipitation in respect to the behavior condition investigated, and found statistically significant correlations between weather and conduct, suicide, and other crimes.
Patterson, S.O. (1868–1941)	Noted the human effects of the period of climatic instability that culminated the fourteenth century.

Table D2 (Continued)

Author	Concepts
Moore, H.L. (1869–1958)	Presented the idea of economic cycles as influenced by the climatic conditions.
Brunhes, Jean (1869–1930)	It is not influences that are sought but geographical relations between physical facts and human destinies; humans are creations of habit and habit once established becomes a part of their environment and exerts considerable influence on their later development.
Huntington, Ellsworth (1876–1947)	Refined the climatic hypothesis as related to climatic causation.
Bowman, Isaiah (1878–1950)	There is widespread evidence that there are climatic limits to profitable agricultural settlement in spite of the production of quicker maturing crops for hardier cattle.
Taylor, Griffith (1880–1963)	Humans are not free agents. If humans are wise they should not depart from the directions as indicated by the natural environment.
Visher, Stephen Sargent (1888–1967)	Of all the geographical influences to which humans are subjected, climate seems to be the most potent. Despite the fact that most climatic influences are “permissive”, “not deterministic”, various aspects of climate are so highly restrictive as to be in effect controls.
Toynbee, Arnold J. (1889–1975)	Was influenced by Huntington’s ideas about the relation between human beings and their physical environment; is not a determinist.
Mills, Clarence A. (1891–1974)	A professor of experimental medicine; he put forward many ideas in his book <i>Climate Makes the Man</i> , a title that expresses clearly his philosophy.
Markham, S.F. (1897–1975)	Related the relative

Accordingly, he noted that people who live in cold climates are stronger, more courageous, less suspicious and less cunning than those in hot climates, who tend to be like old men and are timorous, weak in body, indolent and passive. A similar theme was presented by the philosopher Immanuel Kant (1724–1804), who also added that outside of temperate climes the inhabitants of both hot and cold lands were stiff and unsupple because too much or too little perspiration makes blood thick and viscous while too much heat and cold dry out nerves and veins.

Many other thinkers and writers, such as Ritter (1799–1859) and Humboldt (1767–1835) expressed opinions that, although more cautious, exhibited a similar outlook. Table D2, while far from complete, provides a list of writers who contributed toward the ideas of climatic determinism.

The twentieth century

The two names most closely associated with determinism in the twentieth century are Ellen Churchill Semple (1863–1932) and Ellsworth Huntington (1876–1947), with Semple being closely associated with environmental determinism in all its aspects and Huntington being best known as the archetypal climatic determinist. The work of Huntington is dealt with here.

Huntington’s early work was influenced by his travels in Asia and by James Geikie’s book *The Great Ice Age and its Relation to the Antiquity of Man*. Arising from these early influences was his book *The Pulse of Asia* (1907), in which he developed the idea that climate in postglacial time was becoming drier and that in Central Asia not only the habits but also the character of the people were molded by the environments resulting from climatic change. In effect, climatic change is one of the greatest factors in determining the course of human progress.

While continuing to work on climatic change, Huntington also developed the idea that there is a climatic optimum for the human being regardless of race or background. Studies on human productivity in New England led to the conclusion that

temperature is the most significant variable and that the people in Bridgeport and New Haven are physically most active when the average temperature is between 60°F and 65°F, and mentally most active when outdoor temperature is about 38°F. Further, people do not work well when the temperature is fairly constant or extremely changeable. The ideal conditions are moderate changes, especially a cooling of the air at frequent intervals. These ideas were further developed in articles such as “The handicap of the tropics” (1913) and “The adaptability of the white man in tropical America” (1914).

These two main themes – climatic change and history and climate and the human response – are represented in much of Huntington’s further work. About the former, Martin (1973) has written:

His bold scheme, imaginatively wrought, involving tree rings, lake levels, valley terraces, dunes, disappearing rivers, wilderness ruins and the whole apparatus for climatic change, was applied to history...it revealed an ever-changing climatic milieu explaining nomadic migrations, the fortunes of Kings, the downfalls of empires, outbursts of intellectual advance and lesser matters concerning rhythms.

His work on climate and human activities was marked by less scientific evidence and oversimplification of complex variables. Nonetheless, Huntington did recognize, long before it was popular, many aspects of applied climatology (see Fonaroff, 1965).

Current thought

There are few climatologists today who would admit to being climatic determinists. The sweeping generalizations, backed by minimal evidence, of Huntington and other writers cannot be accepted at face value. However, the extreme stance of determinists of the midtwentieth century led to a backlash effect in which climate and environment, when considered in any aspect

of human activities, became an area of nonresearch. Voluntarism, the other end of the spectrum of thought, became viable.

Fortunately, other schools of thought, taking a midpath between the two extremes, were introduced and today a more rigorous approach to human-climatic relationships and the rise and fall of civilizations has again made it a respectable area of study.

DEW/DEWPOINT

Dew is any water that is condensed onto the ground, rocks, grass, and so on. It generally forms at night due to radiational cooling (most effective on clear, still, cool nights), which causes the temperature of the air to fall below its dewpoint.

Dewpoint is the temperature at which saturation of the air occurs, i.e. the temperature at which the observed vapor pressure is equal to the saturation vapor pressure. If a parcel of air is hypothetically held at constant pressure and vapor content, the temperature at which it must be cooled to reach saturation is called its dewpoint or, if below 0°C, its frost point. Provided that any change in temperature of a parcel of air occurs without change in pressure or vapor content, the dewpoint will always be constant, i.e. conservative. On the other hand, if the parcel rises adiabatically, the dewpoint is quasi-conservative, because the dewpoint of moist air drops only at about one-fifth the rate of the dry adiabatic lapse rate.

A dewpoint hygrometer may be used to determine surface dewpoint. A refrigerated metal surface is brought in contact with air, causing condensation when it is slightly below the temperature of the thermodynamic dewpoint. More usually dewpoint is simply determined with a psychrometer (wet and dry bulb thermometers), used with appropriate tables (Table D3).

If the temperature is below freezing, hoar frost will form, but if the temperature drops below freezing after the dew has formed the result is white dew. Dew is especially effective when the ground layer of air has a high relative humidity, as along river valleys, near swamps, etc. Dew is often the only form of moisture available to plants and animals in extreme deserts.

An optical effect of dew is known as heiligenchein or Cellini's halo, brought about by an early-morning sun producing a shadow over the observer's head. Reflection from the dew-covered surface produces a "saintly" halo, said to have been described first by Cellini, who found it a divine sign.

DOLDRUMS

Doldrums are the calms of the Intertropical Convergence Zone. The regions are characterized by low atmospheric pressure, high humidity, and thunderstorms. They are often associated with the source of tropical hurricanes, the sites of water spouts, and windlessness, sometimes alternating with sharp squalls. They are not to be confused with the calms of the horse latitudes.

Doldrums is an old English word meaning an unpleasant, depressed feeling. According to the *Oxford English Dictionary* there apparently arose a misunderstanding of the phrase “in the doldrums” used by some sailors, the human physiological state or condition of being transferred to a geographic belt or locality. Maury in 1855 used the term in this sense, and the usage became widespread. The colloquial French for doldrums is *potau-noir*, literally the boot-polish jar. Figuratively, *être dans le pot-au-noir* means exactly “to be in the doldrums”, hence the extension of the meaning to the equatorial calms later on. Most other European languages have no special name for these equatorial calms.

While the term doldrums is now seldom used in the literature, descriptions are common in older works. As pointed out by Brunt (1939), the doldrums are not by any means continuous throughout the year and do not form an uninterrupted equatorial belt. A sharp discontinuity occurs in the equatorial Pacific where the northeast and southeast trades meet; the latter rise over the former, accompanied by heavy rainfall. In the Pacific area, therefore, true doldrums only occur near the continental shores; while in the Atlantic they fluctuate both in width and in position (Durst, 1926).

Over the continents the equatorial belts are regions of calms and are subject to diurnal instability and thermal systems with heavier rainfall than over the oceans.

DROUGHT

Drought is an insidious natural hazard that results from a deficiency of precipitation from expected or “normal” that, when extended over a season or longer period of time, is insufficient to meet the demands of human activities. As the world’s population increases, societies are placing greater and greater pressure on finite water supplies and other limited natural resources – thus potentially increasing our vulnerability to extended periods of drought. In addition, growing concern over the impact of human activities on climate has heightened awareness of our sensitivity to climatic extremes such as drought. The results from scientific investigations indicate that the frequency and severity of drought may increase for some regions in the future as a direct result of increasing concentrations of greenhouse gases in the atmosphere.

Scores of definitions of drought exist, reflecting different climatic characteristics from region to region and sector-specific impacts. Although droughts are usually classified as meteorological, agricultural, hydrological, or socioeconomic, all types of drought originate from a deficiency of precipitation that results in water shortage for some activity or some group. Drought must be considered a relative, rather than absolute, condition. The ultimate results of these precipitation deficiencies are, at times, enormous economic and environmental impacts as well as personal hardship. Impacts of drought appear to be increasing in both developing and developed countries, a clear indication of nonsustainable development in many cases. Lessening the impacts of future drought events will require nations to pursue development of drought policies that emphasize a wide range of risk-management techniques, including improved monitoring and early-warning systems, preparedness plans, and appropriate mitigation actions and programs.

Drought concepts and definitions

Drought differs from other natural hazards in several ways. First, drought is a slow-onset, creeping natural hazard. Its effects often accumulate slowly over a considerable period of time and may linger for years after the termination of the event. Therefore, the onset and end of drought is difficult to determine. Because of this slow-onset characteristic it is difficult to recognize the onset of drought, and scientists and policy makers continue to debate the basis (i.e. criteria) for declaring an end to a drought. Second, the absence of a precise and universally accepted definition of drought adds to the confusion about whether or not a drought exists and, if it does, its degree of severity. Realistically, definitions of drought must be region- and application- (or impact-) specific. This is one explanation for the scores of definitions that have been developed. Third, drought impacts are nonstructural and spread over a larger geographical area than are damages that result from other natural hazards. Quantifying the impacts and providing disaster relief are far more difficult tasks for drought than they are for other natural hazards. These characteristics of drought have hindered the development of accurate, reliable, and timely estimates of severity and impacts and, ultimately, the formulation of drought preparedness plans.

Many people consider drought to be largely a natural or physical event. Like other natural hazards, drought has both a natural and social component. The risk associated with drought for any region is a product of both the region's exposure to the event (i.e. probability of occurrence at various severity levels) and the vulnerability of society to the event. The natural event (i.e. meteorological drought) is a result of the occurrence of persistent large-scale disruptions in the global circulation pattern of the atmosphere. Exposure to drought varies spatially and there is little, if anything, that we can do to alter drought occurrence. Vulnerability, on the other hand, is determined by social factors such as population changes, population shifts (regional and rural to urban), demographic characteristics, technology, government policies, environmental awareness, water-use trends, and social behavior. These factors change over time and thus vulnerability is likely to increase or decrease in response to these changes. Subsequent droughts in the same region will have different effects, even if they are identical in intensity, duration, and spatial characteristics, because societal characteristics will have changed.

Defining drought

Drought is the consequence of a natural reduction in the amount of precipitation received over an extended period of time, usually a season or more in length, although other climatic factors (such as high temperatures, high winds, and low relative humidity) are often associated with it in many regions of the world and can significantly aggravate the severity of the event. Drought is also related to the timing (i.e. principal season of occurrence, delays in the start of the rainy season, occurrence of rains in relation to principal crop growth stages) and the effectiveness of the rains (i.e. rainfall intensity, number of rainfall events). Thus, each drought event is unique in its climatic characteristics, spatial extent, and impacts. The area affected by drought is rarely static during the course of the event. As drought emerges and intensifies, its core area or epicenter shifts and its spatial extent expands and contracts throughout the duration of the event.

Because drought affects so many economic and social sectors, scores of definitions have been developed by a variety of disciplines. In addition, because drought occurs with varying frequency in nearly all regions of the globe, in all types of economic systems, and in developed and developing countries alike, the approaches taken to define it also reflect regional differences. Impacts also differ spatially and temporally, depending on the societal context of drought. A universal definition of drought is an unrealistic expectation.

Many disciplinary perspectives of drought exist, often causing considerable confusion about what constitutes a drought. Research has shown that the lack of a precise and objective definition in specific situations has been an obstacle to understanding drought, which has led to indecision and/or inaction on the part of managers, policy makers, and others. It must be accepted that the importance of drought lies in its impacts. Thus definitions should be region- and impact- or application-specific in order to be used in an operational mode by decision makers.

Drought is normally grouped by type as follows: meteorological, hydrological, agricultural, and socioeconomic. Meteorological drought is expressed solely on the basis of the degree of dryness (often in comparison to some normal or average amount) and the duration of the dry period. Thus, intensity

and duration are the key characteristics of these definitions. Meteorological drought definitions must be considered as region-specific since the atmospheric conditions that result in deficiencies of precipitation are climate regime-dependent.

Agriculture is usually the first economic sector to be affected by drought because soil moisture supplies are often quickly depleted. Agricultural drought links various characteristics of meteorological drought to agricultural impacts, focusing on precipitation shortages, differences between actual and potential evapotranspiration, and soil water deficits. A plant's demand for water is dependent on prevailing weather conditions, biological characteristics of the specific plant, its stage of growth, and the physical and biological properties of the soil. A definition of agricultural drought should account for the variable susceptibility of crops at different stages of crop development.

Hydrological droughts are associated with the effects of periods of precipitation shortfall on surface or subsurface water supply (e.g. streamflow, reservoir and lake levels, groundwater) rather than with precipitation shortfalls. Hydrological droughts are usually out of phase or lag the occurrence of meteorological and agricultural droughts. More time elapses before precipitation deficiencies are detected in other components of the hydrological system (e.g. reservoirs, groundwater). As a result, impacts are out of phase with those in other economic sectors. Also, water in hydrological storage systems (e.g. reservoirs, rivers) is often used for multiple and competing purposes (e.g. power generation, flood control, irrigation, recreation), further complicating the sequence and quantification of impacts. Competition for water in these storage systems escalates during drought, and conflicts between water users increase significantly.

Finally, socioeconomic drought associates the supply and demand of some economic good or service with elements of meteorological, hydrological, and agricultural drought. Socioeconomic drought is associated directly with the supply of some commodity or economic good (e.g. water, hay, hydroelectric power) that is the result of precipitation shortages. Increases in population can alter substantially the demand for these economic goods over time. This concept of drought supports the strong symbiosis that exists between drought and its impacts and human activities. Thus, the incidence of drought could increase because of a change in the frequency of meteorological drought, a change in societal vulnerability to water shortages, or both.

Drought characteristics and severity

Droughts differ from one another in three essential characteristics: intensity, duration, and spatial coverage. Intensity refers to the degree of the precipitation shortfall and/or the severity of impacts associated with the shortfall. It is generally measured by the departure of some climatic index from normal and is closely linked to duration in the determination of impact. Another distinguishing feature of drought is its duration. Droughts usually require a minimum of 2–3 months to become established, but then can continue for months or years. The magnitude of drought impacts is closely related to the timing of the onset of the precipitation shortage, its intensity, and the duration of the event.

Droughts also differ in terms of their spatial characteristics. The areas affected by severe drought evolve gradually, and regions of maximum intensity shift from season to season. In larger countries, such as Brazil, China, India, the United States, or Australia, drought would rarely, if ever, affect the entire

country. During the severe drought of the 1930s in the United States, for example, the area affected by severe and extreme drought never exceeded 65% of the country. However, because of its size and diverse climatic regimes, drought occurs somewhere in the country each year. From a planning perspective the spatial characteristics of drought have serious implications. Nations should determine the probability that drought may simultaneously affect all or several major crop-producing regions within their borders, and develop contingencies if such an event were to occur. Likewise, it is important for governments to know the chances of a regional drought simultaneously affecting agricultural productivity in their country as well as adjacent or nearby nations on whom they are dependent for food supplies.

The impacts of drought

The impacts of drought are diverse and often ripple through the economy. Thus, impacts are often referred to as direct or indirect. Because of the number of affected groups and sectors associated with drought, its spatial extent, and the difficulties connected with quantifying environmental damages and personal hardships, the precise determination of the financial costs of drought is an arduous task. It has been estimated that the average annual impacts of drought in the United States are \$6–8 billion, but drought years often occur in clusters.

The impacts of drought can be classified into three principal areas: economic, environmental, and social. Economic impacts range from direct losses in the broad agricultural and agriculturally related sectors, including forestry and fishing, to losses in recreation, transportation, banking, and energy sectors. Environmental losses are the result of damages to plant and animal species, wildlife habitat, and air and water quality; forest and range fires; degradation of landscape quality; and soil erosion. Although these losses are difficult to quantify, growing public awareness and concern for environmental quality has forced public officials to focus greater attention on these effects. Social impacts mainly involve public safety, health, conflicts between water users, and inequities in the distribution of impacts and disaster relief programs. As with all natural hazards, the economic impacts of drought are highly variable within and between economic sectors and geographic regions, producing a complex assortment of winners and losers with the occurrence of each disaster.

Drought preparedness

Drought planning is defined as actions taken by individual citizens, industry, government, and others in advance of drought for the purpose of mitigating some of the impacts and conflicts associated with its occurrence. Because drought is a normal part of climate variability for virtually all regions, it is important to develop plans to deal with these extended periods of water shortage in a timely, systematic manner as they evolve. This planning process needs to occur at various levels of government and be integrated between levels of government.

The purpose of a drought policy and plan is to reduce the impacts of drought by identifying the principal sectors, groups, or regions most at risk and developing mitigation actions and programs that can reduce these risks in advance of future drought events. Generally, drought plans have three basic components: monitoring, early warning, and prediction; risk and impact assessment; and mitigation and response. Plans will also

improve coordination within agencies of government and between levels of government. Before developing a preparedness plan, government officials should first define, in consultation with principal stakeholder groups, the goals of the plan.

The awareness of the need for drought planning has increased dramatically in both developed and developing countries. For example, in the United States, the number of states with drought plans has increased from three in 1982 to 34 in 2002. This trend demonstrates an increased concern about the potential impacts of extended water shortages and the complexity of those impacts. Drought plans are at the foundation of improved drought management, but only if they emphasize risk assessment and mitigation programs and actions.

Summary

Drought is an insidious natural hazard that is a normal part of the climate for virtually all regions. It should not be viewed as merely a physical phenomenon. Rather, drought is the result of an interplay between a natural event and the demand placed on water supply by human-use systems. Drought should be considered relative to some long-term average condition of balance between precipitation and evapotranspiration.

Many definitions of drought exist; it is unrealistic to expect a universal definition to be derived. The three characteristics that differentiate one drought from another are intensity, duration, and spatial extent. The impacts of drought are diverse and generally classified as economic, social, and environmental. Impacts ripple through the economy and may linger for years after the termination of the drought episode.

It appears that societal vulnerability to drought is escalating in both developing and developed countries, and at a significant rate. It is imperative that increased emphasis be placed on mitigation, preparedness, and prediction and early warning if society is to reduce the economic and environmental damages associated with drought and its personal hardships. This will require improved coordination within and between levels of government and the active participation of stakeholders.

DYNAMIC CLIMATOLOGY

Dynamic climatology, now frequently termed “climate dynamics”, is an attempt to study and explain atmospheric circulation over a large part of the Earth in terms of the available sources and transformations of energy (Court, 1957). Hare (1957) notes that dynamic climatology is the prime approach for explanation of world climates as integrations of atmospheric circulation and disturbances. It also attempts to derive circulation types at the regional scale.

Agreement on the scope of dynamic climatology is not universal, and differences among dynamic, complex, and synoptic climatology are not always well defined. For example, Bergeron (1930) and others considered what is now synoptic climatology to be dynamic climatology. Interest in weather patterns among synoptic climatologists has also obscured contrasts with complex climatology. A history of the origin and content of dynamic climatology has been given by Rayner et al. (1991) while a modern survey of the field is available in a text by Barry and Carlton (2001).

Principles

The dynamic climatological approach is based on motion characteristics and the thermodynamic processes that produce them. Dynamic meteorologists have as their principal interest the development and interpretation of relationships that describe these latter items; their usage separates the climatologist from the meteorologist, although the boundary between the disciplines is a tenuous one. An excellent introduction to dynamics and thermodynamics as they apply to the atmosphere is contained in Hess (1959) and Atkinson (1981).

Moving air is the result of forces brought about by thermodynamic processes that originate primarily at the Earth–air interface. The driving force for all processes is the radiant energy supplied to the Earth–atmosphere system by the sun.

A small fraction of available solar energy is absorbed directly by atmospheric constituents. About three times as much energy reaches the surface of the Earth and is absorbed in differing amounts, depending on the geometry and physical properties of the surface. Various unevenly distributed energy sources and sinks are thus created. Energy is defined as the capacity to do work, to move an object (mass) through a distance by application

of a force. Disposition of thermal energy in this case alters temperature, density, and pressure values, thereby yielding unbalanced vertical and horizontal forces that cause air to move. Heat, moisture, and momentum transfers result from such motions at various scales. Ultimately, the Earth–atmosphere system returns thermal energy to space through radiation in an amount equivalent to the solar energy originally received, thus balancing long-term gains and maintaining the atmospheric heat engine in a steady state.

The fundamental equations (often called the Primitive Equations) that describe processes and motion in the atmosphere are the Ideal Gas Law, the First Law of Thermodynamics, the Equation of Motion, the Equation of Moisture Conservation, and the Equation of Continuity (Table D4). They are used to describe the interactions and characteristics of the basic building blocks comprising the Earth–atmosphere system. Manipulations of the basic equations allow us to decipher relationships among thickness between layers in the atmosphere, temperature, the wind field, and to develop stability–change equations, pressure–tendency equations, and the vorticity equation, among others. Some concepts that follow from these relationships include geopotential and geopotential height, isobaric and constant level representations, streamlines and trajectories, circulation, and divergence.

Imperfect characterization

If the entire atmosphere could be confined to a laboratory setting, application of the equations in Table D4 would be a straightforward problem. Application to the real, unconfined atmosphere presents several difficulties. For example, data on the state of the atmosphere are not available at every point at all possible moments. This means that climatologists must work with average, or smoothed, data among sampled points. Unfortunately, such smoothing often eliminates small-scale density or temperature patterns that may have a significant but unknown effect at some location and time. Ramage (1978) points out that it is small-scale factors embedded within the atmosphere that prevent numerical weather forecasting efforts from being more accurate.

Lack of continuous, pervasive sampling also requires that boundaries be fixed on the edges of an area of interest; the west coast of the United States serves as one such large boundary because data on conditions over the Pacific Ocean are not widely available. Changes at the boundary become difficult to determine and ultimately filter through all equations used to characterize the atmosphere.

Turbulent eddies (small-scale air currents produced by frictional interaction by juxtaposed, unlike airmasses) also contribute substantially to the status of the atmosphere at any time. Again, unfortunately, the ability to describe energy transfers by

Table D4 Fundamental variables and equations

Velocity	Equation of Motion

Source: After Panofsky (1956).

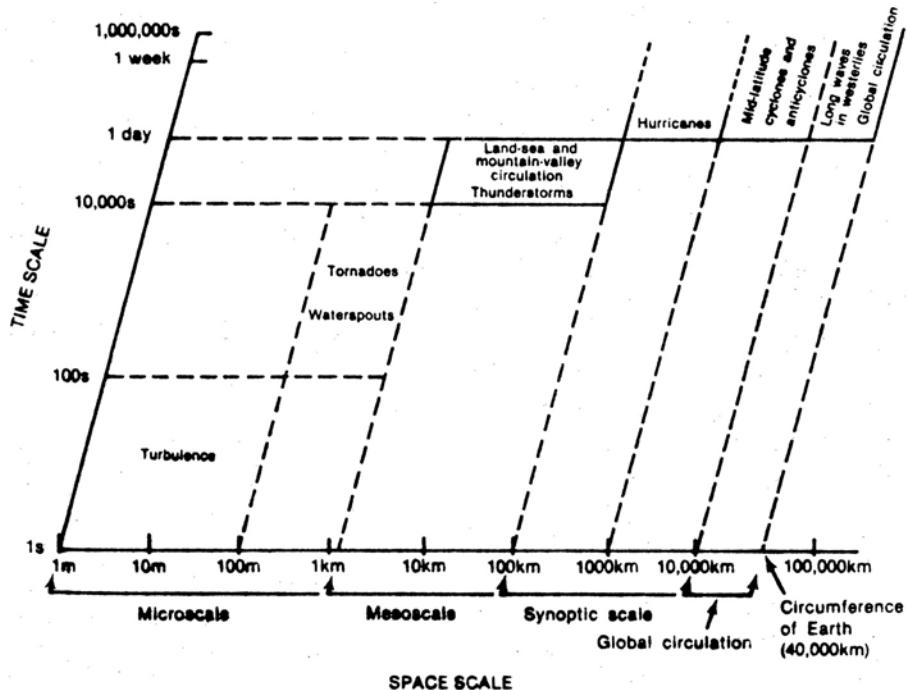

Figure D15 Time and space scales of atmospheric motion (after Anthes et al., 1981).

eddy conduction, diffusion and friction within the friction layer (the lowest 1500 m of the atmosphere) is limited; such transfers are neglected.

Finally, the basic equations used to describe the workings of the atmosphere are nonlinear. This means that, even at large scales, irregular fluctuations above and below mean values of variables do not cancel. Equations can be made to perform as though they were linear by using an artifice that considers all turbulent contributions as perturbations on the mean pattern. Given the contribution of turbulence to the mean state of the atmosphere, this introduces errors, is unsatisfactory, but is all that can be done at present without the use of numerical methods.

Description of motion

Although forces producing motion are interwoven in the atmospheric fabric, some equation terms and variables can be excluded at certain scales, because their contribution to an event or process is minimal (Figure D15). For example, at the level of the global circulation, vertical motion can be neglected, but not heat transfer, because at the global scale motion is overwhelmingly horizontal. On the other hand, certain microscale processes allow neglect of all thermodynamic equations and the variables temperature, moisture, and density if the atmosphere is considered incompressible. Thus, complexity is decreased without decreasing understanding of important processes and the results.

The Equation of Motion listed in Table D4 describes a vector and thus has three parts, each expressing Newton's Second Law of Motion (force = mass \times acceleration) for three directions in a Cartesian system. Manipulations of this general equation yield the collective forces that must be specifically

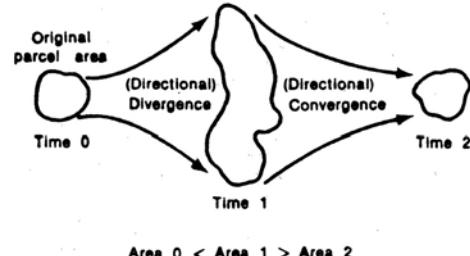

Figure D16 Horizontal divergence.

expressed; namely, gravity, pressure gradient, Coriolis force, and friction. Stated as a vector in words:

$$\text{Changes in velocity per unit time} = \text{Coriolis force} + \text{gravitational force} - \text{pressure gradient force} + \text{effect of friction.}$$

Motion that takes place on a plane (two equations describe motion on a plane) above the friction layer between straight, parallel isobars (i.e. accelerations are not produced by the pressure field), is called the geostrophic wind, and is expressed as a balance between the pressure gradient and Coriolis forces. Consideration of curved isobars and the effect of friction yields other types of flow regimes, such as gradient (observed around low- and high-pressure systems), cyclostrophic (typical of tornadic circulation), and cross-isobaric motion due to the effect of friction on the velocity component of the geostrophic wind. Subtraction of geostrophic winds at two levels yields the thermal

wind, which provides ties among thickness between layers, virtual temperature, and warm or cold air advection.

The third equation of motion applies to movement along a vertical axis. The Coriolis and frictional forces are neglected because their vertical components are small. Vertical motion then represents an interplay between an upward-directed pressure gradient force and gravity as a restoring force; this relationship is called the Hydrostatic Equation.

Manipulations of the three motion equations yield other concepts that are used in the dynamic climatological approach. For example, divergence and its opposite convergence occur when flow leads to increasing or decreasing area changes through time, as in Figure D16. Mass is neither created nor destroyed in the Earth-atmosphere system, and this principle (the First Law of Thermodynamics) stated in the form of the Equation of Continuity, ties changes in the horizontal with vertical motion (Figure D17). As the atmosphere contracts horizontally (converges), it expands vertically (stretches), and vice-versa. If we consider the troposphere as the region where these compensating mechanisms operate, then a general pattern like Figure D18 results. These patterns can also be related to vertical motion and typical convergence-divergence patterns in an eastward-moving upper-air wave system (Figure D19).

Finally, vorticity (which can be derived from the two horizontal equations of motion) area changes and vertical motion

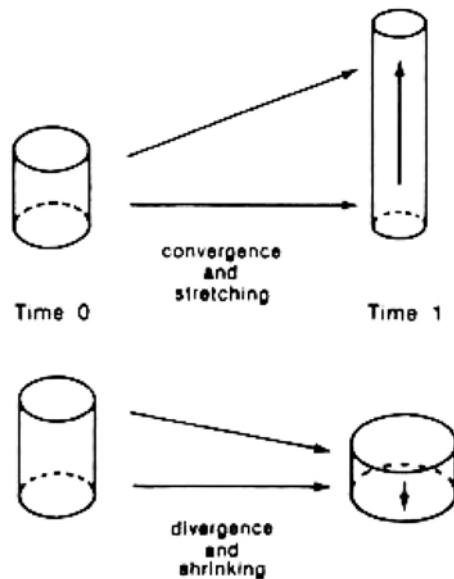

Figure D17 Convergence and stretching (upward vertical motion); divergence and shrinking (downward vertical motion).

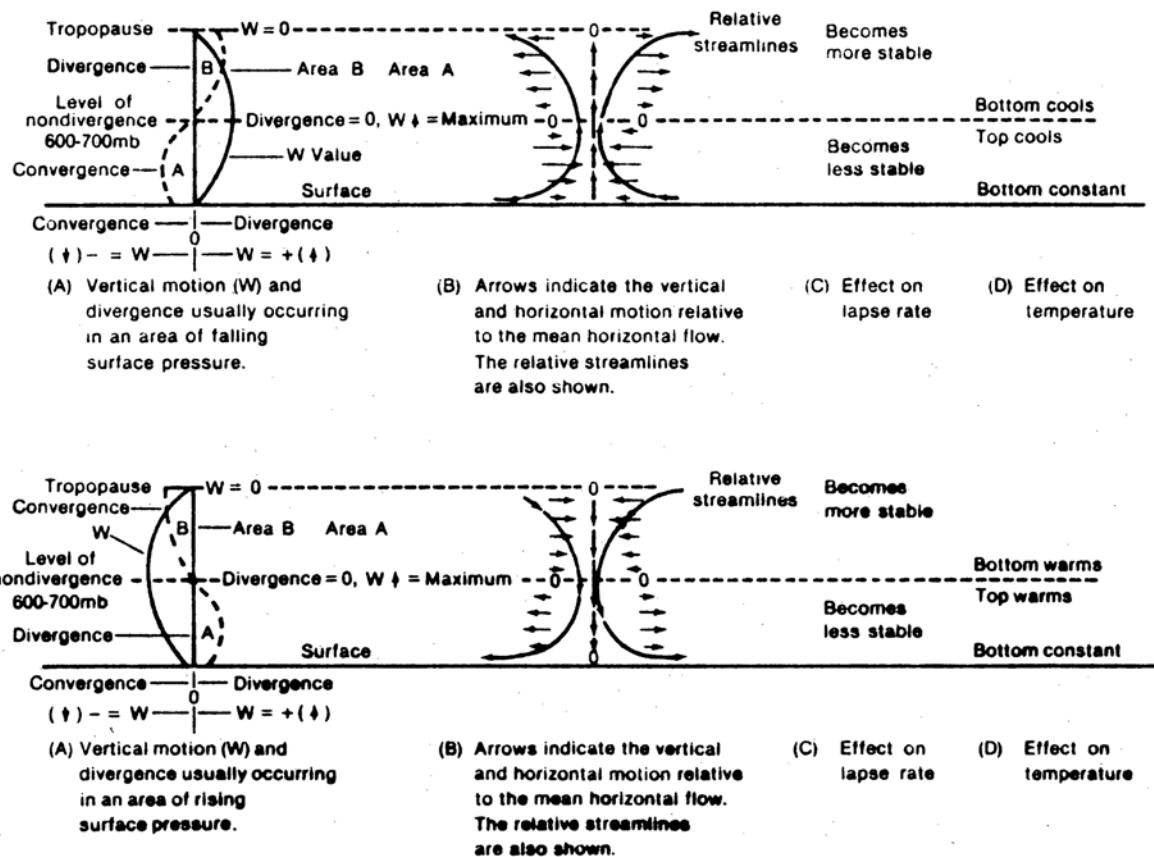

Figure D18 Convergence, divergence, and vertical motion in a typical atmospheric cross-section in the midlatitudes.

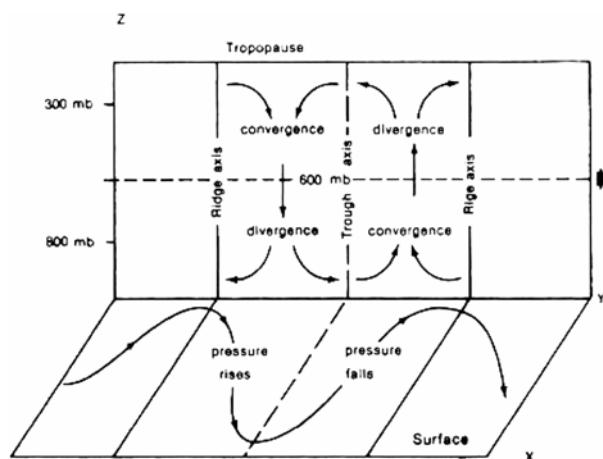

Figure D19 Organized patterns of convergence and divergence in an eastward-moving system in the midlatitudes.

are related through the vorticity equation. Vorticity is defined as circulation (velocity along a closed path times the length of path) per unit area; since circulation for most processes is relatively constant through time, absolute vorticity (composed of relative plus Earth vorticity) times area is a constant. Again, equation of continuity is used to relate area changes to depth changes; i.e. decreases in area are related to convergence, upward motion, and positive vorticity (counterclockwise spin). Positive vorticity is normally associated with weather system development. Negative vorticity (clockwise spin) is associated with divergence, downward vertical motion, and lack of significant system development.

An example of the interplay among area, depth, and vorticity changes is shown on Figure D20. Figure D21 shows these latter items as they change when topographic changes are encountered. Lower-level air moving perpendicular to a topographic barrier is forced to ascend as it approaches. Decreases in absolute vorticity below the value that should exist at the given latitude occur as the cylinder reaches the mountain crest, causing an increase in divergence, subsidence, and ultimately anticyclonic deflection of the air parcel. As the column leaves the crest, the lower levels are free to expand, thereby increasing upward vertical motion and positive spin. The topographically forced condition depicted in the figure often is the situation prevailing to the lee of the Rocky Mountains, and may lead to development of large cyclonic storm systems.

Thermodynamic processes

The use of thermodynamic principles shows how changes in heat content of the atmosphere, which behaves as a fluid under most circumstances, affect its dynamic characteristics. Volume and pressure changes within the atmosphere are produced by heat addition to, or subtraction from, an air parcel or by work done on or by the parcel within its surroundings. Thermodynamic laws describe what occurs among pressure, volume, and heat content as changes take place.

For example, the First Law of Thermodynamics states that heat added to a parcel can be used to increase its internal energy

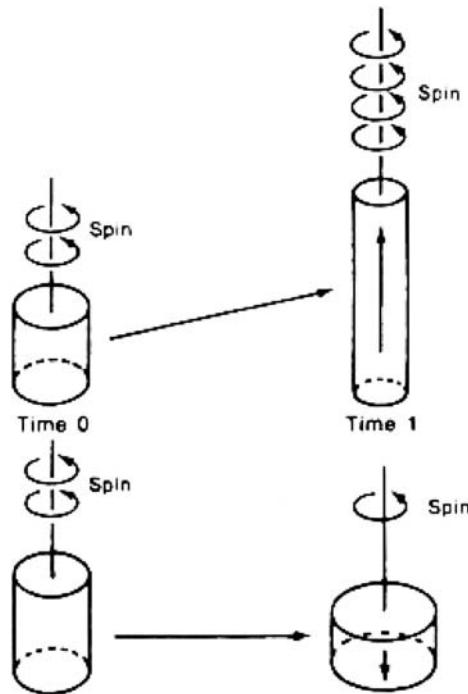

Figure D20 Relationship among vorticity, vertical motion, and area.

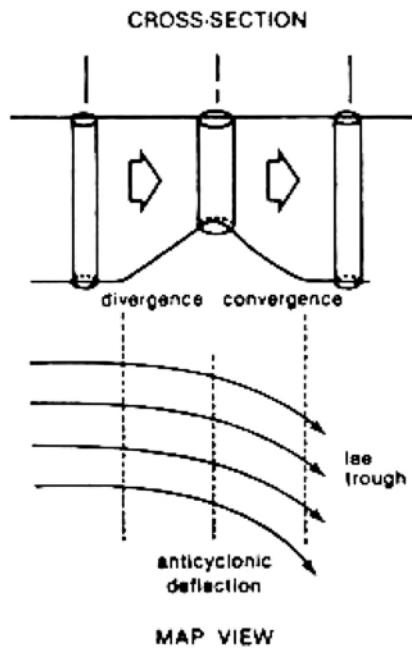

Figure D21 Patterns of convergence and divergence in an air current crossing a topographic barrier.

or to do work on its surrounding environment. From the First Law we can derive the adiabatic relationship, which states that all temperature changes within a parcel are due to expansion or compression if no external heat is added or taken away. External heat may come from radiation, eddy heat conduction,

evaporation, or condensation. The adiabatic relationship allows stability to be determined and tells us what will happen to parcel air temperatures as parcels move about in the atmosphere.

The state of the atmosphere at any moment can be described by application of the Ideal Gas Law, which relates pressure, density, virtual temperature, and a gas constant for air. The Moisture Equation allows determination of changes in water vapor content of air parcels through time. The equation relates changes in specific humidity (grams of water vapor per unit mass of air including moisture) to occurrence of condensation, evaporation, molecular diffusion and eddy diffusion of vapor between unlike air masses.

E

EASTERLY WAVES

On the western sides of oceans in the trade wind belt, surface winds vary little and heavy rainfall occurs mostly as periodic rather than continuous events. This rainfall is most frequently associated with a wavelike disturbance of the normal isobaric pressure pattern, a disturbance called an easterly wave.

In the North Atlantic Ocean, between 5 and 15 degrees north, the waves are first seen in April or May and continue until October or November. With a wavelength of about 2000–2500 km, and a period of 3–4 days, they move at approximately 18–36 km/h. Passing from the Africa onto the cool Eastern Atlantic Ocean, the waves generally decay, but some survive to regenerate over the Western Atlantic and Caribbean. About 10% of all easterly waves survive to develop into gale-force tropical storms or hurricanes.

Ahead of the wave, the east or northeast trade wind backs to northeast or north, the pressure falls, and the trade wind inversion lowers, producing fine weather. Low-level divergence and high-level convergence are accompanied by subsidence and suppressed convection. About 320 km (200 miles) ahead of the wave trough, the moist layer reaches a minimum, often at 1500 m (5000 ft). As the wave trough approaches, the depth of the moist layer increases. Behind the wave, low-level convergence and upper divergence result in ascending motion. The pressure begins to rise, heavy cumulus and cumulonimbus develop as the moist layer destroys the inversion and reaches a maximum height of about 7500 m (25 000 ft). Shower and thunderstorm activity, if present, reaches a maximum intensity some 320 km (200 miles) behind the surface trough (Figures E1 and E2).

Easterly waves vary widely among themselves with respect to stability and the amount of rainfall produced. Weak waves produce no rain over the open sea but usually intensify as they pass over islands. The variation in precipitation amount depends on whether the divergence or convergence extends to 850 mb or to 700 mb. Even with small divergence in weak disturbance, the precipitation amount may vary greatly in different parts of the waves.

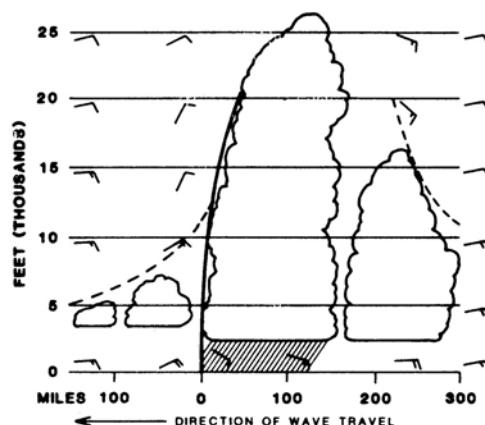

Figure E1 Cross-section of an easterly wave (after Malkus, 1957).

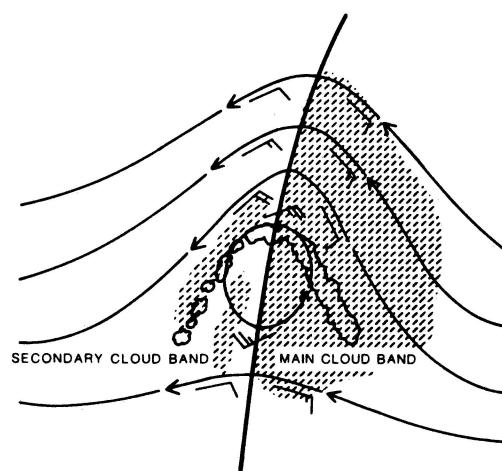

Figure E2 A deep easterly wave. The shaded area represents extensive rain and cloud amounts.

It has also been observed that when an upper-air polar trough penetrates deeply into low latitudes its tropical portion sometimes breaks off from the parent body in the westerlies. The fractured trough then may reverse its direction to move westward in the form of a wave in the easterlies.

Yanai (1961) suggested that easterly waves receive their energy from horizontal shear in the zonal flow and that the cold cores result from dynamically forced lifting associated with weak temperature gradients. The required horizontal shear may be provided by an Intertropical Convergence (ITC) that has become displaced some distance away from the equator. In general, the zonal shear is nearly three times as large as the meridional shear while the contribution of the curvature term to vorticity is negligible. Such unstable barotropic waves caused primarily by north-south shear are common in the eastern Pacific Ocean during the summer season.

On those occasions when the easterly wave develops rapidly, convection becomes organized into a definite pattern, pressure falls and a deep, intense tropical storm forms. These provide the potential genesis for hurricane formation.

EKMAN (SPIRAL) LAYER

The lower layers of the troposphere include a transition zone between the free atmosphere above and the surface boundary layer close to the Earth's surface. This zone, extending from perhaps 100 m above the surface to the geostrophic wind level, is sometimes considered as the spiral layer. The upper free atmosphere behaves as an ideal fluid with air motion responding to pressure and Coriolis forces; near the Earth's surface the shearing stress may be considered constant. Between these two the spiral layer needs be considered separately.

In this intermediate layer there is ideally an *Ekman spiral*, in which there is decreasing stress. Here the coefficient of eddy viscosity and density are assumed to be constant (for ease of calculation), but in nature considerable departures from the ideal are recorded. The spiral was originally worked out by W.F. Ekman in 1902 for an ocean current condition and was named for him (Figure E3). Shortly thereafter its applications to the atmosphere were identified.

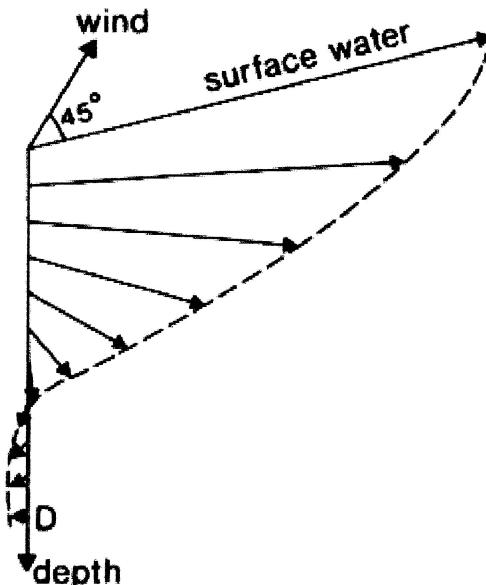

Figure E3 The Ekman spiral applied to increasing water depth.

In the spiral layer the wind blows across the isobars toward the lower pressure, as a so-called *secondary flow*, being at a maximum angle near the surface (less than 45°); with rising altitude, the wind bears to the right (veers) in the northern hemisphere, but bears left (backs) in the southern hemisphere. The Ekman formula provides the horizontal wind components u and v in the x and y directions, x being parallel to the pressure gradient and y normal to it for any altitude level z , thus in Cartesian coordinates, as follows:

$$u = v_g e^{-\beta} \sin \beta$$

$$v = v_g (1 - e^{-\beta} \cos \beta)$$

where v_g is the geostrophic wind speed, e the vapor pressure, and $\beta = z \sqrt{f/2K_M}$ with f as the Coriolis parameter and K_M the eddy viscosity. The wind vector in the spiral layer deviates from the geostrophic wind by an amount that diminishes upward at an exponential rate. An ideal graphical solution of this spiral can be seen on a polar-coordinate plot of wind direction tangentially against wind speed radially for successive altitudes.

ELECTROMAGNETIC RADIATION

Electromagnetic radiation is energy propagated through space (as from the sun or the cosmos) or through various solid media in the manner of a vibrating electric and magnetic field. According to James Clerk Maxwell, light was to be explained not by a transverse wave motion in an elastic medium, but by electric and magnetic charges, vibrating at right angles to each other and to the direction of propagation. The electric charges were supposed to transmit energy as an electromagnetic wave. According to the quantum theory these charges behave as particles, with mass and momentum.

Electromagnetic radiation (or simply radiation, in common practice) is characterized by wavelength (or frequency) and amplitude (or flux density). Wavelength (in one or two words) is generally given as λ , being related to frequency f and phase speed v by $\lambda = v/f$. The reciprocal of wavelength is wave number, or the number of waves per unit distance in the direction of propagation. Wavelength is usually measured from midpoint (going from negative to positive) in one cycle to similar midpoint on the next; however, in oceanography, oscillating sea waves are measured from crest to crest. A phase is a hemicycle. In an oscillation of uniform amplitude, two cycles are said to be 100% out of phase if the positive part of the one cycle exactly matches the negative part of the other.

The propagation speed of an electromagnetic radiation is given as

$$\frac{c}{\sqrt{\mu K}}$$

where the constant c (the speed of light) = $2997\,930 \times 10^{10}$ cm/s, the magnetic permeability is μ and the specific inductive capacity is K . The speed through vacuum, and roughly speaking through air, approximates c .

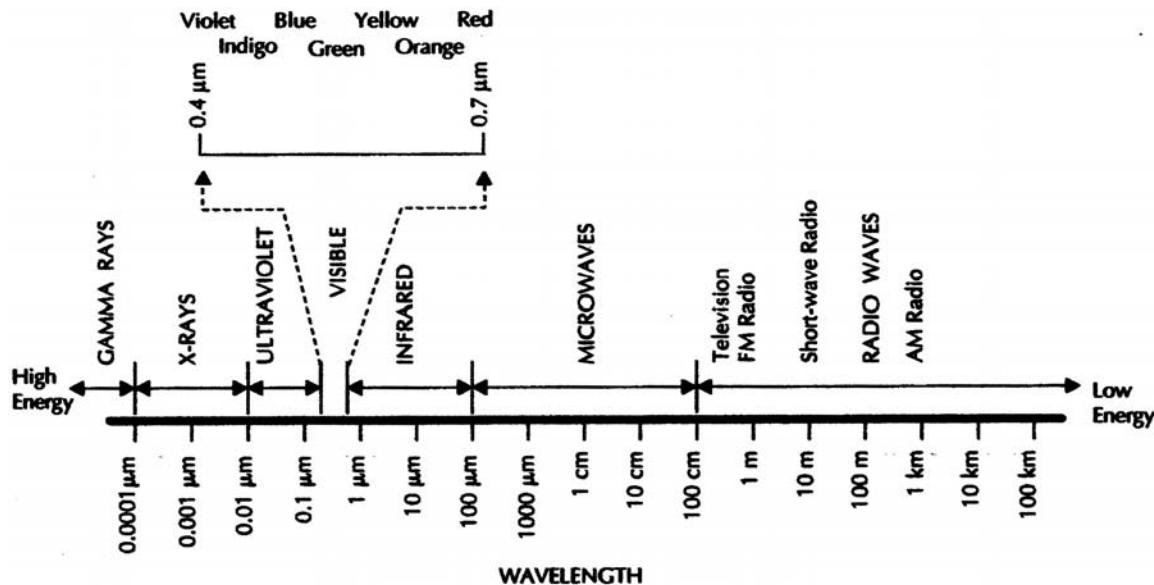

Figure E4 The electromagnetic spectrum.

The electromagnetic spectrum covers a vast range, from about 20 km down to microns (10^{-6} meters), angstroms (10^{-10} meters), and less (see Figure E4). Of longer wavelength than 20 km is the audio-frequency range (sound waves, of about 20 kc to 20 cycles). One may note the relative narrowness of the visible light band. Solar radiation covers the spectrum from about 1500 Å (ultraviolet) to over 40 000 Å (in the infrared).

Frequencies are expressed in cycles per second, or in the radio wavelengths in kilocycles and megacycles. Since it was the German physicist Heinrich Rudolf Hertz (1857–1894) who studied Maxwell's theory, but actually first demonstrated the nature of electromagnetic wave propagation, measuring wavelength and frequency, the unit hertz, one complete cycle per second, is used. Radiowaves are often expressed in kilohertz and megahertz. The relationship of wavelength λ in meters to frequency (f) in kilocycles (or kHz) is: $\lambda \times 3 \times 10^5/f$, or 1 kc = 30 000 m, e.g. a 6-Mc radio transmission uses the 50-m band.

EL NIÑO

Newspaper headlines are increasingly highlighting stories about “severe”, “bizarre”, “crazy”, “extreme”, and “anomalous” weather patterns that have disrupted human activities in many parts of the world and have caused devastation to life and property on a local, national, and regional scale. Much of this unusual weather – and even an infinitesimal slowing of the Earth’s rotation – has been blamed on an oceanic-atmospheric interaction known as El Niño.

The eastern equatorial Pacific is usually dominated by coastal upwelling – the upsurge of deep, nutrient-rich cold water to the ocean’s surface. Such waters provide excellent breeding grounds for various levels of the food chain from phytoplankton to anchovies. Exploitation of this fish population made Peru the number one fishing nation in the world by the early 1970s. However, every Christmas season the winds that blow along the coast from the southeast slacken, the strength of the upwelling weakens, and the surface waters begin to warm and the fish population is less available to the fishing boats. This warming trend usually lasts for a few months and by March or so the strong upwelling resumes again. Occasionally the warm water continues to accumulate in the eastern and central equatorial Pacific, resulting in a large area of warm surface water.

This appearance along the coast of a large mass of warm water is associated with sharply reduced catches off the coast of Peru and with destructive rains that occur in normally dry areas of Peru and Chile. It has also been associated with the development of drought in Bolivia and northeast Brazil, and other impacts such as outbreaks of malaria and cholera in various parts of South America.

El Niño can be defined as an invasion of warm surface water from the western part of the equatorial Pacific into the normally cooler waters of the central and eastern part of the Pacific Basin off the western coast of South America – mainly Peru and Ecuador.

El Niño is usually described as an anomaly, an unusual or abnormal interaction between air and sea in the equatorial Pacific that is not part of the normal regional or global climate system. While we can talk of sea surface temperatures in the eastern and central Pacific Ocean departing from a mathematically identified average condition, we should not view an El Niño-related departure from the average as being abnormal and unexpected. In fact, El Niño is a normal and to-be-expected part of it.

Under El Niño conditions the warm water heats the air above it, and if the right conditions exist aloft, the rising water vapor condenses and forms clouds. Heavy rains then fall over normally dry areas, and as this warm mass of air eventually moves out of the region, sinking in the western Pacific, it inhibits rain in this usually wet area. Many atmospheric scientists believe that the atmospheric processes set in motion during an El Niño event also influence climate in regions outside the tropics.

Although El Niño originally referred to local conditions off the coast of Peru and Ecuador, the use of the term has been broadened by many scientists to represent all surface temperature warming in the eastern and central Pacific. Because this warming process typically begins around Christmastime, Peruvian fishermen called it El Niño, which is Spanish for the Christ Child.

Recurrent phenomenon

El Niño is only the warm phase of a larger cycle called ENSO, or El Niño–Southern Oscillation. The Southern Oscillation refers to a seesaw-like shift in sea level pressure systems across the Pacific Basin. When sea level pressure is high at Darwin, Australia, it tends to be low at Tahiti, and vice versa. ENSO includes a cold phase – La Niña. Extreme weather events around the globe have also been associated with La Niña, though many policy makers are unaware of its existence or its potential impacts. Some scientists suggest that, in various regions, La Niña-related extreme events are the opposite of those related to El Niño. For example, in southern Africa drought accompanies El Niño, while rain is associated with La Niña. In the United States, some researchers claim that La Niña’s impacts are more costly than those of El Niño. Researchers are just beginning to realize that they should focus more attention on the cold part of the cycle to enhance their overall forecast possibilities.

El Niño (a warm event), like its counterpart La Niña (a cold event), is an integral part of the global climate system. It is a recurrent phenomenon with an average return period of 4½ years, but can recur as little as 2 or as much as 10 years apart. Such events have occurred for millennia, and can be expected to continue to occur in the future. Indeed, to go through a decade or two without an El Niño would be truly unusual. Since El Niño does not represent unusual global climate behavior, we can attempt to prepare for it.

Although El Niño events have occurred throughout the twentieth century, the 1982–1983 event was the one that first sparked serious interest. Decision makers in water resources, agriculture, energy and health realized that they could benefit from advance warnings of weather conditions. That is why there is so much interest in El Niño.

Researchers and policy makers, in particular in Australia, Brazil, Chile, Ecuador, Peru, Southern Africa and the United States of America, became interested in developing an improved understanding of El Niño and its impact on weather systems.

The onset of a strong El Niño in early 1997, later called “the El Niño of the century” because of its costly impacts, intensified general interest in the phenomenon, especially in the potential value of planning to mitigate its direct effects. However, still needed is a better understanding of the ways El Niño events can develop and evolve. Also, societies have not yet seen all of the ways that they can affect society and ecosystems.

Policy makers, governments and scientists are increasingly focusing on El Niño as a tool for forecasting climatic conditions months in advance, particularly for identifying the potential for droughts or floods. Droughts can have devastating impacts on communities, affecting food and energy production and, in arid zones, the very survival of humans and animals. Floods can destroy property and kill people. In January 1998, in northern Peru and Kenya, for example, heavy rains and flooding had serious consequences for their built environments, including communications and transportation networks.

Timely warning of such extreme events can enable civil defense experts to plan for evacuation of at-risk populations. If reservoir managers are given a reliable forecast of seasonally above-average rainfall, they can lower reservoir water levels to make storage room for the expected excess water.

El Niño-associated flooding has many adverse effects: it can disrupt farming along river borders; drinking water can become contaminated during excessive rainfall and flooding; and local water delivery systems can be damaged or destroyed, with negative consequences for human health.

Effects on water resources

Knowing that an El Niño is due can enable managers of reservoirs supporting irrigation schemes in the affected region to alter their decisions about when and how much water to allocate and to whom, if the El Niño effect is likely, for example, to bring drought. It could perhaps have helped planners in southern Africa during the 1982–1983 El Niño-induced drought, when lack of water led to the closure of factories, with workers laid off for many months.

That same El Niño brought severe flooding to northern Peru and southern Ecuador. There had been no warning. In November 1997 the northern Peruvian city of Piura, which typically receives about 6 mm of rain in November, received almost 600 mm of rain. This time, however, the Government of Peru took the El Niño forecast seriously and was able to mobilize engineering and civil defense resources to mitigate some of the worst impacts of flooding in the north.

Not every weather anomaly throughout the world that occurs during an El Niño year is caused by the El Niño itself, though in 1997 there was an increasing tendency to blame it for everything. For example, floods in the Midwest United States of America during 1993 were blamed on that year's El Niño, even though scientific evidence for this conclusion was very weak. On the other hand, research did support the conclusion that the severe drought in the same region in the summer of 1988 was caused by La Niña and not necessarily global warming as some scientists had suggested at the time.

Extreme record-setting weather events are occurring around the globe, even in non-El Niño years. Only some parts of the globe are directly influenced by El Niño and even these areas are not influenced in the same way by each event.

Teleconnections, or long-distance effects between El Niño and regional climate anomalies around the globe, have been identified statistically and by observations of direct links between warm surface water in the central and eastern equatorial Pacific and distant anomalies such as drought in northeast Brazil or Ethiopia.

El Niño can have positive and negative aspects at the same time. For example, during an El Niño the number of hurricanes and tropical storms along the Atlantic and Gulf coasts of North America and in the Caribbean is noticeably reduced. During the 1997 El Niño, the hurricane season was almost non-existent and no devastating storm occurred. For many this was good news, but not for everyone. The absence of tropical storms also reduces the amount of freshwater that tropical islands normally receive from passing storms. The rain from these storms usually fulfills their water needs until the onset of the next year's hurricane season.

The impact of global warming on El Niño is not yet known, though there are hundreds of studies on the possible effects of global warming on the global hydrological cycle and what these effects might mean for regional and local hydrological cycles. Some researchers suggest that dry areas will become drier with global warming and wet areas wetter; others have suggested the opposite.

Forecasting

Knowing when an El Niño will strike, however, is different from forecasting the effect it will have in different areas. Although some kinds of impacts tend to recur in the same places, each El Niño can cause a different set of impacts (droughts, floods, fires). Predicting its arrival is likely to prove

relatively easy compared with forecasting what will actually happen to disparate locations around the globe.

But forecasting can provide useful insights. Certain teleconnections do have a tendency to occur when an El Niño has been forecast. In areas where the link seems reliable, authorities can begin to prepare for seasonal changes in water resources.

El Niño as a spawner of natural hazards

El Niño's characteristics fit well within the analytical definition of a natural hazard. However, it seems that hazards researchers prefer to argue why El Niño should *not* be viewed as a natural hazard. Perhaps it is time for El Niño to be viewed as a legitimate hazard (in this broader sense).

El Niño is a natural process that has been associated with various kinds of hazards. It is only since 1969 that it was discovered to have such impacts around the globe. The hazards it spawns include, but are not limited to, droughts, floods, frosts, fires, and landslides. Perhaps if researchers can link what it is that spawns natural hazards (e.g. El Niño) more closely to the potentially spawned hazards, societies can shift their short-term responses toward proaction (i.e. prevention and mitigation) and away from reaction (i.e. adaptation and cleanup). Doing so would tend to push the early warning of specific El Niño-related hazards further "upstream", thereby providing more lead time for societal coping mechanisms to come into play. This would make El Niño forecasts the earliest possible warning that a government might get of climate-related impacts they wish to avoid.

During El Niño events, almost all the Pacific islands suffer from drought and, as a result, water shortages are highly likely to follow. Water is a scarce commodity in these island nations even under "normal" conditions (and it is growing scarcer). Expanding population, combined with agricultural and industrial growth, are increasing the pressure on limited freshwater supplies. So now El Niño has become synonymous with drought in the North and South Pacific island states. The only exception is Kiribati, which receives considerable rain during El Niño and suffers drought during La Niña events.

Disaster managers in this region clearly have their hands full. This has always been the case, even before they became aware of El Niño and La Niña. What is different now is that the onset of drought or flood can be linked to the ENSO cycle. Therefore, El Niño and La Niña forecasts can convert disaster responses from reaction to proaction. Based on the adage that "forewarned is forearmed", disaster managers in these island nations can prepare their countries to reduce the damage of El Niño-related adverse impacts.

The intensity of an El Niño event can vary from weak to moderate to strong to extraordinary. A strong event is more likely to influence the climate conditions far from the Pacific Basin, whereas weak events are likely to have their strongest impacts in Pacific Rim countries. El Niño hotspots are regions that are likely to be affected by an El Niño event. A list of likely El Niño hotspots might include, among others, the following:

- Drought in Zimbabwe
- Drought in Mozambique
- Drought in South Africa
- Drought-related food shortages in Ethiopia
- Warm winter in the northern half of the United States and southern Canada
- Heavy rains in southern Ecuador and northern Peru
- Drought in northeast Brazil (a region known as the Nordeste)

- Flooding in southern Brazil
- Drought and fires in Indonesia
- Drought in the Philippines in the tropical Atlantic
- Coral bleaching worldwide
- Droughts in various South Pacific island nations
- Drought in eastern Australia
- Heavy rains in southern California

Often the actions that a society needs to take to mitigate or avoid the worst impacts of an El Niño-related societal or environmental impact are those from which society would benefit anyway: cleaning up our dry river channels so torrential rainwater can pass to the sea; repairing leaky roofs; shoring up bridges, rail lines, and roads that are in poor condition.

Clearly, the science and art of forecasting El Niño are in their early stages. For some locations around the globe, and for some socioeconomic activities worldwide, El Niño information can provide a “heads up” to decision makers in climate-and weather-sensitive regions and sectors. Such information provides power to those who choose to use it.

ENERGY BUDGET CLIMATOLOGY

The energy budget of a surface or an object is the amount of heat energy, in any form, that arrives at or departs from the surface of the object in a specified time period. Energy budget climatology most commonly is the climatology of the energy budgets of the Earth’s surface that are studied at a variety of scales. The term may also be broadened to include the energy budget of the atmosphere as a whole or any part of it. We will concentrate here mainly on the energy budget climatology of the Earth’s surface.

The energy budget of a surface is an application of the law of conservation of energy for the Earth’s surface. The most simple form of the law may be expressed as:

$$Q^* = H + LE + G$$

where Q^* is net radiation, H is sensible heat (enthalpy), LE is latent heat (L being the latent heat of vaporization of water and E the amount of water evaporated), and G is the flow into or from the submedium. Each term can be positive or negative. The net radiation term may be further broken into the component terms of the radiation budget. The form of the energy budget described by this equation is one-dimensional and refers to flows of heat in the vertical direction to and from the surface of the Earth. In some applications of the concept, such as when advective influences are important, it is useful to take into account the two horizontal space dimensions as well.

According to Miller (1965), it was during the nineteenth century that George Perkins Marsh in the United States and Alexander Voeikov in Russia independently suggested that estimation of the energy budget of the Earth’s surface and its parts would greatly enhance our understanding and explanation of climate. However, with a few exceptions, and owing to a lack of measurement technology, the idea was not really developed until the middle part of the twentieth century. At that time ongoing work in the western hemisphere was stimulated by the translation and publication of Mikhail Budyko’s *The Heat Balance of the Earth’s Surface* and its associated atlas. Since that time it has been realized that energy budget climatology not only provides insights into the causal explanations of the Earth’s climates, but it has many other advantages as well. In general, these include its interdisciplinary function in linking applications in hydrology, glaciology, and bioclimatology, its link with the water budget through the evaporation term, its use for quantifying human influences that alter the surface of the Earth, and its application to the phenomenon of climatic change. Some of the most comprehensive sources detailing energy budget climatology, its uses and advantages include the works of Budyko (1958, 1974), Miller (1965), Sellers (1965), Oke (1987), Gates (1980), Rosenberg et al. (1983), Campbell and Norman (1998) and the continuing series of reports of the Intergovernmental Panel on Climate Change (e.g. Houghton et al., 2001).

A brief description of how surface energy budgets are measured and modeled is provided below. The energy budgets of different surfaces are then described for the micro- and mesoscale. Consideration is then given to the energy budget climatology of the regional (synoptic) and global scale. The application of energy budget climatology to climatic change is discussed. Finally, recent trends in energy budget climatology are noted.

Measurement of the energy budget at the surface

There have been many advances in the measurement of the energy budget at the surface since the mid-1950s. These advances range from relatively low-cost surface flux eddy correlation measurement systems to increasingly accurate satellite measurements. In a typical instrumented site at any point on land on the Earth’s surface, net radiation and the ground heat flow would normally be measured directly by a net radiometer and one or more soil heat flux plates. The turbulent flows of latent and sensible heat are still sometimes estimated from measurements of temperature and water vapor pressure gradients in the vertical direction with adjustments made for the

stability of the air, which may vary over time. The profile measurement of the turbulent fluxes assumes no major changes of the wind field or the radiation budget over a short measurement period, no vertical divergence of the fluxes, and the equivalence of the diffusion coefficients for momentum, sensible heat, and water vapor. Since these assumptions are not always fulfilled, the most common turbulent flux estimation methods based on profile measurements, usually known as the Aerodynamic method and the Energy Balance or Bowen ratio method, are not always the most accurate. Greater accuracy may be achieved at larger expense. Direct measurements of the turbulent fluxes may be made, for example, by the eddy correlation method, which directly measures the fluctuating part of the turbulent heat fluxes using highly sensitive, fast-response sensors and a real-time computer to separate the instantaneous deviations from the time-averaged mean. The eddy correlation technique has become more frequently used with the emergence of commercially available equipment. Networks of Flux Tower measurements are also being formed; the best known of these being organized by the Ameriflux and Euroflux programs as well as a worldwide program called Fluxnet. Sensitive, large weighing lysimeters that track the loss or gain of the weight of water from a soil monolith are an accurate though expensive way of directly measuring the latent heat flux. Oke (1987) presents a clear description of the detail of these common methods of energy budget instrumentation.

On a larger geographic scale, satellite data are increasingly being used to estimate surface energy budget values. A number of important multidisciplinary national and international programs have concentrated on research to find out how best satellite measurements may be used to estimate surface energy budget and other parameter values. Simultaneous measurements are made at the Earth surface and from space-borne and airborne sensor platforms. Some of the more important of these programs include the First ISLCP Field Experiment (FIFE) for grasslands in Kansas (Sellers and Hall, 1992), and a program for the Boreal forests of Canada (BOREAS) (Sellers et al., 1995). Remote sensing results have also played a role in the debate over desertification in West Africa and elsewhere. The bright star for remote sensing and the derivation of even better surface energy budget values is the Earth Observing System (EOS) that is beginning to give us huge amounts of highly relevant and fascinating data.

There are a number of difficulties in making actual observations of the surface energy budget. These include the inherent complexity of the energy flux processes, especially those dealing with the turbulent fluxes, and the need for continual attention to the instrumentation, particularly in severe environments. Gradually these difficulties are being overcome. A prime example is the flux tower at the Harvard Forest Site in central Massachusetts. At this site energy balance values and other fluxes have been measured continuously for about a decade (Waring et al., 1995). More and more actual accurate surface energy budget observations are being made. Eugster et al. (2000) report 38 different sets of measurements for just the Boreal forest and Arctic Tundra surfaces alone. The energy budgets of most major surface types of the Earth have now been investigated in detail, including that of the urban surface (Grimmond and Oke, 1995, 2002). Russian scientists used energy budget measurements in the middle of the last century to estimate the effects of human activities such as the flooding or draining of land areas. Similar uses of the energy budget approach are still being made today. In California, for example,

investigators are using the technique to monitor the effects of restoring wetlands in the San Joaquin river delta area (Anderson et al., 2002).

Modeling energy budgets

Historically, several important works used standard meteorological data to estimate the surface heat budget. Probably the most significant is that of Budyko (1958) in his initial establishment of the heat budget of the Earth. Vowinckel and Orvig (1968) did pioneering work to estimate the heat budget of the Canadian Arctic. The *Heat Budget Atlas of the Tropical Atlantic and Eastern Pacific Ocean* by Hastenrath and Lamb (1978) and the comparable volume for the Indian Ocean (Hastenrath and Lamb, 1979) at one time represented the state of the art in these endeavors. Between about 1960 and 1990, when actual measurements of the surface energy balance were difficult to make, considerable attention was given to modeling such values. With greater access to surface and satellite measurements, modeling activities have become a little less pronounced. However, modeling still remains important, especially where large areas are concerned. Estimates of surface heat balance and other climate changes accompanying deforestation of the Amazon Basin are a prime example. Most of these estimates show potential increases in albedo value and a reduction in Q^* and LE , as well as a decrease in "recycled" precipitation (Hahmann and Dickinson, 1997). Another conceptual area where modeling remains important is in the field that has become known as Land Surface Parameterization (LSP). This field encompasses the estimation of the exchange of surface energy, momentum, water, heat, and carbon between the land surface and the atmosphere. The generation of LSP developed in the late 1990s combine energy, water and momentum balance values with the biophysics of photosynthesis and recognize vegetation as part of the climate system (Stocker, 2001, p. 442).

Further insights into energy budget climatology may be gained by examining the actual budgets of different surfaces.

The local scale

An examination of energy budgets of different surfaces demonstrates the manner in which the energy budget concept quantitatively explains the complex two-way interaction between the surface and the atmosphere. Oke (1987) has gathered together data on the energy budgets of many different surfaces and most of the following description is based on his efforts. One of the most simple surfaces in terms of energy budgets is bare ground. Table E1 lists the mean daily energy budget values for such a surface in the Turkestan mountains (41°N) for the month of September. Note that for the horizontal surface the largest proportion of the heat received as net radiation (Q^*) is expended into the atmosphere as sensible heat (H). Equally small amounts are lost to evapotranspiration (LE) and into the submedium (G). The data also show the effect of aspect in helping to determine the amount of net radiation received, and thus the amount of heat energy available for heating the air and the ground on slopes facing in different directions. Note, however, that the proportioning of use of the available net radiant energy is not too different on the two slopes from that on the horizontal surface. The bare-ground situation is in contrast to a vegetated surface. The energy budget for one day over a barley crop in southern England, for example, shows that almost all energy available in the form of net radiation is used for evapotranspiration

Table E1 Energy budgets for different surfaces

Surface	Q^*	H	LE	G	Data source
Bare soil; Turkestan Mountains					
Horizontal surface	14.4	9.4	2.1	2.1	Aisenstat, 1966
North-facing slope	6.0	3.5	1.7	0.7	
South-facing slope	17.6	—	3.1	1.9	
Barley crop; southern England	15.7	-1.1	12.2	1.2	Long et al., 1964
Ocean surface; Tropical Atlantic	22.2	1.2	16.2	4.8	Holland, 1971
Melting glacial ice; Peyto Glacier, Alberta	11.4	-3.7	-0.9	16.0	Munro, 1975
Urban building air volume; Vancouver (10 h period only)	16.9	5.7	7.0	4.2	Yap and Oke, 1974

Note: Values are in MJ/m² per day.

(Table E1). In fact the sensible heat flow exhibits negative values, indicating heat was passed down from the atmosphere to the ground. The high amount of LE is not unusual for a vegetated surface, especially when the surface is irrigated. Under these conditions, and with the horizontal influx (advection) of warm air, LE often exceeds Q^* . The irrigated vegetated surface in many respects acts like an ocean surface. The ocean surface energy budget, as might be expected, shows that most of the heat income is used in evaporation. The energy budget for this surface does not balance in Table E1, however, because some heat is involved in a seasonal heat storage change in the water and in advective heat exchange by the water currents. Heat used at the surface is also important in the case of the energy budget of a melting ice surface of a glacier. Here, downward flows of H and LE (in the form of condensation on the ice surface) are used to supplement Q^* to sustain the amount of heat used in melting the ice. The presence or absence of snow on a surface makes a large difference to the net radiation received because of the higher reflectivity of the snow surface. Ohmura (1982) has documented this for the Arctic tundra surface. The energy budgets of urban surfaces show that some of these surfaces are not as arid as might be expected. The energy budget values for an urban building air volume in Vancouver (Table E1) actually show a larger amount of latent heat loss than sensible heat loss. This is due partially to the presence of urban vegetation and irrigated lawns (Suckling, 1980). The energy budget values of a suburban Vancouver surface have been found to be intermediate between those for truly urban and surrounding rural vegetated surfaces (Kalandra et al., 1980).

Finally, the effect of human manipulation of a surface may be discussed. One of the most common manipulations is the flooding or draining of a land surface. Either procedure greatly alters the ratio of surface heat loss between H and LE . Surface energy budgets related to these activities and to certain kinds of vegetation management have been discussed by Budyko (1958, 1974). The effect of another common kind of surface manipulation may be demonstrated by quoting the energy budgets of a bare soil plot and the same soil covered by mulches of different types (Table E2). Net radiation is strongly influenced by the reflectivity (albedo) of the surface. Lower albedos, usually associated with darker, less reflective surfaces, give rise to a higher absorption of solar radiation and thus higher values of net radiation. Consequently, compared to the bare soil, the black plastic mulch has higher Q^* values and the paper surface has lower Q^* values. The different surfaces have varying permeabilities to water vapor flow. This is reflected in the different amounts of latent heat loss with no loss for the black plastic surface and increasingly greater losses, respectively, with the paper, hay, and

Table E2 Energy budgets of bare soil and soil with various mulches, Hamden, Connecticut

Surface	Q^*	H	LE	G
Bare soil	642	363	195	84
Black plastic	711	635	0	42
Paper	432	349	42	35
Hay	607	488	84	35

Note: Units are W/sq m. Observations taken near noon in June.

bare soil surfaces. The opposite effect is seen with the sensible heat loss. All of the mulches decrease the flow of heat into the ground, but the effect is least with the black plastic, partly because the surface receives more net radiation. Studies are now paying attention to the manipulation of surfaces at larger geographic scales. Bonan (1999) used simulation modeling to indicate a regional cooling of 1–2°C over the last century in the east and midwest of the United States due to enhanced LE values and increased winter albedo associated with the agricultural cultivation of large areas. This brings us to the regional and global scale.

The regional and global-scale

The value of the energy budget approach in comparing the climates of different regions of the Earth is demonstrated by examining the variation of the values of the energy budget components over the annual period for stations representative of different climatic environments. Data for six stations whose annual energy budgets were calculated and first presented by Budyko (1958) are shown in Figure E5. On this figure the usually negative values of LE and P (H) are shown with a reversed sign (i.e. positive) in order to save space on the diagram. The normal convention is to regard heat traveling towards the Earth's surface (either from above or below) as positive and vice-versa.

The equatorial, continental climate of Manaus, Brazil, is notable for the high proportion of heat used in evapotranspiration. It is also significant that, owing to cloudiness, Q^* is relatively small, being surpassed in some seasons by that in the midlatitude climate of Paris, France, and equaled even, during the summer time, by the values in the subarctic climate of Turukhansk, Russia (also spelled Turukhansk). Energy budget values at Thanh Pho Ho Chi Minh (listed on Figure E5 as Saigon), Viet Nam, manifest the importance of a hot dry season in a monsoonal regime. During this season LE is reduced with a corresponding rise in H (for which the symbol P is used on

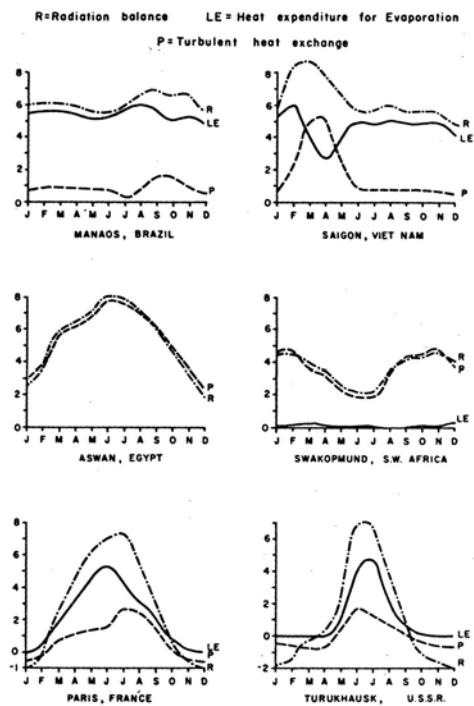

Figure E5 Heat balance regimes for different climates. Units are in kilocalories per square centimeter per month (after Budyko, 1958).

Figure E5), whereas in the wet season the energy budget is similar to that of Manaos. A distinct lack of surface moisture available for evapotranspiration is shown by the heat budget values for the tropical continental climate of Aswan, Egypt. It is significant here, however, that the highest value of net radiation is lower than that of Saigon owing to the greater albedo of the desert surface. Swakopmund (Namibia), in South West Africa, is the only southern hemisphere station presented here. Its energy budget is similar to that of Aswan, although the available heat (Q^*) is generally lower because of the higher latitude. A midlatitude maritime example is given by the energy budget of Paris, France, where Q^* and LE values follow their expected course. A noteworthy point arises here, in that, during the winter months, a net radiation loss is registered. This situation, if prolonged, would lead to very low air temperatures, but in this case it is ameliorated by the downward flow to the surface of sensible heat as shown by the negative values in the graph. This extra source of heat in the air is originally derived from the adjacent, warm ocean current. Thus the mild winters of the northwest European type of climate are guaranteed as long as the ocean remains warm. Such a state of affairs may be contrasted with that of the continental, subarctic climate exemplified by the energy budget of Turukhast in Siberia. Here, although there is some downward transfer of sensible heat, the net radiation loss in the winter is even greater due to the high latitude of the location and the continual snow cover. The result is the severe winters of this continental climate characterized by very low air temperatures.

Although only a few features of the energy budgets of this selection of stations have been discussed, it is possible to see the value of the energy budget approach in comparing the climates of different areas. Possibly more important is the

demonstration of many of the causal factors of these climates by placing emphasis on the physical processes at work in the fundamental link between the Earth's surface and the atmosphere. These links are of vital importance on a global basis as well. Budyko (1958, 1974) has published energy budget values for the whole globe on an annual basis and for selected months. The classic nature of this work is demonstrated by the fact that the pattern identified by Budyko is reconfirmed by later authors (e.g. Hartmann, 1994). The principal features of the global energy budget are now described briefly.

Global values of net radiation show a rather zonal (latitudinal) distribution as might be expected. Values over land are generally lower than those over water. The maximum difference is in the tropics, with the discrepancy becoming less as latitude increases. A distinction between land and sea surfaces is also exhibited in latent heat flux. Over land LE values are a maximum near the equator, decrease in the subtropics, increase in midlatitudes and decrease again at high latitudes. Over the oceans LE values are at a maximum in the area under the subtropical high-pressure zones, remain fairly high in midlatitudes, especially where there are warm ocean currents, and then decline in high latitudes. Maps of sensible heat flux show maximum values over land in the subtropics and decreasing values toward both higher and lower latitudes. Over the sea this flux increases steadily with latitude.

The global heat energy budget is the link between the surface of the Earth and the atmosphere. Together with an understanding of the general circulation of the air flow across the globe, the concept helps not only to explain present-day climates but also provides a framework for discussion of possible past and future changes of the climate of the Earth.

Energy budget climatology and climatic change

Studies of the planetary energy budget have played an important role in the development of climate models because exchanges of energy and matter at the Earth's surface are so important to explaining the climate of the planet. These models have, in turn, been used to further our understanding of the Earth-atmosphere climate system and its possible changes over time. Simple one- or two-dimensional energy balance models are still used for approximate estimations of possible climate change as well as for instructional purposes. However, most current estimation of possible climate change is made with General Circulation Models (GCM) that couple the ocean and atmosphere dynamics and are run in a transient mode (Houghton et al., 2001). Surface energy budget climatology could be said to be at the heart of these models because it is through surface processes that the coupling between land and water surfaces and the atmosphere is achieved. However, the surface energy budget climatology is not as "visible" in the GCM as it used to be in the simpler models.

Trends in energy budget climatology

The fundamental importance of energy and mass exchanges between the Earth's surface and the atmosphere is now so well acknowledged that no other type of climatology can ignore it. There are several channels for research endeavors in the field. Some of the most productive are: (1) further development of land-surface parameterization (LSP) techniques for complex surfaces, (2) the further refinement and application at the meso-scale of three-dimensional surface energy budget models, and (3) the incorporation of satellite data into energy budget modeling systems.

Current LSP efficiently combine biology and atmospheric physics. Stocker (2001) describes how the models and parameterizations provide more opportunities for parameter calibration, constraint, process submodel validation, and “upscaling” algorithms through comparison with observations. These models may be used with global datasets of vegetation type at monthly time steps and a spatial resolution of about one degree of latitude and longitude. The vital importance of the two-way interaction between vegetation and atmosphere has now been recognized at all spatial scales and it is likely that future work will provide further revelations related to this interaction. Three-dimensional mesoscale models have seen a rapid development and are now being used for climate as well as meteorological purposes (e.g. Liston and Pielke, 2001). These models have also shown the importance of the nature of the ground surface in affecting such things as the location of the development of convective storms. Finally, the rapid development of satellite technology has revolutionized energy balance climatology by providing formerly unavailable estimates of energy balance components over large areas. The technology has also, to a certain extent, caused greater attention to be given to certain energy budget factors, such as albedo and surface resistance, in ways that were not previously contemplated. Undoubtedly, further huge advances will occur in all of the above areas, and many more, as the twenty first century continues.

EUROPE, CLIMATE OF

Analysis of climatic data

Most climate data are assembled and kept in databanks held at regional climate centers or in research centers. The data are then analyzed using powerful statistical tools that enable the

researcher to search for patterns and correlations. An example of one such data set is NACD – the North Atlantic Climatological Dataset containing temperature and precipitation series. Regional or subregional datasets are then compiled and adjusted to build a homogeneous dataset (Tuomenvirta, 2001). Other regional datasets are compiled for use in climate analysis computational programs covering a wide range of aspects from global warming through to hydrological management. This item has been compiled from a combination of descriptive sources and of analytical studies. In places there is some difficulty in linking together the climatic ensemble and this must be borne in mind by the reader. Many datasets are now available on websites.

Factors affecting the climate of Europe

The continent of Europe extends from the mid-Atlantic islands of the Azores (29°W) across the open North European Plain to the Ural Mountains of the Soviet Union (60°E) and from the islands of the Mediterranean Sea in the south (35°N) to the islands of the Barents Sea, which lie well within the Arctic Circle. Europe, along with its islands and peninsulas, is the most maritime of the continents. Large areas to the west of the 20°E longitude experience a temperate oceanic climate where extremes of temperature and rainfall are rarely experienced. The chief factors promoting this comparatively unique assemblage of climates are:

1. The predominant west-to-east movement of weather systems.
2. The extensive area of abnormally warm surface waters of the North Atlantic.
3. The virtual absence of north–south-aligned mountain ranges between latitudes 45°N and 60°N that might otherwise alter the nature of the westerly flow.
4. The presence of large inland seas such as the warm Mediterranean, the cooler Baltic, and the smaller, less warm, Caspian and Black seas.

Elements of the climate of Europe

Energy

In common with other midlatitude regions, Europe experiences a net deficit in radiation except at its southern margins. Values derived from satellite information for the Earth–atmosphere system indicate that annual deficits increase from -20 W m^{-2} over central Italy to around -80 W m^{-2} over southern Scandinavia and northern Norway (Raschke et al., 1973). The deficit cannot be attributed principally to the excessive loss of heat from the land surface, though this loss may be significant in cold snowy winters over central and eastern Europe. Compensation for this deficit in radiant energy is effected by the transfer of sensible and latent heat from lower latitudes. Radiative cooling is at its maximum at mid-tropospheric levels around latitude 60°N , and it is in this region that maximum cooling takes place in winter (Figure E6). The effects of this cooling on European climates are profound. In the long term such cooling produces latitudinal zones of temperature gradient in the atmosphere. These zones are associated with high winds and disturbed weather conditions so frequently experienced over Europe.

Temperature

The influence of the warm waters of the Atlantic Ocean is most clearly seen in the winter pattern of surface temperatures

(Junge and Stephenson, 2003). Average January values of 7°C over western Ireland decline steadily eastward to around minus 10°C in the vicinity of Moscow, producing a north–south thermal pattern between latitudes 45°N and 60°N . In summer the heating of the continental area leads to a more zonal thermal pattern with isotherms tilted WSW–ENE (see Figure E7). The 17°C isotherm for July (2005) now lies through southern England across to the southern Baltic Sea toward Leningrad. Summers in north European Russia, though warm, are usually short and are constantly being threatened by outbreaks of cold air of Arctic origin.

A measure of the increasing warmth from north to south through European Russia has been visualized using summer daily air temperatures that exceed 10°C . Accumulated summer temperature values of 750°C occur at around 70°N , increasing to 2000°C at 55°N and exceeding 3000°C around the Black Sea

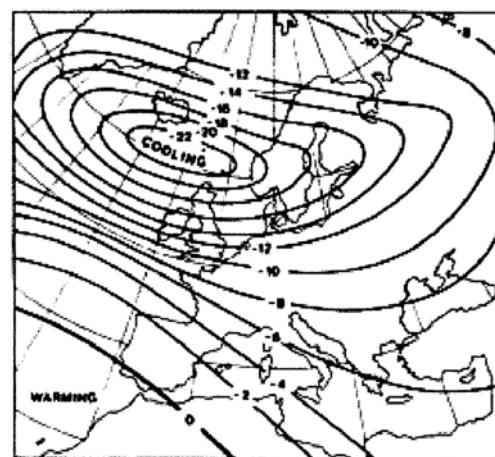

Figure E6 Change in the heat content of the troposphere from mid-November through mid-December in W/m^2 . Average values for 1955–1959. Values are relatively small with maximum cooling representing 1.8% of the solar constant (after Crowe, 1971; Tucker, 1965).

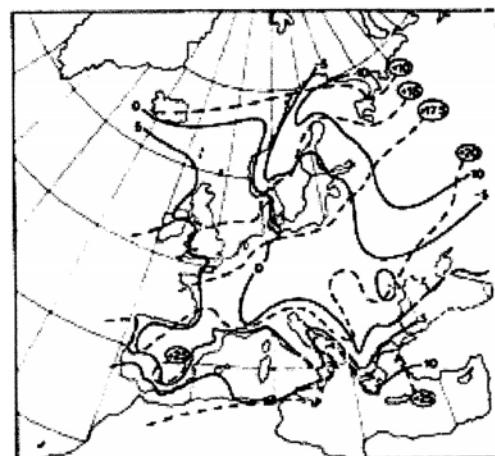

Figure E7 Mean temperature for January (solid lines) and July (dashed lines) in $^{\circ}\text{C}$.

at 45°N (Budyko, 1974). In the cloudier climate of the British Isles these values are usually lower. They range from below 500 in northern England (55°N) and approach 1000 in the Channel Islands (49°N). Using this method the equivalent value for Moscow would be 722. Analysis of temperature data by Gerasimov (1964) showed that average daily temperatures rose above 10°C by 21 April in the Crimea, but not until July along the coastlands of the Barents Sea. The average date when temperatures have fallen below 10°C in the fall have been 15 of October for the Crimea and 11 August for North Russia. Using a slightly different definition of the growing season, Mitchell and Hulme (2002) show that for Central England there has been an increase in length of the growing season over the twentieth century of 28 days, much of this in the period 1980–2005. Recent research by Zhou et al. (2001) and Menzel and Fabian (1999) has confirmed that this is also true for most of Europe. A more detailed daily temperature dataset has been compiled for the ECA (European Climate Assessment) at De Bilt in The Netherlands by Klein Tank et al. (2002), and shows a good correlation with existing gridded data sets for Europe.

Frost-free period

Closely associated with the growing season is the average length of the frost-free period. Over the open plains of European Russia this increases from at least 75 days in the north to around 200 along the northern shore of the Black Sea. Further west, across the European Plain, the length of the frost-free period becomes less easy to determine because of the alternating airflows from cold and warm sources (Lednicky, 1985). Over lowland France mid-twentieth-century values have ranged from 160 days in Alsace in eastern France to 240 days along the coastlands of the Bay of Biscay (Garnier, 1954). In contrast, the determination of the frost-free period in mountainous countries such as Austria is largely a function of elevation. In the Austrian Alps the frost-free season at 800 m above mean sea level lasts for about 155 days per year. At a height of 1600 m this is reduced to 104 days, whereas above 2500 m spells of below freezing temperature may even be expected in cold summers. In the Iberian Peninsula the frost-free period is governed both by altitude and proximity to the Mediterranean Sea and Atlantic Ocean. Much of interior Spain may experience less than 250 days frost-free. Only the extreme southeast and southwest of the peninsula are likely to be entirely free of frost during most years.

Extreme values

Extreme values of temperature tend to reflect the local controls of topography as well as distance from the North Atlantic Ocean. Very low temperatures show a much greater variation in time and space than high temperatures. Very dry, cold air with little wind is required for temperatures to fall below -15°C. Such an occurrence is far more common in winter over countries such as Finland, where temperatures below -30°C are recorded nearly every winter. The lowest temperature indicated in the standard climatic tables is -51°C at Syktyvkar (61°40'N, 50°51'E) in northeast European Russia. Moscow, along with many stations in northern Russia and Finland, has experienced temperatures of -40°C at screen height. The penetration of cold air into parts of eastern Europe also means that very low temperatures have occurred at relatively low latitudes. This may be seen from cities such as Iasi (Rumania) at 47°N, recording -30°C and Sofia (Bulgaria) 42°30'N, -27.5°C. There were also reports of -26°C from several locations in Thrace

(Greece) in December 1972. Only the southernmost part of Spain and a part of the Mediterranean island of Crete have absolute minimums at or above 0°C. Comparatively, maritime countries such as Spain experience frost in severe winters. Madrid recorded -10.1°C during the period 1901–1930, and Rome (Italy) reported -7.4°C. Over the British Isles, minimums of -10°C have been recorded along the western seaboard. Inland values of -25°C are very rare, but were registered in the Dee Valley of the Grampians in Scotland and in the West Midlands of England during the winter 1981–1982. An extensive climatology of extreme temperatures has been assembled by Yan et al. (2002).

In contrast, there is little variation in absolute maximums. Over much of northern Europe, temperatures have occasionally climbed into the low 30s (Jenkinson, 1985) whilst over the remainder of Europe temperatures between 35°C and 39°C have sometimes occurred, as in the summer of 2003 (Eden, 2003). Apart from isolated events, temperatures in excess of 40°C have only been recorded south of latitude 42°N. Absolute maximums of 45°C (Palermo, Sicily) and 47°C (Malaga, Spain) testify to occasional incursion of very warm desert air from the Sahara. Trends in minimum temperatures (Weber et al., 1997) over the period 1901–1990 for Central Europe, show significant increases across the plains, whereas little change was found across the mountains.

Continentiality

Various indices have been formulated to express the degree of continentality over Europe. In a general sense the indices make use of the range of the mean temperature between the coldest and warmest months of the year, and this is recorded as the annual range of mean temperature. The range increases from the Atlantic coastlands eastward across Europe into Russia (Figure E8). A relatively simple index has been used by Tsenker (in Borisov, 1965), who proposed that $K = A/\phi$ where K is the index, A is the annual range and ϕ the latitude. Similar values are obtained from Conrad's index (Conrad, 1946). More complex formulae appear in Russian literature, an example being that of Ivanov (1959).

Figure E8 Annual range of mean monthly air temperature in °C.

Using Conrad's equation a value of 4 is obtained for western Ireland, 12.5 for London, 24 for Berlin, and 40 for Moscow. Indices of over 30 are also found in parts of the Mediterranean countries, especially where inversions of temperature occur in winter such as in North Italy (Milan: 32). A different index may be calculated for an individual year to describe the degree of Atlantic influence, such as by adding the number of days of westerly flow either using Lamb's weather types or the North Atlantic Oscillation Index (Jones and Hulme, 1997).

Precipitation

Annual precipitation

Values of annual lowland rainfall show little spatial variation in the zone stretching from the English Midlands through to the Urals of the USSR (Figure E9). The passage of fronts usually ensures moderate precipitation across the European Plain, excessive falls being rare and usually associated with slow-moving disturbances. A slow decline from 640 mm to 500 mm can be observed eastward, and is evidence of the ease with which moist Atlantic air can penetrate across Europe. A few areas such as Bydgoszcz (northwest of Warsaw) and coastal regions of Lithuania record annual values less than 500 mm. As a general rule, annual rainfall over lowlands declines both northward toward the Arctic and southward toward the Mediterranean. Everywhere the existence of hills, mountains, enclosed basins, and peninsulas complicates this simple pattern. Highest annual values are found in mountainous areas where valleys are open to the southwest or westerly airflow. A few localities have recorded in excess of 5000 mm mean annual precipitation for the period 1961–1990, notably south of Nordfjord (Norway) and Sprinkling Tarn (English Lake District) and possibly inland from Boka Kotorska near the Yugoslav–Albanian border. A value of 4000 mm may have occurred at Monchsgrat in the Bernese Alps, although heavy winter snow makes measurement difficult. It is probable that one or two localities in the Bavarian Alps (West Germany) and in the Sierra de Gredos (west of Madrid, Spain) receive 3000 mm, whereas 2000 mm would seem feasible for the highest parts of the Central Massif and Jura mountains in France.

Seasonal pattern

Invasions of moist air across Europe are most frequent when the circulation is vigorous and depressions are moving quickly east across Scotland and Scania into the Baltic region. Such a situation is most likely to occur in early winter and is least likely in spring or early fall when anticyclones are usually present over some parts of Europe. In fact, over much of Europe the percentage of annual precipitation falling in spring is remarkably constant, lying between 16% and 21% (Table E3). A winter maximum in rainfall might well be expected to occur fairly widely. That this is not so indicates the many other factors that influence the seasonal distribution. In particular, higher summer temperatures over much of central and eastern Europe can lead to enhanced convection. This shower activity may be random if pressure gradients are weak, or may be organized along cold fronts as incursions of cool maritime polar air from the Atlantic travel southeast over much of the region. As may be seen from five of the stations listed in Table E3, a summer maximum occurs over eastern England and central, eastern, and northern Europe. A zone of fall maximum occurs from Portugal through

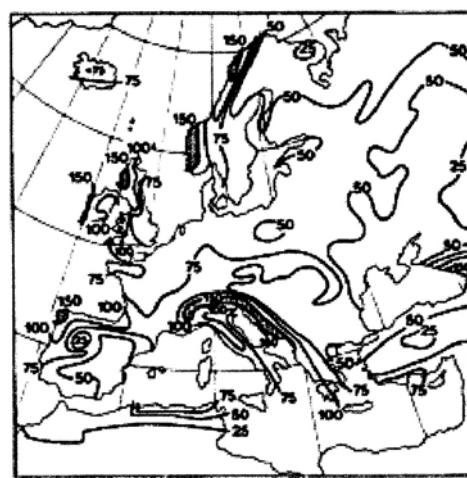

Figure E9 Mean annual precipitation in cm.

Table E3 Seasonal precipitation as a percentage of the annual precipitation (1931–1960)

	Latitude	Winter (DJF) (%)	Spring (MAM) (%)	Summer (JJA) (%)	Fall (SON) (%)	Annual total (in mm)
Northern Europe						
Bergen (west coast)	60°23'	27	17	22	34	1958
Stockholm (central)	59°17'	22	16	33	29	555
Arkhangelsk (northeast)	64°40'	18	18	33	31	539
Central Europe						
Valentia	51°56'	31	19	20	30	1398
Brussels	51°51'	26	17	29	27	817
Warsaw	52°13'	19	19	39	22	471
Moscow	55°45'	17	21	37	25	575
Southern Europe						
Madrid	40°25'	28	30	12	30	436
Rome	41°54'	35	20	6	39	749
Athens	37°58'	42	21	7	30	402

western France, central Britain, the coastlands of the Low Countries and Norway (see Bergen, Table E3). In a climatic context this maximum is the result of relatively high sea surface temperatures leading to upward transfer of water vapor into the boundary layer. The moisture may then be ingested into the circulation of midlatitude depressions via a conveyor belt mechanism (Barry and Chorley, 2003) These depressions become more vigorous and active from September through November across central and northern Europe.

The Mediterranean region with its mountains, peninsulas, islands, and inland sea presents a more complex pattern of seasonal precipitation (Figure E10). It is more convenient to state the driest period of the year, which is summer, when extensions of the subtropical high pressure lie over the region. During the remainder of the year, although frontal depressions can sometimes be identified, many disturbances are ill-defined and rather transitory. Moreover, their activity in terms of producing rain varies on both a seasonal and annual basis. One or two very wet Octobers can lead to an imprint on the climatic record that can be misleading if arithmetic averages are employed. Bearing this in mind, it is generally true that a fall maximum is more likely in the western and northern Mediterranean and that a winter maximum is more evident in the southern and eastern Mediterranean (see Athens, Greece, Table E3). A bimodal maximum (spring, fall) is a feature of much of Spain, at least when the westerly flow is relatively strong. Comprehensive analysis of seasonal rainfall frequency in the Mediterranean was carried out by Reichel and Huttary (in Trewartha, 1981). More recent investigations have employed indices and statistical analyses in attempts to describe present rainfall patterns and to search for regular periodicities (see Fukui, 1966; Tabony, 1981). It should also be noted that there is a tendency for the general characteristics of a rainfall regime to change over periods of 30 years. Thus fall may be considered "wet" in one decade, spring in the next (Boucher, 1994). More detailed gridded analysis of precipitation has recently been carried out for a 25 km grid over the entire region of the European Alps and then extended over the time period 1901–1990. This reveals an increase in winter precipitation of 20–30% per 100 years over the western part of

the Alps and a decrease of 20–40% fall precipitation in the southern part of the Alps (Schmidli, 2002).

Types of rainfall and duration of heavy falls

Attempts have been made to classify rainfall into three categories of cyclonic (predominantly frontal uplift), convective (thunderstorm type), and orographic (uplift over mountains). It is not easy to distinguish clearly between these categories, though convective thunderstorms contribute significant amounts to summer rainfall over much of Europe. Precipitation over mountainous areas is enhanced by uplift of airmasses on windward slopes. Extreme maximum precipitation over periods of less than 24 hours is highest at lowland stations where convection is dominant. Continuous heavy rain depends on steady inflow of moisture into a region usually associated with slow-moving low-pressure systems. Recent analysis of heavy rainfall events in Central Europe (Ulbrich et al., 2001, 2003a,b) has shown that extreme rainfall periods have return periods of between 300 and 1000 years with rainfall totals over 5–10 days exceeding the monthly rainfall by 300%. Data from Ulbrich and others are shown in Table E4. Such widespread rainfall usually combines three components: uplift of moist air over mountains, vigorous wave activity along a quasi-stationary frontal zone, and convective instability. Two examples are given in Table E5, in which over 600 million cubic meters of rain fell over a limited area.

Thunderstorms and related phenomena

Over much of continental Europe, thunderstorms are typically a summer phenomenon. Within European Russia about 50% of the thunderstorms are associated with cold fronts, 22% with warm fronts, and 28% with convergence within airmasses. Thunderstorm frequency increases with the rise in surface temperatures in early summer and reaches a maximum in June in parts of southern European Russia; in July over much of central and northern Europe, including northern Italy; in August in parts of Sweden; in September and October in the western

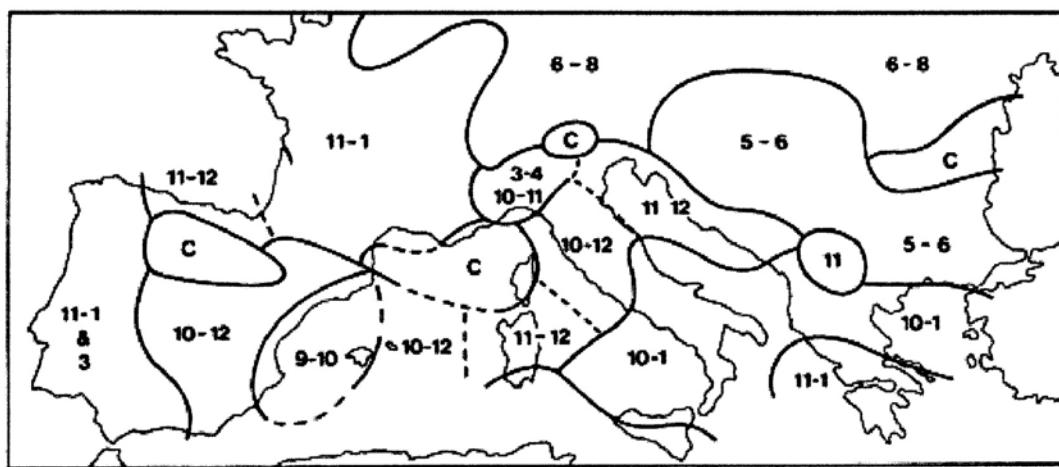

Figure E10 Seasonal distribution of maximum rainfall. The figure shows months of maximum rainfall over southern Europe based on World Meteorological Organization Data 1961–1990. Months are numbered from January (1) through December (12). Complex regimes with no distinct seasonal maximum are indicated by C.

Table E4 Maximum precipitation sample extreme values – Europe 1960–2005

Event	Location	Amount	Time period/date	Notes
1	Northampton, England	48 mm	15 hrs/9 April 2002	Frontal
2	Mid-Thames, England	80 mm	27 Dec–3 Jan. 2002–3	Frontal systems
3	Lower Elbe, Austria	610 mm	6–7 Aug. 2002	Low moving East
4	Devon, England	300–500 mm	15 Aug. 1952	Thunderstorm
5	Udine-Rivolti, Italy	44 mm	4 Aug. 2002	Small mesoscale convection
6	North Wales, UK	417 mm	30 Jan.–5 Feb. 2004	6 days of cyclonic rain
7	Majorca, Spain	200 mm	5 Sept. 1989	Cyclonic storm–Cold pool

Table E5 Data relating to two notable rainfall events with return periods in excess of 100 years

Central and northern Rumania	12–14 May 1970	Duration: 48 hours
Isohyet	Area enclosed	Rainfall in $m^3 \times 10^9$
25 mm	50 000 km ²	2.5
100 mm	6000 km ²	0.66
Scottish Highlands	26–27 March 1968	Duration: 36 hours

Mediterranean and in winter over southern Italy as well as parts of northwestern Britain.

The occurrence of hail is most closely associated with air-mass thunderstorms, especially where these develop in hilly or mountainous regions. They may be accompanied by squally winds that are best attributed to storm downdraughts. Small-scale tornadoes occasionally accompany storms, but nowhere have they been reported to attain the magnitude and frequency of those in the United States. Over western Europe they may be closely associated with cold fronts at any time of the year. Their tracks rarely exceed 1 km. There have been fairly frequent sightings of water spouts over the western and central Mediterranean during thundery weather. Small-scale whirlwinds and tornadoes occur fairly regularly during summer months.

Snowfall

The relatively high sea surface temperatures in winter mean that snowfall in winter is variable over low ground in western Europe. Snow cover may persist for more than 7 days only in the coldest winters. As a general rule, monthly average temperatures must lie below 1°C for snow cover to persist. The number of individual days with complete snow cover increases northeast across the European Plain from 5 days in the Midlands of England to 40 over central Poland, 135 days around Moscow and up to 200 along the Arctic fringe. The mean maximum depth of snow cover increases from 20 cm in southwest Russia to about 75 cm on the lowlands to the west of the Urals. Most mountain areas are liable to receive heavy snowfall, though aspect and character of individual winters along with recent rise in temperatures have reduced snow accumulations. Prolonged snowfall exceeding 25 cm over parts of western Europe is only

likely to the north of an active frontal zone. Such a situation leads to very cold continental air being drawn west over northern Germany toward central Britain, while humid air is forced to ascend over the cold easterlies. Snow enhancement occurs if small disturbances run east, typically along the English Channel into central Germany. Polar lows occasionally bring blizzards to Scotland, and eastern parts of the North Sea, but their activity depends on unstable cyclonic disturbances developing in cold northerly airflows crossing warm ocean waters.

Drought

Lack of precipitation is a normal part of the seasonal climatic cycle within the Mediterranean in summer. An appropriate index is used to describe the rainless period. Aridity indices, such as that of De Martonne, have traditionally been employed by Italian and French climatologists to describe summer drought (Pinna, 1957). The existence of a rainless period is closely associated with midtropospheric subsidence. Therefore the existence and maintenance of summer drought depend on the strength and position of the Azores anticyclone and its eastward extension. When this anticyclone is well developed, drought is complete and may last for up to 4 months in southern parts of Spain, Italy, and Greece. Occasionally during summers such as those of 1959, 1976, 1992 and 2003 the belt of high pressure may be located farther north over northern France and the North Sea, bringing drought to areas usually well supplied with precipitation and delivering summer rainfall to the Mediterranean (Perry, 1976). Such annual variations are of deep concern, not only to countries such as Spain and Portugal (Estrela et al., 2000), but also to the grain-growing areas of Poland and Russia where the failure of adequate snowmelt and spring–summer rain may seriously reduce yields, as in 1972 and 2003. Hydrological droughts (low streamflow) have continued to be cause for anxiety (EEA, 1998) but show both spatial and temporal variations (Lloyd-Hughes and Saunders, 2002). Increasing drought deficit volumes have occurred in the eastern sector of East Europe and large parts of the UK, but decreasing deficits have characterized many parts of central Europe (Hisdal et al., 2001).

Severe droughts are associated with rainfall deficiencies of 50% over periods of 6 months or more. The impact of such droughts is greatest if they occur during the soil moisture recharge period (Hounam et al., 1975). As elsewhere, the intensity of the drought is increased by high winds, low humidity, and high temperatures. Areas likely to suffer such conditions lie along the southern border of Europe and across the steppes of the Ukraine and Kazakhstan (north Caspian Sea). In the latter area the steppe climate is characterized by extreme annual range of temperature approaching 80°C, frequent droughts, and desiccating, dust-laden winds known as *sukhovei*. During the period 1880–1950, serious drought occurred on average every 3.5 years

(Poltarus, in Borisov, 1965). The effect of one year's drought is magnified by the tendency of one drought year to follow another. Such was the case over much of European Russia from 1889 through 1892, and in southern Spain from 1917 to 1919.

Within the midlatitude belt of Europe the occurrence of drought is closely associated with the position, height and persistence of ridges in the middle part of the troposphere. Persistence of high pressure tendency over a number of years may produce general deficits in precipitation. The droughts of the early 1970s in European Russia prompted a number of studies (Buchinskiy, 1975; Chistyakova, 1975). In an earlier investigation Davitaya (1958) found that droughts over southern Russia reflected shifts in the midtropospheric ridge-trough pattern. A thorough investigation by Rauner (1980) into the simultaneous recurrence of drought in different regions of Europe revealed that drought affected the whole of the grain zone of the USSR in 5 years during the period 1891–1975. On a regional basis droughts were found to have affected the Ukraine in 43 out of 106 years (1870–1976) and the Volga region, a 1000 km further east, in 41 out of 96 years (1880–1976) of which 19 years were common to both regions. The occurrence of drought simultaneously in European Russia and Western Europe evidently has taken place in 20 years during the period 1700–1976, three of which occurred consecutively from 1747 to 1749.

Climate change

Rising surface temperatures in the European sector have been shown by Parker and Alexander (2002) whilst their annual analysis of rainfall reveals high variability on time scales of 10 years with no easily discernible trends.

Synoptic climatology

Weather types

Regional assessment of climate has often been carried out on the basis of a classification of air movement and associated

weather conditions. British research (Lamb, 1972) has favored a less rigorous system than a number of German and Russian climatologists (see Hess and Brezowsky, 1969; Chubukov, 1977). Despite its limitations, an example of such an annual regime is included. Other circulation indices include that of Namias (1950) and some variants used by Dole and Gordon (1983). Research has also focused on indices that affect part of, or all of, the northern hemisphere, such as the North Atlantic Oscillation (NAO). This fluctuation in pressure gradient between the Icelandic low (65°N) and the Azores high (40°N) is believed to influence weather patterns over much of Europe in winter (van Loon and Rogers, 1978). Since 1989 the NAO has been mostly positive, leading to warmer winters over many parts of Europe (Barry and Chorley, 2003).

Spells of weather

The term "singularities" has been applied to periods of distinctive weather lasting between 7 and 14 days that have a tendency to recur in most years on or about the same dates. Trewartha (1981) associates this calendar of weather episodes with the *Grosswetterlagen* of German climatologists. For a certain region of Europe a calendar sequence of probable types of weather may be assembled. In essence, singularities represent adjustments of the general circulation to various distributions of energy within the boundary layer and in the troposphere above. A singularity such as an anticyclonic spell may be regarded as a statistical probability of a circulation pattern occurring for a given period of the climatic record. An example of such a calendar is presented in Table E6, which refers chiefly to the British Isles. Most singularities shown also occur over Germany; however, the region of European Russia lies too far downstream in the west-erlies for statistical correlations to be significant.

Due to the ridge-trough nature of the air flow at 5000 m periods of anticyclonic activity over western Europe are likely to be associated with cyclonic activity over eastern Europe. It might appear from Table E6 that periods of cyclonic activity alternate

Table E6 Abbreviated calendar of singularities

Dates	Singularity	Probability of occurrence over British Isles	Comments for Germany
11/22–12/10	Early winter storms	>50% (1)	zonal westerlies
12/17–12/24	Continental anticyclones	25%	>60%
12/26–1/12	Storms of midwinter	westerly 60%	westerlies 72%
1/19–1/25	Continental anticyclones	25% (5)	>75%
1/27–2/4	Renewed winter storms	variable (1)	precipitation peak 70%
2/7–2/22	Anticyclones	25%	>60%
2/26–3/9	Cold spell	50%	no regular features
3/12–3/22	Anticyclones	35% (1)	>60%
3/30–4/15	Atlantic depressions	westerly 40% (5)	rainfall peak
4/16–5/20	Spring northerlies	25%	3 days 75% (1)
6/10–6/30	Increase in Westerlies	westerly 52% by 20th	westerlies 80%
7/15–8/15	Unstable cyclonic	30–35%	westerlies >80%
8/17–9/2	End of summer	westerly 50%	rainfall peak
9/6–9/19	Anticyclones	30–40%	>70%
9/21–9/30	Atlantic storms	25%	anticyclones >70%
9/30–10/15	Anticyclones	peak 40% (5)	part > 70%
10/24–11/13	Late autumn rains	westerly 35%	anticyclones >60%
11/15–11/24	Anticyclones	30% (1)	anticyclones >70%

Notes: Statistically tested figures exceeding the level of 5% probability of occurrence are indicated by (5) and 1% probability by (1) usually for part of the period indicated in column 1. Length of the record in total was from 1873 to 1961. Some figures refer to parts of this period.

Source: After Lamb (1964), pp. 176–188.

with anticyclones, but such a deduction can be misleading. The singularity table is not a forecasting tool. For reasons not well understood, certain singularities become statistically significant for limited periods of the record before declining, even disappearing, for a number of years only to re-emerge at a later period. It is interesting to postulate that such changes form part of a climatic signal in the atmospheric system, indicating fundamental adjustments of the general circulation (see Lamb, 1982).

The general circulation

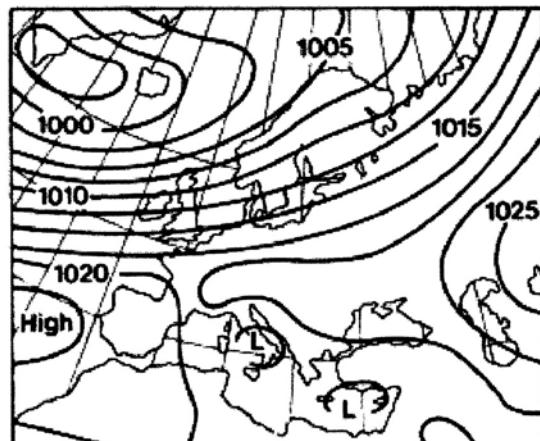

Pressure patterns at the surface

The mean centers of both anticyclonic and cyclonic activity lie over the Azores islands, west of Portugal, and southwest of Iceland respectively – outside continental Europe. In periods when the westerly flow is well established, ridges and troughs move eastward away from these centers across central Europe. These may be associated with closed isobaric highs and lows at the surface. On the average monthly mean pressure charts for 1951–1966 (Meteorological Office, 1975), the shape of the North Atlantic low changes, being at its most intense in December (997 mb); thereafter it declines until July when there is no easily identifiable center of low pressure close to Europe. The Azores anticyclone appears weakest in March (1020 mb) and lies equatorward of 30°N. It reasserts its dominance and is at its most extensive in July (1025 mb) with ridges extending east and northeast across Europe (Figure E11). It has been noted that July is also the wettest month over much of Europe, indicating that breakdowns in the high pressure are frequent in some summers. The greatest monthly variation in pressure during the period 1951–1966 occurred west of Ireland in February and November, with standard deviation values of 11 mb and 8 mb, respectively. This indicates marked changes in flow patterns in these months from one year to another, indicating the variable nature of West European climate (Tables E7 and E8).

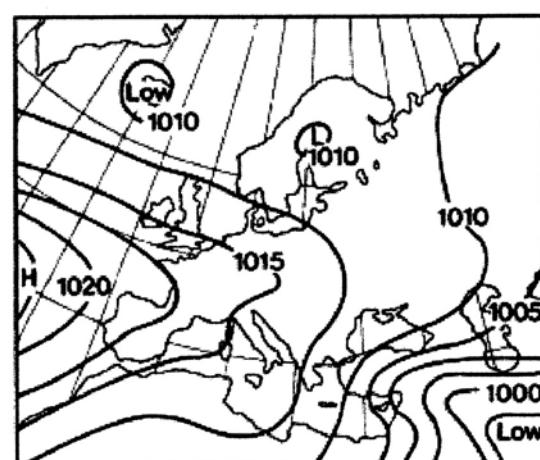

The jet flow across Europe

Mean airflow over Europe in the troposphere is predominantly from the west between high pressure to the south and low pressure to the north. Imposed on this pattern are waves of large amplitude having a wavelength of several thousand kilometers. Their position, movement, and intensity produce an ever-changing pattern of airflow. Embedded in this flow lie narrow zones of fast-moving air known as jet streams that extend downstream for several thousand kilometers. They may be about 400 km wide, and are associated with airmass boundaries of the Polar Front. They appear and disappear with the changes in the circulation pattern. Within the core of the Polar Front jet, winds may exceed values of 60 m/s over Europe.

It is not possible to represent a mean position of the Polar Front jet, but some idea of its strength and location at 700 mb is given in Figure E12, which shows the axes of maximum wind at around 3000 m. The direction and movement of midlatitude depressions in any one month are closely associated with the mean position of the Polar Front jet during that month. The Subtropical jet is far more persistent. Its mean winter position lies over the central Sahara. Figure E13 shows cross-sections of the average zonal wind components in January and July: (1) 40°E; (2) 15°E; and (3) 10°W. The position of the Polar

Table E8 Meridional mean difference in the height of the 500 mb level in geopotential meters between 40°N and 60°N

	20°W	0	20°E	40°E
January	140	82	68	76
July	92	86	66	60

Note: Positive values indicate westerly flow.

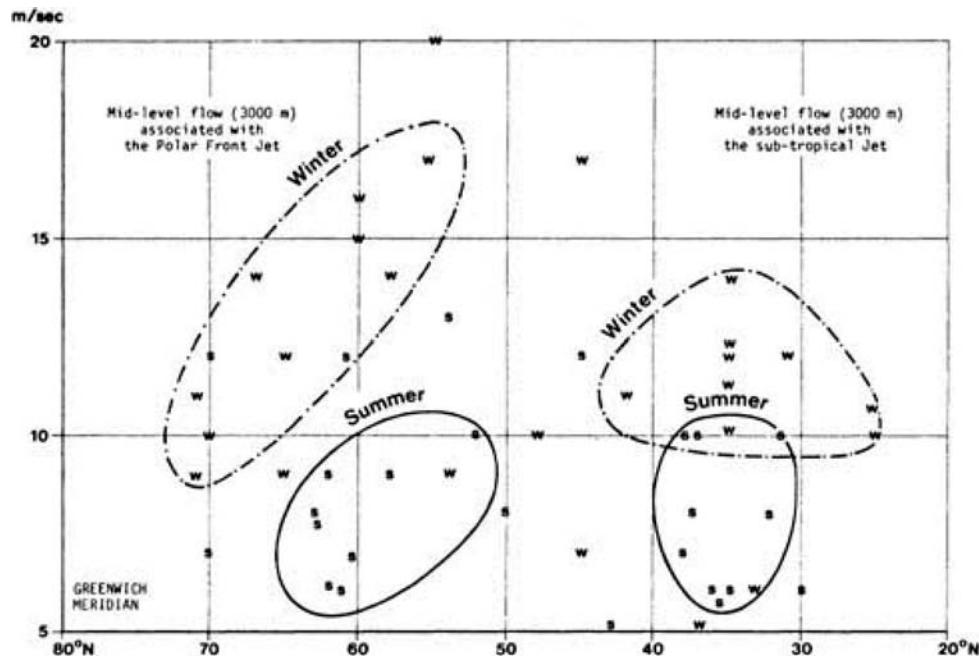

Figure E12 Envelopes showing the position and strength of the monthly mean maximum geostrophic wind at 700 mb for winter (December to February) and summer (June to August) along the Greenwich Meridian. Plots for individual months are also shown for 1969–1975 (partial record).

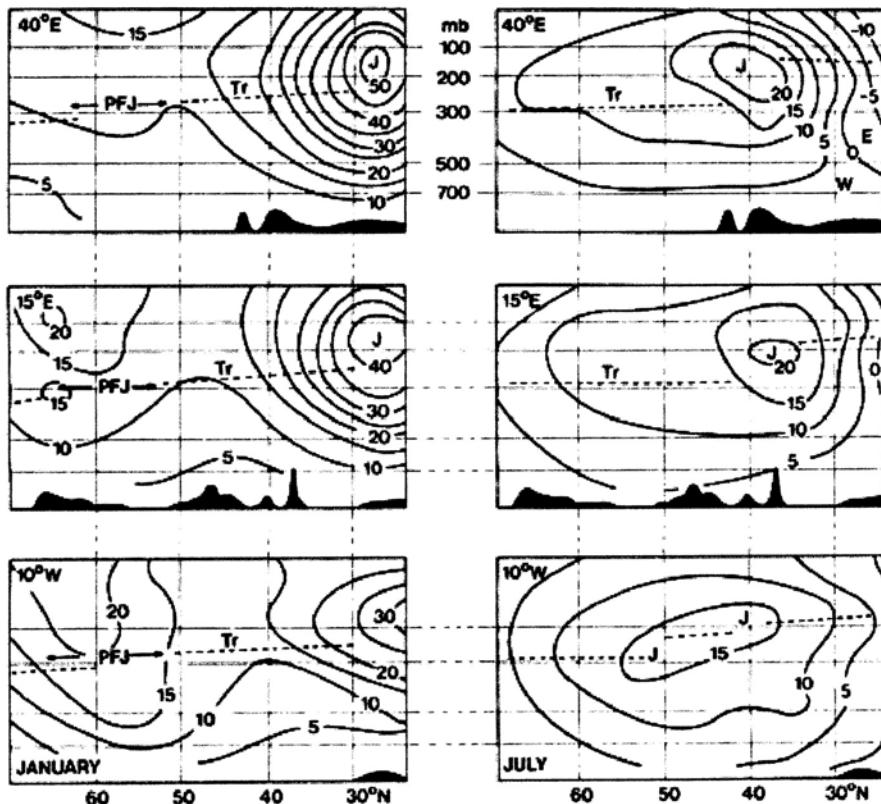

Figure E13 Meridional cross-sections at 10°W, 15°E, and 40°E showing the westerly (zonal) component of the wind in meters per second. Positive speeds represent westerly wind, negative values easterly wind. Schematic position of the tropopause (Tr) is also shown (after Meteorological Office, 1975, p. 121). PFJ indicates the likely position of the Polar Front Jet.

Front jet is purely schematic. In winter it may be found anywhere between 30°N and 70°N, but it is too ephemeral to imprint its presence on average maps of zonal flow. In summer only one jet flow is recognizable at 300 mb over Europe even if there is a suggestion of two axes at 700 mb.

Blocking patterns

One of the most frequent interruptions to the westerly flow over Europe results from “blocking” high-pressure patterns developing either upstream in the mid-North Atlantic or over Europe. The presence of a large anticyclone, persisting on average for 16 days, causes disruption of and breakdown in the mid-level flow. This blocking may be dominant in some years (such as 2003) or only weakly developed in most other years. The effect of blocking on the distribution of precipitation is potentially important. Abnormally low temperatures in winter may also result, as in February 1986. Much attention has been given to these features in the literature. Rex (1950) has provided a comprehensive review of the climatic data relating to blocking over Scandinavia.

Obstruction to westerly flow below 3000 m also results from the development and persistence of a cold anticyclone or thermal high over snow-covered Siberia. The westward extension of this high into European Russia causes continental temperate air to flow around the southern margin of the high in winter. On average, air associated with the Siberian high is found on 24 days in January over the lower Volga Plain, decreasing to 12 days in the vicinity of Leningrad (Lydolph, 1977).

Surface anticyclones and depressions

Anticyclones

Throughout the year, “cells” may break away from the semi-permanent Azores anticyclone over the east central North Atlantic and travel slowly northeast, close to the English Channel and across the European Plain or central Europe into southern European Russia. Two to four new anticyclones a year tend to form along this axis. Another favorite center for anticylogenesis lies over Scandinavia, while high values over the

Mediterranean represent the relocation and development of the Azores high. Annual mean speeds of eastward (progressive) moving highs are of the order of 6° of longitude per day at 55°N. Somewhat surprisingly, anticyclones moving westward (retrogressing) away from Europe traveled at 7° per day on average (Meteorological Office, 1975) and accounted for 40% of mobile anticyclones. There was little significant seasonal pattern evident. Figure E14 shows the total number of days in which the center of a high was located within a 5° × 5° grid. Counts were made daily. Climatological interest in this empirical aspect of climatology has since declined.

Midlatitude depressions

In European literature the term “cyclones” usually is applied to tropical storms. Midlatitude cyclonic disturbances are referred to as depressions or lows. Frontal depressions affect much of Europe north of 45°N throughout the year, and parts of the Mediterranean during the winter half. A wide variety of non-frontal depressions also occur and include heat lows (thunder lows), polar lows (Businger, 1985), and lee depressions. Most of these are associated with infrequent synoptic weather patterns. Major depressions that develop central pressures below 980 mb originate over the western North Atlantic and attain maximum intensity before reaching land. This is evident from Figure E15, which shows the diminishing influence of low pressure southeastward into central Europe. A feature of great importance over the sea areas bordering northwestern Europe is the ability of some lows to suddenly deepen, creating high winds and storm surges as in 1987.

Figure E16 shows the areas most likely to experience cyclogenesis. It should be noted that the map does not convey any dynamic information about the development, movement, and intensity of the lows (Campins et al., 2000). For example, the center over northern Italy reflects the formation of many shallow but active lee depressions (see Zenone and Lecce, in Wallén, 1977). Other “centers” are less geographically fixed and do not appear on all map interpretations of the data (see Trewartha, 1981; Borisov, 1970).

The movement of depressions over the northern hemisphere has been investigated by Klein (1957) and others, and is shown in Figure E17. The continuous lines denote main tracks and the

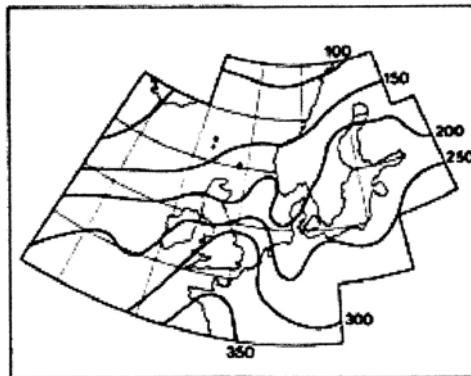

Figure E14 Total number of days with anticyclonic centers at 1230 GMT, 1899–1938 (after Meteorological Office, 1975, p. 63).

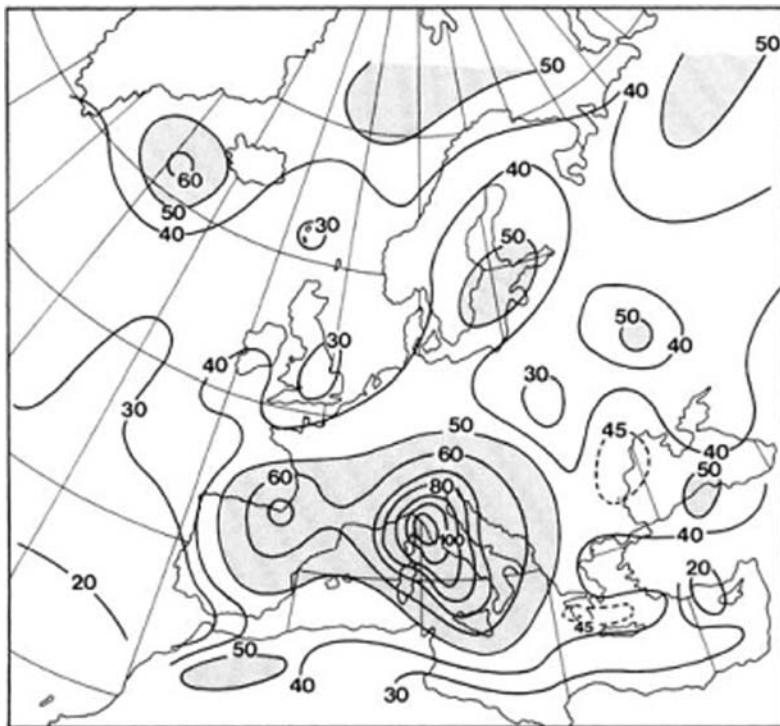

Figure E16 Twenty-year frequency distribution of cyclogenesis, 1909–1914 and 1924–1937 (after Meteorological Office, 1975, p. 57 and Trewartha, 1981).

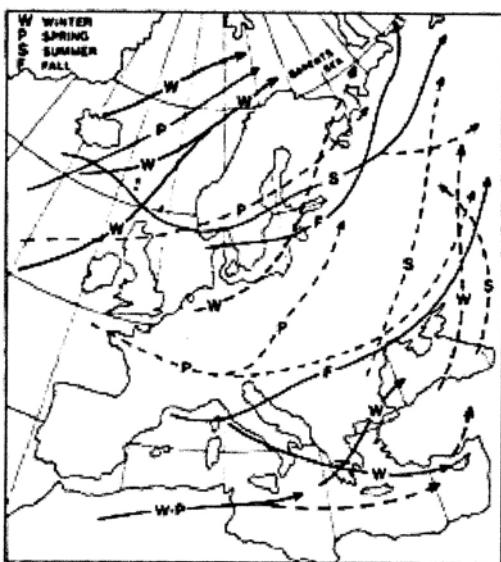

Figure E17 Main tracks of traveling depressions (after Klein, 1957, p. 15).

dashed lines indicate less frequent routes. The main Icelandic low is renewed by depressions originating further west. Tracks across northwestern Europe are usually followed by subsidiary lows circulating around the parent depression, although some do break away beneath the westerly jet and travel across the

Barents Sea. Most European lows either follow the northern or southern boundary of the continent in winter, whereas in summer a central route across the North and Baltic seas has been established. Over European Russia, tracks are difficult to identify in winter when high pressure predominates, but low pressure is more in evidence in summer. This is particularly so in central European Russia – a region that stretches from the western borders with Poland eastward toward the southern Urals. In this region there are twice as many cyclonic centers in summer as in winter. Some of these lows will be associated with fronts and outbreaks of cool polar air. Others are more easily identified with zones of marked baroclinicity (Ulbrich et al., 2001) sometimes associated with unusual pressure features (Pearce et al., 2001; Barry and Chorley, 2003).

Depressions in the mediterranean

It is unusual for the whole of the Mediterranean, which extends 3700 km eastward from Gibraltar, to be free from depressions at any one time, even in summer. When depressions form within or travel through the Mediterranean, there is often a quasi-stationary anticyclone over central or western Europe. Other factors contributing to cyclogenesis in the Mediterranean are the presence of a baroclinic or frontal zone, lee effects in strong airflows, and instability in airmasses (Meteorological Office, 1975). Analysis of upper-air charts shows that depressions travel in the direction of the flow at 200 mb, whereas thunderstorms are more likely to follow the flow pattern at 700 mb. On the other hand, Perry (1981) has drawn attention to the role of sea surface temperature anomalies in promoting cyclonic activity within the Mediterranean.

Cold pools

During periods of low index and meridional flow masses of cold air may be transported southward over Europe and may become entirely surrounded within the troposphere by relatively warm air. The severing of the tip of this tongue of cold air produces a tropospheric cold pool. When this occurs over the Mediterranean it becomes the source of instability, thunderstorms, and abnormal precipitation (Boucher, 1982). One notable cold pool and accompanying storm developed in late January 1986 with central pressure falling below 980 mb.

Conclusion

The ever-changing pattern of the climate of western Europe provided the stimulus for the development of the science of meteorology in the early part of the twentieth century – notably the establishment of the Bergen School founded in 1918 by the Norwegian physicist Vilhelm Bjerknes (Jewell, 1981). This day-to-day variability has posed a challenge for climatologists who seek to establish order out of seeming chaos (see Volkert, 1985 and Lamb, 1985). Others have turned their attention to archived records across Europe in an attempt to place the climate records across Europe into a meaningful sequence (New et al., 2001). Elsewhere the emphasis on classification and indices has enabled greater understanding of climatic processes to be combined with issues such as that of global warming. Even so, the quantitative expression of the regional characteristics of climate remains a daunting task for climatologists and statisticians alike (Trewartha, 1981).

EVAPORATION

Natural evaporation is the process whereby water at the Earth's surface, either in liquid or solid form, is converted to vapor and transferred into the atmosphere. It is therefore the reverse component to precipitation in the global water cycle and, in

total over the whole surface of the Earth, the two must balance on the average. Furthermore, since the storage capacity of the atmosphere for water in all phases is equivalent to only a few centimeters depth of liquid water, whereas the average evaporation for the whole Earth approaches 100 cm year^{-1} , this balance must hold over comparatively short intervals of time.

It should, however, be stressed that the balance is achieved only on a global reckoning, the world patterns of evaporation and precipitation showing gross differences. The consequent transfer of water vapor from the source of evaporation to the area of precipitation, with the associated transfer of latent heat, provides the most important single factor in the overall redistribution of heat over the Earth's surface. It is for this reason that knowledge of the distribution of evaporation over the whole Earth is basic to an understanding of the general circulation of the atmosphere, while the economic importance of evaporation over the continents is being increasingly recognized as water usage grows rapidly. Over the oceans the latter aspect is, of course, of no consequence, but the combined study of evaporation and precipitation in these regions will lead to increased knowledge of drift currents in and between the oceans, which are already known to be considerable.

Measurement of evaporation

The measurement of evaporation presents difficult problems, the difficulty varying with the nature and extent of the evaporating surface. Here we shall discuss briefly the principal methods that have been developed to meet different requirements, indicating the applicability and limitations of each.

Hydrological balance

When all other factors contributing to the hydrological or water balance for a given area are known, evaporation may be estimated as a residual. The hydrological balance may be expressed as

$$P = R + S + E$$

P being precipitation, R the surface runoff of water, S the seepage of water into the ground, which may increase the local storage or percolate to deeper levels and be removed as underground currents, and E the evaporation. Adequate measurement of P and R presents problems in sampling over the area in question. S is obviously a difficult term to assess, although in certain circumstances (when it is known from the local geological structure that underground currents out of the area do not exist) it can, over a sufficient time interval, be assumed to be zero. This method of estimating evaporation must evidently be very approximate in general, although in certain favorable circumstances, for example catchment areas of easy topographical form, results of acceptable accuracy may be obtained.

In certain studies, e.g. in agricultural research, the gravimetric method of determining evaporation is of prime importance. This technique, which is a specific refinement of the hydrological balance method, consists of isolating in an impermeable container *in situ* a soil block of appropriate size, whose water balance is known in terms of water applied and water lost by successive weighings of the block. This method is capable of high accuracy and, depending on the precision of the weighing equipment, can be used for the measurement of evaporation over periods less than 1 h when the evaporation rate is high. There are, however, obvious limitations to the size of such

installations and the method is unsuitable for the study of evaporation when the terrain carries irregular cover.

Soil moisture profile

Other methods of measuring the water loss from soil by evaporation may be mentioned briefly. They are all based on the determination of the vertical distribution of moisture in the soil, the "soil moisture profile", and its change with time, and include measurement of the moisture content by sampling and weighing; measurement of electrical conductivity of materials placed in the soil, whose conductivity is moisture-dependent (gypsum, fiberglass, nylon, etc.); the measurement of the thermal conductivity of soil, which is also moisture-dependent; and the determination of the scattering of neutrons by the hydrogen atoms in water. Each is subject to limitations of one sort or another (for details and reference to original work, see review by Deacon et al., 1958).

Pan evaporation

The measurement of water loss from pans and tanks has occupied a central position in experimental studies of evaporation. The results from such observations are usually presented by means of a formula due originally to Dalton (Shaw, 1993):

$$E = C(e_w - e_a)$$

where E is the rate of evaporation, e_w is the saturation water vapor pressure at the surface temperature of the water, e_a is the vapor pressure in the air, and C is a factor that incorporates the effects of wind speed, barometric pressure and other variables such as exposure. Much of this work was originally carried out in the United States, in particular by Rohwer (1931) at Fort Collins, Colorado. Rohwer summarized the results of his studies, made from a tank 3 ft (0.9 m) square, in the formula

$$E = 0.771(1.465 - 0.0186B) \\ (0.44 + 0.118w)(e_w - e_a)$$

where E is measured in inches per day; B (the barometric pressure), e_w and e_a , in inches of mercury; and w (the wind speed near the ground), in miles per hour.

Such measurements, if they can be related to water losses from larger water bodies such as dams and reservoirs and from freely transpiring vegetation, are of obvious economic importance. What is wanted, ideally, is a single conversion factor

(pan coefficient) applicable at all times under any conditions. Consideration of the basic dependence of pan evaporation on the size, design, and exposure of the pan and its comparatively rapid response to changing atmospheric conditions (whereas the larger body of water will be more or less thermally inert depending on its size) emphasizes the difficulty of achieving this factor. This is clearly brought out in the results of evaporation studies over Lake Superior. Figure E18 shows the monthly evaporation rates from Lake Superior and a nearby small shallow lake, both calculated from Rohwer's formula. The physical reasons for the curves being 6 months out of phase are obviously connected with the relative thermal inertia of the two lakes. This case is admittedly extreme, but it does emphasize the fact that each water body will have its own pan coefficient, and that this is likely to vary with pan or tank type and season. Nevertheless, such instruments, particularly if they are standardized, have a useful role to play in assessing the comparative evaporative needs of different regions, even though their quantitative indications must be interpreted with caution.

Other methods

A direct method of measuring evaporation has been developed in recent years, which stems from the recognition of evaporation as a process of turbulent diffusion. It can be shown that the product, averaged over any time interval, of the instantaneous values of vertical air velocity and specific humidity near the evaporating surface represents the average evaporation for the period. Instrumentation has been designed to measure the fine structure of the air in respect of these properties (Deacon et al., 1958) and the technique has been verified in the field. This method has the advantage that it can be used for the measurement of evaporation from any type of uniform surface and is subject to none of the restrictions that limit many other techniques. Though up to the present time its use has been confined to research studies of evaporation, it is capable of development for routine use (Shaw, 1993).

Evaporation in the climatic context

Each of the above methods finds its particular use in specific studies of evaporation over relatively small areas, the interest being chiefly in the economy of water storages and in the water needs for agriculture. None is suitable in the larger context of the delineation of evaporation on the climatic scale, although

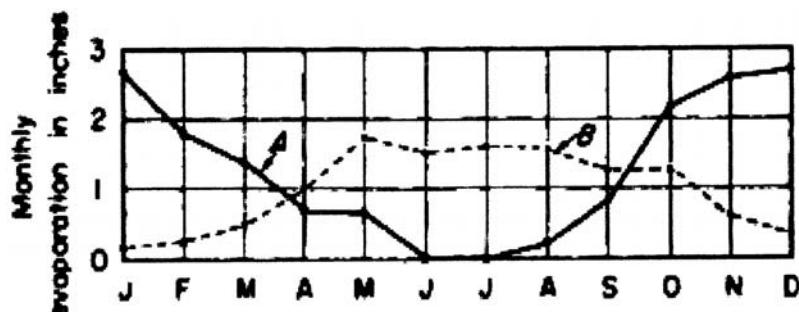

Figure E18 Estimated monthly evaporation rates for (A) Lake Superior and (B) nearby shallow lake (from Wisler and Brater, 1959).

the hydrological balance method in favorable circumstances provides an exception to both of these statements.

For such surveys, where it is sought to estimate evaporation in terms of climatological variables, there are two principal approaches. In the first, which is usually known as the aerodynamic method, the rate of evaporation E is related to the difference in water vapor content of the air at two levels above the evaporating surface and some function $f(u)$ of the wind speed in the diffusion formula

$$E = f(u)(q_1 - q_2)$$

where q_1 and q_2 represent the specific humidity of the air at the levels z_1 and z_2 .

The quantity $f(u)$ is determined empirically, or may be derived from the theory of atmospheric turbulence as

$$f(u) = \frac{\rho k^2 u_2 (1 - u_1/u_2)}{(\ln z_2/z_1)}$$

where u_1 and u_2 are the wind speeds at the levels z_1 and z_2 , ρ is the air density and k is von Karman's constant (~ 0.4). It must be stressed that this formulation for $f(u)$ is valid only when the air is in or near neutral equilibrium. However, over much of the Earth's oceanic surface the assumption of neutral stability is justified, and then u_1/u_2 has a constant value so $f(u)$ reduces to a constant factor times the wind speed, and

$$E = A(q_1 - q_2)u$$

For the empirical determination of $f(u)$ it is necessary for the evaporation to be known independently, either from consideration of the water balance or from energy conservation. In the latter method, which can be used in its own right for the determination of evaporation and is the second principal approach referred to above, the latent heat expended on evaporation can be estimated as a residual when all other components in the energy balance at the evaporating surface are known. This balance is represented as

$$R_N = H + LE + S$$

where R_N is the net radiant energy reaching the surface, which can be estimated from empirical formulas in terms of climatological variables or can be measured; H is the sensible heat conduction from the surface to the air; L is the latent heat of vaporization of water; and S is the rate of heat storage below the evaporating surface. Over land, S is a relatively small component and, over long periods, may be neglected. However, over the oceans this is not so, and for this reason among others, the aerodynamic method has been preferred over these regions, as we shall see below.

The mechanism of transfer of sensible heat into the air is similar to that of water vapor, and so the problem of determining evaporation from the energy balance resolves into that of correctly apportioning the available energy $R_N - S$ (or, nearly enough, R_N) between sensible and latent heat transfer. For this purpose the Bowen ratio technique is available. In this method, identity of the transfer mechanisms of heat and water vapor is assumed, and the ratio of the transfer of sensible heat H to latent heat LE (the Bowen ratio) may be written

$$\frac{H}{LE} = \frac{c_p (T_1 - T_2)}{L(q_1 - q_2)} = \beta$$

where T_1 and T_2 are the temperatures of the air at the levels z_1 and z_2 , and c_p is the specific heat of air at constant pressure.

Hence, from the equation representing energy balance, E may be expressed as

$$E = \frac{R_N}{L(1 + \beta)}$$

Although each method may, in principle, be used for the measurement of evaporation, each requires great accuracy in the determination of the small differences in temperature and specific humidity that usually occur. The instrumentation for achieving this on a routine network basis is not yet available. Over the oceans, however, the difficulty is relieved by the fact that differences in temperature and vapor pressure between the surface and the air are relatively large, and a knowledge of the surface temperature automatically provides the value of the vapor pressure there. Over the land no such simplification is generally available. Furthermore, departures from neutrality that call into question the assumptions of equality of transfer coefficients, referred to above, are much more pronounced over the land than over sea. For reasons such as these, evaporation surveys over land areas have, up to the present, had to rely largely on estimates made from the hydrological balance and, being subject to the inherent errors of this method, can at best be only very approximately correct.

One of the most extensive surveys of evaporation yet published is that due to Budyko (1956). Evaporation is estimated by the aerodynamic method, the appropriate transfer coefficient being determined from a variety of evidence including energy balance, studies of lake evaporation, etc. The formula used by Budyko is

$$E = 2.4 \times 10^{-6} u(q_s - q_a)$$

where E is in $\text{g cm}^{-2} \text{s}^{-1}$, u is the wind speed in cm s^{-1} at the usual height for shipboard observation, and q_s and q_a are the specific humidity of the air at the sea surface and at shipboard level, respectively: q_s is assumed to correspond to saturation at the sea surface temperature.

Since the world totals of evaporation and precipitation must balance, and since the estimates of either must be made on grossly inadequate observations, there is considerable latitude for interpreting and reconciling the observations of precipitation from coastal and island stations with estimates of evaporation from formulae whose coefficients are only approximately known and that necessarily use observational material whose quality may often be questionable. Observations of wind speed, temperature, and humidity can only properly be made on shipboard if special precautions are taken, and the measurement of sea surface temperature is another source of error.

Although estimates of evaporation show a variation in excess of 20%, and thus emphasize the approximate knowledge of the level of oceanic evaporation, there is nevertheless reasonably good agreement in the evaporation pattern on the broad scale. A notable feature is the distribution of evaporation rates in the subtropical high atmospheric pressure belts, with high rates over oceanic areas reaching a maximum in the central Indian Ocean interrupted by low values over land areas. The equatorial minimum reflects the comparatively high cloudiness of that region. The marked contrast in the precipitation-evaporation relationship between land and ocean surfaces is brought out in Figure E19. Over the land areas, where evaporation relies largely on local precipitation, the patterns of the two quantities are in good agreement, in strong distinction to the precipitation minima and evaporation maxima over the oceans in the trade wind belts. Table E9 presents final estimates of average annual

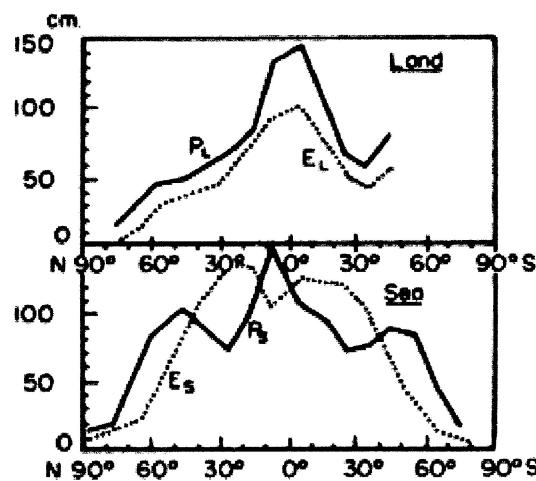

Figure E19 Mean annual precipitation (P) and evaporation (E) for land and ocean surfaces (cm).

Table E9 Average annual rates of evaporation for oceans and continents (cm year $^{-1}$) (after Budyko, 1956)

EVAPOTRANSPIRATION

Moisture is returned directly to the atmosphere through a number of processes. The change in state from solid or liquid form to gaseous water vapor comprises the process of evaporation and sublimation. Evaporation occurs when input of energy onto an evaporating surface causes water molecules to pass from that surface to the atmosphere; this will occur when the vapor pressure of the air is below its saturation value. The rate of evaporation is governed by the state of a number of variables including water vapor, temperature and air motion, and several formulae are available to determine the rate at which it occurs. Perhaps the oldest of these is the Dalton equation, given as

$$E_0 = (e_s - e)f(u)$$

where e_s is the vapor pressure of the evaporating surface, e is the vapor pressure at some height above that surface, and $f(u)$ is a function of the horizontal wind speed. Since these parameters vary widely over the Earth's surface, the rates of evaporation vary enormously.

Transpiration

Just as moisture is returned to the atmosphere through evaporation, it is also returned by the process of transpiration. Transpiration is the term applied to the loss of moisture by plants, such losses occurring through stomata on the exposed leaf surface, with the rate of loss of water being controlled by guard cells on the leaf. During the day these are usually open to expose the moist leaf interior, with resulting high transpiration; at night they are generally closed. Some question exists concerning the role of transpiration in plant growth and development, but it is generally agreed that transpiration rates control the movement of moisture through plants, and this is obviously related to the transport of materials through the plant. The relative amounts of moisture lost through evaporation and transpiration obviously vary appreciably, depending on the nature of the ground surface. But, as shown in Table E10, transpiration rates are often significantly higher than evaporation rates over densely vegetated areas.

While the study of both evaporation and transpiration is significant in itself, it is convenient to treat them as a single process in applied climatic studies. The loss of water through the combined process is termed evapotranspiration.

Evapotranspiration measurement

The rate at which evapotranspiration occurs depends on both meteorological and botanical characteristics, but it can be

Table E10 Evaporation and transpiration losses for selected forest types

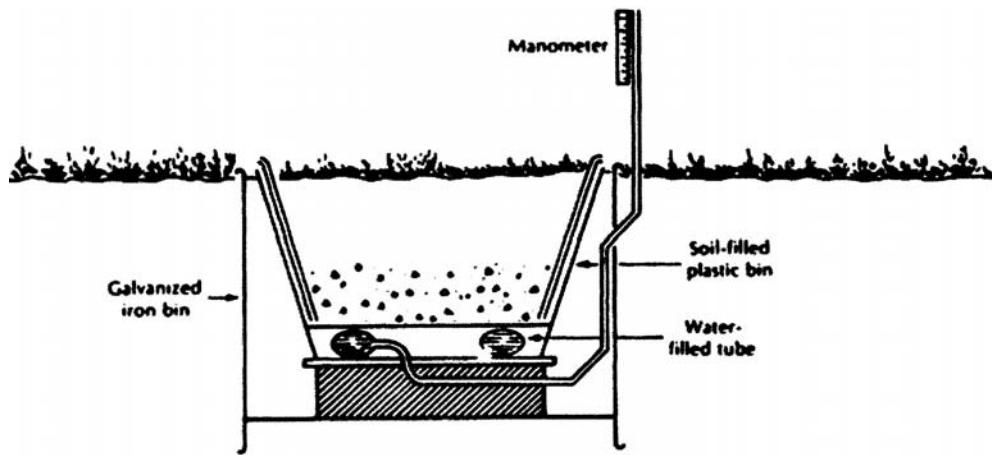

Figure E20 Section through a simple weighing lysimeter.

assumed that, under a given set of conditions, an upper limit will exist. Clearly, to satisfy this maximum rate there must be sufficient moisture available. If moisture is in limited supply the loss of water will be lower than the maximum rate. It is therefore necessary to recognize two evapotranspiration rates. Potential evapotranspiration is the maximum amount of water lost, assuming all moisture requirements can be met; actual evapotranspiration is the observed amount that, if moisture is limited, will be lower than the potential rate.

Problems exist in determining both the evaporation rate and the transpiration rate. It follows then that the estimation of evapotranspiration rates is equally problematic. In measuring the potential rate, water can be added at known quantities and its disposal can be determined more readily. A number of instruments have been designed to measure both rates. The evapotranspirometer, since it is measuring potential evapotranspiration, gives fairly reliable results. It consists of a number of tanks that are filled with a soil of similar constituency to that of the surrounding area and covered by a continuous vegetation cover. Since all of the moisture entering the system is accounted for by evapotranspiration or by percolation into the collecting jars, then the moisture consumed by evapotranspiration can be calculated. The measurement of the actual rate is open to larger experimental error. An example of the type of instrument used, in this case the floating lysimeter, is shown in Figure E20.

The emplacement, location and operation of lysimeters require great care and expenditure. Clearly, they must be large enough to provide a representative sample of a given area and deep enough so that they do not significantly alter the natural profile of soil moisture. Such instruments are rarely found outside of experimental stations and thus provide standards and supplements to evapotranspiration rates derived using other methods.

With the lack of observed data, investigators have turned to other methods of estimating evapotranspiration losses. Essentially, these concern analysis of the variables that influence moisture losses: derived formulae include such factors as solar radiation, temperature, plant cover, and wind speed. Three approaches are available: the empiric in which derived equations are based on observation, the aerodynamic where the physics of

the atmospheric processes responsible for evapotranspiration are evaluated, and the energy budget approach, which estimates the amount of energy available to cause moisture transfer back to the air. Numerous formulas have been derived using each approach. Empirical methods are represented by the work of Thornthwaite (1948), Blaney and Criddle (1950) and Makkink (1957). The aerodynamic approach is illustrated by the method of Thornthwaite and Holzman (1942), whereas the energy budget approach has been investigated by Bowen (1926), Budyko (1956) and Penman (1963). In a call for standardization, the FAO suggest use of the Penman-Monteith method.

Estimating methods

Penman's method uses the combined influences of turbulent transfer and the energy budget. His derived equation for the determination of evapotranspiration uses vapor pressure, net radiation and the drying power of air at a given temperature. To derive this formula, Penman had first to obtain an expression that allowed determination of both net radiation and the drying power of air. Such a formula is necessarily quite complex, as is the expression for the evaluation of the drying power of air. The formula was derived through research in the UK, but results obtained from its use appear to hold true for many other parts of the world. As shown in Table E11, it appears to provide fairly reliable results for the Australian region in which it was tested. Investigators looking into the agricultural potential of most regions would do well to consider the Penman approach in estimating moisture requirements.

Thornthwaite's method is probably the best known and most widely used for estimating potential evapotranspiration in the United States. Working in the eastern part of the country, Thornthwaite devised a formula that essentially is based on the availability of temperature data. His method uses mean monthly temperature and an empiric heat index, which is itself an exponential function of temperature, as inputs. The derived unadjusted potential evapotranspiration is corrected by using actual daylight hours and number of days in the month in question.

While the method is widely used, it has been criticized. Perhaps the fault most often cited is the fact that temperature,

^a ET_g based upon observed values of seven lysimeters.^b A simple empiric statement, where T is mean monthly temperature, which appears to provide a reasonably good estimate.

which is the major variable used in the system, is not the best indicator of evapotranspiration rates; radiation values probably provide a more precise guide. Chang (1959) gives a number of examples where, because of the time lag between incoming radiation and temperature maxima, the Thorntwaite method gives imprecise results. Furthermore, since the formula was based on lysimeter data observed in watersheds in the eastern United States, the method does not always give good results elsewhere in the world. Criticism is also made of the fact that Thorntwaite assumes that evapotranspiration ceases at temperatures below 0°C.

Despite such criticism, there is little doubt that the Thorntwaite method is a useful and valuable approach, particularly when monthly data are used (shorter-term results are more questionable). Its value is enhanced since the only data required to estimate evapotranspiration are temperatures, and these variables are readily available for many stations throughout the world. The numerous publications by the Thorntwaite Associates (in 1950 and following years) are also an asset to its application.

Other estimates, in which actual plant types are considered, are also available. The method proposed by Blaney and Ciddle (1950) uses the equation

$$U = KF = kf$$

where U = the consumptive use (evapotranspiration) in inches, F = the sum of the monthly consumptive use factors (the sum of f , the product of mean monthly temperature and monthly percentage of daytime hours) and K = the empiric coefficient for the plant in question (k being the monthly coefficient). Estimates of the plant coefficient (K) are derived from observed data for crops in arid and semiarid regions. Typical values are alfalfa 0.85, corn 0.80, citrus trees 0.06 and rice 1.20. When used in humid regions the coefficient values need to be decreased by 10%.

Papadakis (1966) has used evapotranspiration under different climatic regimes to formulate a climate classification based on agricultural potential. Although the classification he

proposes is somewhat complex, it contains much that is interesting regarding climate and water needs. For example, in evaluating evapotranspiration he uses saturation vapor pressure corresponding to monthly temperatures. This is given by

$$E = 0.5625(e_{ma} - e_d)$$

where E is the monthly potential evapotranspiration in centimeters, e_{ma} is the saturation vapor pressure corresponding to the average daily maximum temperature, and e_d is vapor pressure corresponding to the mean monthly temperature. In tests of various estimates of potential evapotranspiration the Papadakis formula appears to hold up well.

Calls for standardization

Given the high variability in results derived from the calculation methods, there have been calls for selection of a single approach. In particular the FAO suggested that the Penman-Monteith method be used as a standard for derivation of evapotranspiration from meteorological data.

The Penman-Monteith equation is:

$$\lambda ET = \frac{\Delta(R_n - G) + \rho_a c_p \frac{(e_s - e_a)}{r_a}}{\Delta + \gamma \left(1 + \frac{r_s}{r_a} \right)}$$

where:

R_n is the net radiation,

G is the soil heat flux,

$(e_s - e_a)$ represents the vapor pressure deficit of the air,

ρ_a is the mean air density at constant pressure,

c_p is the specific heat of the air,

Δ represents the slope of the saturation vapor pressure-temperature relationship,

γ is the psychrometric constant, and

r_s and r_a are the (bulk) surface and aerodynamic resistances.

A full explanation of the equation and methods of calculation are provided by Allen et al. (1998).

EXTRATROPICAL CYCLONES

Extratropical cyclones are among the largest disturbances of atmospheric circulation found on Earth. These giant low-pressure systems of the middle latitudes typically span the entire depth of the troposphere vertically, frequently involve lower stratospheric air, and extend 1000–3000 km in horizontal diameter. Central pressure values within extratropical cyclones vary markedly and are typically less than those for smaller

cyclonic systems, ranging between 990 and 1000 mb, achieving much lower values in intense systems. Like all organized low-pressure systems, extratropical cyclones rotate in sympathy with the Earth's spin in the hemisphere of occurrence. This cyclonic motion, forced by the interaction of pressure gradient force, centripetal acceleration and Coriolis effect, is disrupted near the Earth's surface by friction, inducing low-level convergence. Thus, midlatitude cyclonic storms are marked by large values of absolute and relative vorticity.

The circulation of air within midlatitude cyclones induces a complex pattern of rising and sinking motion and generates atmospheric discontinuities in temperature, moisture and wind shear, known as fronts. The geometry and evolution of circulation and fronts exert a powerful influence on the temperature, precipitation and severe weather climatology of a region. Cyclone behavior is therefore of keen interest to forecasters, as it forms a central component of weather and climate in the midlatitudes.

In addition to influencing the weather elements of the regions where they occur, extratropical cyclones play a key role in the global energy balance. Essentially eddies within the westerly circulation of the midlatitudes, cyclones serve to deplete energy imbalances that exist in the vicinity of the baroclinic zones of the so-called polar front, where regional temperature variations can be quite large, particularly in the cold season of a hemisphere (Palmén, 1949a, 1951a,b). Cyclones move heat and momentum along “storm tracks”, modifying the large-scale flow in which they are imbedded (Holopainen, 1984).

Although models describing the dynamics of midlatitude cyclones have existed for well over a century, meteorologists' understanding of cyclone dynamics did not experience major growth until the second half of the twentieth century. Since the late 1940s the increased availability and sophistication of upper-air observations has revealed the three-dimensional structure of cyclones, particularly the apparent feedbacks that occur between upper and low tropospheric circulation during development. More recently, exponential growth in the ability of computers to process vast quantities of data continues to improve the ability to simulate and investigate cyclone behavior.

Cyclogenesis

Midlatitude cyclones form initially where the westerlies are perturbed and a pre-existing upper tropospheric disturbance, a short wave or isotach maximum, is amplified, often by interaction with a low-level baroclinic zone. Consequently, the initial development of a surface low-pressure feature, termed cyclogenesis, tends to occur east (downwind) of major mountain ranges, over warm water and along semipermanent frontal zones. Cyclones have been classified according to their key mode of development, i.e. orographic, surface front or upper level disturbance; however, most cyclones couple two or more of these mechanisms during their development (Pettersen and Smeybe, 1971).

Orographic cyclogenesis

Orographic, or lee cyclogenesis, as discussed by Buzzi and Tibaldi (1978), Newton (1956) and others, is a mechanism whereby the existing potential and absolute vorticity of a westerly current are modified by passage over a topographic barrier. A zonal current that flows normal to a north–south-oriented

mountain range undergoes diminished relative vorticity as air parcels diverge over the region of elevated topography. In the mountain lee, where tropospheric thickness increases, relative vorticity rises via convergence. In addition, because westerly flow is diverted equatorward by its initial vorticity decrease, it must gain additional relative vorticity in the mountain lee to conserve absolute vorticity (Rossby, 1940; Ertel, 1942). This requisite increase in relative vorticity amplifies the short wave in the westerlies, generating a likely parent trough for a surface cyclone.

Occasionally, an existing cyclonic circulation is masked by divergence as it crosses a mountain range, only to reappear in the lee equatorward of its initial latitude. The portion of the cyclonic circulation equatorward of the storm center descends the mountain range in the direction of flow, undergoing the vorticity adjustments described above and intensification. Easterly airstreams poleward of the storm center ascend the mountain range and become anticyclonic as their relative vorticity is reduced. The new position of the lee cyclone is no longer in synchrony with the old low center, but now coincides with that equatorward portion of the original circulation that was cyclonically enhanced by its passage over the mountain barrier. In North America, cyclonic parent systems enter the Rocky Mountain complex from the northwestern United States, only to form a lee cyclone in the southern Great Plains.

Frontal cyclones and upper level development

Cyclones also form and strengthen as a result of rising air and the destabilization of geopotential height surface inherent in baroclinic zones. Airflow across a strong surface front, such as that found in midlatitude east coast regions during winter, induces powerful geopotential height changes and vertical motions that produce or amplify a disturbance in the troposphere. Amplification of the wave disturbance increases kinetic energy and rotation in the upper atmosphere and activates an unstable cascade of positive physical feedbacks that enable a cyclone to grow.

The interaction between an upper tropospheric short wave and a surface cyclone can be described in terms of the advection of temperature and vorticity. A parent trough, by definition, is a local anomaly of reduced geopotential height and elevated relative vorticity. As air flows through a geopotential trough, it experiences a relative vorticity increase as it approaches the trough axis, followed by a relative vorticity decrease as it moves downstream. Thus, upwind of the trough axis, in a zone of negative vorticity advection, air parcels undergo convergence in the upper troposphere, while downstream, in the zone of positive vorticity advection, air parcels diverge as they exit the trough (Figure E21). According to the principle of continuity, divergent horizontal motion in the upper troposphere (above the level of non-divergence) is accompanied by ascent, which reduces pressure and forces convergence at the surface below – cyclogenesis (Palmén and Holopainen, 1962). Once a low-pressure feature has developed, the surface pressure gradient produces a low-level circulation that advects cold and warm air across the initially stationary temperature gradient.

Quasigeostrophic theory defines two key elements of cyclone intensification, geopotential height falls and upward vertical velocity, in terms of differential vorticity and temperature advection with height. Geopotential height falls, which define the amplification of upper tropospheric disturbances, occur in zones of decreasing cold air advection with height and positive

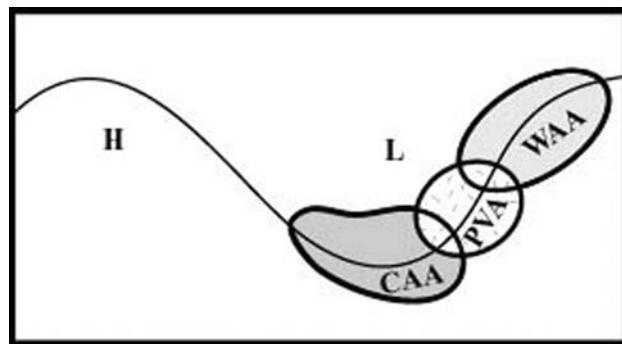

Figure E21 Idealized vorticity and temperature advection patterns in relation to an upper-level baroclinic wave.

vorticity advection. The primary location for upper-level development is downstream of the trough axis, in the regions overlying and behind the surface cold front. In cases of rapid, or explosive, cyclogenesis, upper-level intensification is enhanced by intrusions of stratospheric air and warm air advection aloft (Uccellini et al., 1985).

Rising air defines the location and strength of the surface low by forcing low-level pressure falls, thereby enhancing the pressure gradient and wind speed. Such upward motion is preferred in locations where increasing positive vorticity advection aloft and warm air advection coincide (Bjerknes and Holmboe, 1944; Hoskins et al., 1978; Sutcliffe, 1947; Trenberth, 1978). Because the optimum dynamics for rising air occur downstream of the upper tropospheric geopotential height minimum, midlatitude systems tilt westward with height. This tilted configuration is distinct from other types of low-pressure system, including cold core lows that strengthen with height (e.g. polar lows) and warm core lows that weaken with height (e.g. tropical cyclones).

The mutual enhancement of upper and lower tropospheric pressure features through the advectives described above is essential to the process known as baroclinic instability (Charney, 1947; Eady, 1949). Motions that increase surface pressure falls and upper tropospheric geopotential height falls also serve to strengthen existing horizontal temperature gradients, enhancing baroclinicity (Eliassen, 1966; Sawyer, 1949). A more baroclinic environment is conducive to strong upper-level winds, increased advection and more powerful vertical motion.

As a cyclone strengthens and moves, its low-level convergent circulation entrains moisture, which is then lifted across a broad expanse of the storm's interior. Massive condensation and latent heat release result, further destabilizing the atmosphere and contributing to ongoing vertical motion. Through vertical motion, which strengthens the surface pressure gradient and drives low-level advection, moisture entrainment becomes an additional component of the positive feedback system. The cyclone's intensification can theoretically proceed until its low-level temperature gradient is eliminated or no longer effectively oriented to the advecting flow, a phase known broadly as occlusion.

Cyclone structure, weather and climate

The classical cyclone model of the Norwegian school describes the evolution of surface pressure and fronts in a developing low,

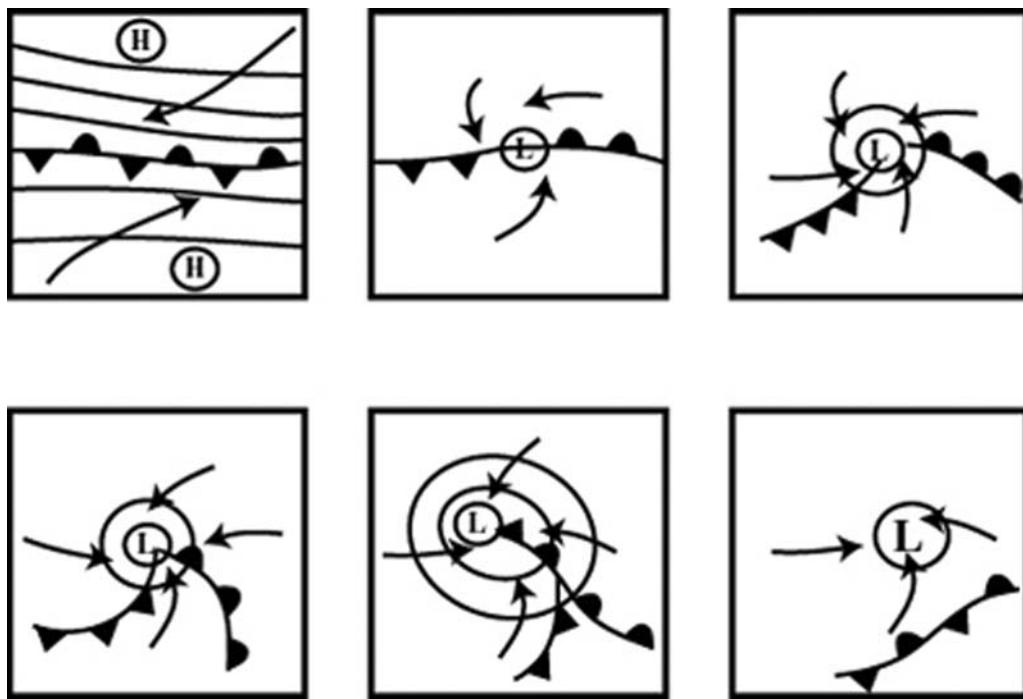

Figure E22 Classical Norwegian cyclone model (after Bjerknes and Solberg, 1922).

based on northern hemisphere observations (Bjerknes and Solberg, 1922). Despite an absence of upper air data during its formulation, this model still captures and generalizes the principal phases of the cyclone life, from cyclogenesis to occlusion.

In the classical model a cyclone originates as a low-pressure disturbance on an existing stationary front. The frontal boundary deforms as cyclonic circulation develops, with active fronts leading the cold air north and west of the low and the warm air equatorward of the low in a cyclonic migration about the center of the low. During the mature phase of the cyclone the surface storm is characterized by regions of markedly different temperature and humidity. Warm air is advected poleward east of the low from within the system's warm sector, where it ascends passively along slantwise trajectories. Cold air sweeps southeastward upstream of the low center, forcing aloft warm air in its path. The high density of the cold air north and west of the low center, coupled with the strong pressure gradient there, enable the cold front to propagate more rapidly than its warm counterpart, a trend that gradually erodes the region of warm air within the storm.

Occlusion, the source of much confusion in the analysis of cyclone evolution, is seen in surface analysis as the general separation of the cyclone center from its cold and warm fronts (Wallace and Hobbs, 1977). In an idealized model of occlusion, polar air behind the cold front appears to overtake the warm front, eliminating or reducing the horizontal temperature gradient that was initially present at the surface (Bergeron, 1937). An alternative form of occlusion, known as instant occlusion, arises when a comma-shaped cloud in cold air poleward and upstream of a polar front overtakes and merges with the front and its attendant cloud-field. The process of occlusion often

marks a turning point in the cyclone's ability to generate the rising motion and geopotential height falls necessary for survival.

The cloud and precipitation fields within a cyclonic system are complex, but can be explained in terms of the vertical motion of airstreams and their frontal boundaries (Browning and Harrold, 1969; Harrold, 1973). The broad corridor of stratiform cloud cover and imbedded precipitation downstream of the low center may be attributed, in part, to slantwise ascent along and in the advance of the warm front. Similarly, the rapid, assertive motion of the cold front frequently corresponds to sharp linear bands of cumuliform cloud cover and shower-type precipitation. Between the fronts, warm, frequently moist air supports general convective cloud development. Fronts correspond spatially to cloud and precipitation edges and marked transitions in humidity and wind direction.

The basic features of the Norwegian model, the surface low, fronts and their evolution toward occlusion, are adequately described by quasigeostrophic energetics. When the synergy between upper-level jet streaks and surface fronts is coupled to this model, much of the typical cyclone behavior is explained. However, precipitation and cloud features are often more complex than suggested by the dynamics of isobaric models and do not correspond directly with the traditional lifting mechanisms of the polar front model. To describe these characteristics, an alternative approach to cyclone description, known as conveyor belt theory, may be employed.

Because three-dimensional flow in the atmosphere does not follow isobaric surfaces, estimation of vorticity and thermal advection along surfaces of constant pressure can provide only a crude measure of storm evolution. Such estimation is adequate locally, for point determinations of geopotential height

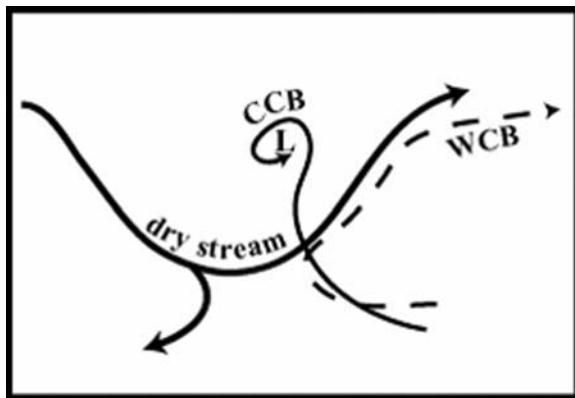

Figure E23 Idealized conveyor belt airflow through a midlatitude cyclone.

change and vertical motion, but is difficult to extrapolate over large areas. Consequently, the quasigeostrophic description of an extratropical cyclone is accurate at each point of assessment, but simplistic in overall scope.

Isentropic analysis provides a more accurate representation of actual airflow and a more intuitive one (Green et al., 1966). Unsaturated air flows along isentropic surfaces (surface of constant potential temperature), which ascend toward cold air and descend in warm regions. Alternatively, the motion of saturated air is well-approximated by the contours of equivalent potential temperature surfaces. When the circulation of a short wave is mapped on representative isentropic surfaces and placed in a relative-motion framework (the translation of the system is subtracted from the environmental winds), several common wind features emerge (Figure E23).

For a northern hemisphere system, two distinct corridors of air dominate cyclone airflow aloft. Arriving from the upper troposphere/lower stratosphere, a dry stream of air flows from north and west of the low, descending, curving cyclonically, and then flowing downstream while ascending. The dry stream closely resembles the position of the shortwave as seen on an isobaric map. However, the isentropic depiction reveals the descent and ascent of this airstream along its path, as well as a significant bifurcation that results south and west of the surface low.

The dry stream interacts with a second airstream, often termed the warm conveyor belt (WCB) or polar front conveyor belt. The WCB approaches the cyclone from the south and east, curves anticyclonically and ascends parallel to the dry stream, in stark contrast to its temperature and humidity properties. Because the dry stream originates in cold, dry environs, its confluence with the warm, moist WCB is a natural frontal boundary, induced by relative motion within the moving system. Examination of a vertical profile of the dry stream–WCB confluence reveals that this upper front tilts forward with height. Thus a front structure exists at many elevations downstream of the traditional model of the surface cold front and located above the warm sector of the cyclone. Advection of cold dry air above the low-level warm sector constitutes generation of static instability. The slantwise ascent of the moist WCB and its western boundary with the dry stream correspond well spatially with portions of the classic “comma cloud” pattern in cyclones, the comma tail and baroclinic leaf features.

Beneath the dry stream and WCB and their confluent boundary flows a third airstream, termed the cold conveyor belt (CCB) by Carlson (1980) and the cyclonic moist airstream by Bierly and Winkler (2001) (they found the airstream to originate in air as warm as, or warmer than, that of the WCB during early phases of the storm life) and polar trough conveyor belt. The CCB, like the WCB, originates in the low troposphere and ascends as it approaches the cold air north and west of the cyclone center. Although contradictory, most analyses of the CCB suggest that it wraps cyclonically around the low center, where it then descends to near the surface (Schultz, 2001). The CCB migrates from a source area near that of the WCB origin shortly after cyclogenesis to a cooler region of origin at high latitude later during the cyclone life span. The CCB delivers moist air beneath the dry airmass domain of the dry stream, elevating the potential instability of the atmosphere near the comma cloud head about the low center.

According to conveyor belt theory, the cloud regions of the familiar comma pattern are explained in terms of relative-wind airstream ascent along isentropic surfaces, confluence between airstreams of different origin and the static and convective instability created by superposition of airstreams of different origin. Temperature, humidity and wind direction aspects of fronts all derive from the airstream confluence model. Finally, upper and low-level fronts are naturally defined through examination of relative wind confluence patterns at multiple levels. Occlusion is seen as the cessation of temperature advection through the onset of airflow parallel to isohypes on surfaces of constant potential temperature.

Cyclone climatology

The geographical distribution of dynamic controls on cyclone development leads to spatial and seasonal patterns in their occurrence. In the northern hemisphere winter, extratropical cyclones develop most frequently over western midlatitude ocean basins and along east coast margins, particularly the eastern Asia–western Pacific Ocean region and the eastern North America–western Atlantic Ocean (Klein, 1957; Pettersen, 1956; Whittaker and Horn, 1982). In both cases, warm ocean currents, the Kuroshio current of the Pacific and the Gulf Stream–North Atlantic Drift of the Atlantic, flow poleward along the cold margin of a large continental landmass. Disturbances moving through these comparable areas amplify from the combined effects of strong baroclinicity and latent heat release over the warm water surface. As thermal contrasts between land and sea diminish toward the warm season, coastal cyclogenesis frequency wanes.

Cyclogenesis in the lee of high elevations in the Coastal Range of British Columbia (Alberta cyclones), southern US Rocky Mountains (Colorado cyclones) and the Alps (Genoa cyclones) is of moderate importance during winter; Rocky Mountains lee cyclones grow in significance during the spring transition of the westerlies. Lee cyclogenesis is less common during the warm season as baroclinicity in the westerlies weakens and contracts poleward, but resumes during fall, particularly Alps–Adriatic cyclogenesis, which peaks in November. The frequency of lee cyclogenesis reflects the passage of short wave disturbances during periods of hemispheric wave number change and proximity of high-elevation disturbance zones to the strongest baroclinicity within the circumpolar vortex of the westerlies.

During the northern hemisphere warm season the origin zones and paths of cyclones move northward with the position of the now-weakened polar front. Storm development during summer is focused in the Hudson–James Bay region and to a lesser extent in the northwest Atlantic Ocean.

Cyclone activity in the southern hemisphere has received considerably less attention than that of the northern hemisphere. Despite fewer and weaker continent–ocean temperature contrasts in the southern hemisphere, cold season cyclogenesis frequency is most pronounced along the Australian east coast and in the lee of the Andes of southern Argentina (Sinclair, 1995). Both locations are characterized by strong SST gradients. In summer, southern hemisphere cyclone activity decreases, with most storm initiation focused east of Argentina and in the Indian Ocean southeast of Madagascar.

FERREL CELL

A Ferrel Cell is a circulation pattern named for William Ferrel (1817–1891), an American meteorologist who discovered the effects of the Earth's motion in wind systems. Although George Hadley had recognized the convective nature of the air in 1735, and M. F. Maury, in 1855, had proposed a good model for the atmospheric circulation, both lacked an appreciation of the nature of the westerlies. Ferrel brought a fundamental knowledge of mechanics and mathematics to the subject (Clayton, 1923) and first sketched the diagram of the planetary surface winds that appears in almost every geography textbook (Figure F1). He pointed out that the total movement of air to the east must balance the total movement to the west or else the Earth's rotation would be accelerated or retarded. His model also included a profile of the upper air winds, which incorporated Hadley Cells (simple convection) north and south of the

equator and at the poles; in the latter a polar anticyclone operated by centrifugal force was postulated. A reversed circulation was shown in the temperate belts (30–60 lat.), thereby recognizing the component of the westerlies.

The warm air of the tropical cell sinks along the high-pressure belts and in parts moves into the northerly setting westerly circulation. This circulation component is now known as the Ferrel Cell. Even though modern models reject the polar anticyclonic cell, the Ferrel and Hadley cells are now fairly well confirmed by observations at all levels. The Ferrel Cell plays a major part in the poleward energy (mainly heat) transport. North of about latitude 38°N in the northern hemisphere the precipitation exceeds evaporation, so that water vapor (representing latent heat) must be transported northward. Beyond this contribution, in an 1856 paper Ferrel also helped expand the convection cell interpretation of vertical motion in the oceans, proposed by A. von Humboldt in 1814, and later developed by M. F. Maury.

Ferrel's Law concerns the principle that relates the deflection of winds by the Earth's rotation, now generally known as the Coriolis Effect. Ferrel stated the law "If a body moves in any direction upon the earth's surface, there is a deflecting force arising from the earth's rotation, which deflects it to the right in the northern hemisphere, but to the left in the southern hemisphere" (Ferrel, 1856).

FLOHN, HERMANN (1912–1997)

Hermann Flohn was born on 19 February 1912 in Frankfurt, Germany. Considered by many as one of the world's greatest climatologists, he began his lifelong learning in medical meteorology and bioclimatology when studying the weather-related spread of influenza in Germany. Pursuing an academic career, at the age of 28 he worked at the regional meteorological offices in Leipzig and Hamburg. Later he was the climatologist at Potsdam for the German air force. This career guided him into the understanding of the climate of the Earth and an interest in synoptic climatology.

Under the Nazi regime in 1941 he was charged to investigate the upper-air flow of three routes over Asia (Siberia, India, and Burma) to Japan, which led to several publications after the Second World War concerning the atmospheric character over Siberia ("Zum Klima der freien Atmosphäre über Sibirien. I. Temperatur und Luftdruck in der Troposphäre über Jakutsk", *Meteorologische Zeitschrift*, 1944), India's monsoons ("Witterungs-Singularitäten im Monsunklima Indiens", *Annals of Hydrography and Marine Meteorology*, 1943), and the equatorial westerlies over the Indian Ocean ("Studies on trade-wind circulation and equatorial westerlies", in *Procès-Verbaux des Séances de l'Association de Météorologie. Union Géodesique et Géophysique Internationale*. IV. Assemblée Générale, August 1951).

Following his release as a German prisoner in 1946, he became involved in establishing a new German weather service, of which he became Head of Research. In 1961 he became the Founding Director and then head of the department at the Institute of Meteorology of Bonn University. He retired as Professor Emeritus in 1977. During this period he was inspired by the birth of his first grandchild and began focusing his research on climate change. The result of his former research interest in medical meteorology and climate change culminated into: "How does human activity influence the climate?" Flohn's enthusiasm for his new avenue of research resulted in his participation in the first international meeting on climate modification in 1971 and contributed to several conferences on the subject: the First World Climate Conference (1979), the Second World Climate Conference (1990), and he held the position of advisor on the Enquête Commission of the German parliament, *Protecting the Earth's Atmosphere*. His concentration on climate modification produced about 360 publications and membership in numerous scientific societies such as the Bavarian Academy, the Leopoldina in Saxonia, and the Royal Belgium Academy.

FOG AND MIST

Fog

Fog is a stratus cloud that lies on, or very close to, the surface of the Earth. The horizontal visibility in fog is reduced to less than one kilometer, according to international definition. Fog is an aggregate of very small water droplets in a size range of 10–50 microns, typically in concentrations of 10–100 per cc. The air in fog usually feels wet because the humidity is very high, often but not necessarily above 95%, and the observer is experiencing contact with many small droplets.

The atmosphere always contains an adequate number of condensation nuclei, though in certain circumstances there will be differing mixes of types of nuclei, e.g. along an ocean shoreline there will be a greater than normal number of salt nuclei, which are highly water-loving, or hygroscopic. The haziness of beaches with breaking surf is accounted for by the fact that salt particles start to take on water at relative humidities as low as 60–70%.

A critical relative humidity beyond which condensation will be initiated, and fog form, can be achieved in four ways: (1) addition of water vapor to the volume of space in question; (2) cooling of the volume by contact with a colder surface; (3) cooling by infrared radiation from the volume itself; (4) expansional cooling due to ascent of the airmass. Of these four ways, the first two are of major importance in the formation of fog.

Fogs may be broadly classified as those that form within airmasses and those that form at the boundaries between different airmasses, i.e., in conjunction with fronts. In outline form:

- I Airmass fogs
 - A Advection types
 - 1. Transport of warm air over a cold surface
 - (a) Land and sea breeze fog
 - (b) Sea fog
 - 2. Transport of cold air over a warmer, wet surface
 - (a) Steam fog
 - (b) Arctic "sea smoke"
 - B Radiation types
 - 1. Ground fog (ice fog if particles are ice crystals)
 - 2. High inversion fog
 - C Expansional cooling for (upslope fog)
 - D Combinations of A, B, and C
- II Frontal fogs
 - A Prefrontal warm front fog
 - B Frontal passage fog

Advection implies primarily horizontal transport, though vertical transport may be significantly present in certain circumstances. When relatively warm air is carried over a

cooler surface its temperature is lowered by contact cooling (conduction) and the relative humidity rises. After the critical value is exceeded, condensation on the cloud condensation nuclei (CCN) begins and fog forms. The cooling of the surface layers is carried to higher layers by turbulent mixing, which results from wind drag over the surface. If the air becomes slightly unstable because of this mixing the fog may have a low ceiling, as is common with the California coastal stratus.

When cold, dry air moves over a warmer, wet surface, rapid evaporation takes place and saturates the colder air. The resultant condensation is the steam fog (steam smoke) seen in the Arctic Ocean areas.

Radiation fog results from a different set of conditions. If skies are clear and the air is relatively still, nocturnal cooling of the ground by escaping terrestrial radiation chills the surface layers of air. Fog forms at ground level when the air temperature is lowered to the dewpoint. Slight turbulent mixing increases the depth of cooling and the thickness of the fog. Ground fog tends to form in the late night or early morning hours; it then "burns off" in the later morning hours when solar shortwave radiation penetrates the shallow cloud, warms the ground, lowers the relative humidity, and causes the water droplets to evaporate.

Upslope fog forms when a stable airmass moves slowly up over higher terrain, cools by expansion, and finds its temperature lowered to the dewpoint. This fog is characteristic of the Western Plains states in the United States.

Frontal fogs form primarily when additional water vapor from evaporating precipitation elevates the dewpoint temperature, and evaporative cooling lowers the temperature of the air. Such fogs are most characteristic of warm fronts.

Mist

According to international definition, mist consists of an aggregate of microscopic sized droplets (~10 microns) producing a thin, grayish veil over the landscape, reducing visibility to a lesser extent than fog. Mist is intermediate in all respects between damp haze and fog. However, in the United States the term *mist* has come to have a popular usage of a hydrometer that is intermediate between fog and drizzle. *Oregon mist* or *Scotch mist* are terms used to describe the occurrences of very light, "misty" precipitation. Mist particles range in size from 50 to 500 microns, the latter large enough to fall from the cloud.

Trees and other objects such as grasses collect moisture from drifting heavy fog or mist, as sometimes occur in the Redwood Forests in Northern California. Fog-drip can collect as much as 0.05 inch of water in a single night – the equivalent of a light shower. This phenomenon prevents excessive aridity in the coastal forests during the rainless California summers.

FOLKLORE, MYTHS AND CLIMATE

Why do humans feel the need to personify or deify the weather? Many academics have attempted to address that need through analysis of the human psyche, ranging from the landmark psychological works of Sigmund Freud and Carl Jung to the anthropological analyses of J.G. Frazer and Joseph Campbell. Some works have linked these myths and legends to deep-seated sexual or cultural motivations in our societies. Others have attempted to associate the diverse mythologies to a basic human trait to create explanations for our surroundings. Yet, despite spirited debate, all can agree that weather is a prevalent aspect of all myths and folklore of the world's myriad societies.

In order to explain the various atmospheric phenomena that early societies and civilizations experienced and suffered, these cultures often depicted higher-order beings, such as gods and other supernatural beings, who were given the various attributes of weather. For the Caribbean islands the god Hurican was the supernatural personification of the oft-deadly tropical cyclones that strike the area – and, indeed, his name has become the term used to refer to the deadliest of these tropical storms in the Atlantic Ocean, the hurricane. In ancient Europe, Jupiter (in Roman myth) or Zeus (in Greek myth) was a god who is often depicted as a god of weather whose weapon of choice was a lightning bolt. For example, in Homer's masterpieces, the *Iliad* and the *Odyssey*, lightning strikes of humans or their structures were considered as vehicles for Zeus's divine justice.

Because weather was the property of the gods, generally imitation of weather was the height of sacrilege. As Virgil recounted, Salmoneus, king of Elis, discovered the consequences of such "hubris" first hand. Salmoneus desired to be worshipped as a god by his people and to this end he rode his chariot over a bronze bridge to show how he could make thunder, while he hurled torches hurled on either side of his chariot to demonstrate that he could produce lightning as well. The allmighty Zeus was not amused and decided to throw the real thing down at Salmoneus. The pretender to divinity subsequently was burnt to a crisp and sentenced to Hades for his blasphemy.

Priests of many early cultures attempted to divine the future and the favor of the gods based on atmospheric signs and portents. In Rome, for example, divination was in the hands of the College of Augurs. Lightning was one of the greatest of the potents for which the augurs scanned the skies. Of great interest to the augurs was the specific direction that lightning took as it crossed the sky. If the flash progressed from left to right, the gods favored the current state of affairs in Rome. If, however, it passed from right to left, the augur was duty-bound to proclaim that the gods did not favor the current actions in the Roman government.

Yet, surprisingly, many of these myths and legends are rooted in accurate observations. Ancient civilizations consistently displayed a strong interest in observing the weather. For example, Homer's epic poem, the *Odyssey*, consistently shows a credible set of weather observations that indicates the tragedies experienced by the ancient Greeks may have been caused by a cyclonic storm crossing the area in the early summer. It is amazing that, given the narrative restrictions of the media imposed on Homer, the *Odyssey* contains vivid and apparently accurate descriptions of weather. Indeed, it may be possible to interpret an episode near the saga's end in the light of an only recently defined meteorological phenomenon, a microburst, a thunderstorm's small-scale blast of air (up to 100 miles per hour) that strikes the ground and spreads out:

"That said, he [Poseidon] massed the clouds, and, as he gripped his trident, whipped the surge and urged all winds to blow at will... Eurus [the East Wind], Notus [the South Wind], and voracious Zephyr [the West Wind] and Boreas [the North Wind], who's born in the bright ether, attacked together" (V, 293-5). . . . The force of all winds crushes me (V, 304).

Similarly, research in the area of the Black Sea by Walter Pitman and William Ryan of Lamont-Doherty Laboratory indicates that the Great Flood chronicled in the Bible as "Noah's Flood", and which many people thought mythical, may actually have occurred as a result of climate change producing an inundation of the Black Sea from the Mediterranean.

As Joseph Campbell has noted, myths often change as civilizations change. With the eventual prominence of monotheism, medieval societies often depicted the elements of weather as aspects of fundamental evil or divine displeasure. For example, by the 1500s the practice of ringing church bells had become established as a means of dispersing lightning. As a result, many medieval bells still bear the inscription "Fulgura Frango" (I break up the lightning). Of course, ringing metal bells posed a certain danger to the bell-ringer. A medieval scholar wrote an interesting treatise on the subject entitled "A proof that the ringing of bells during thunderstorms may be more dangerous than useful", in which he stated that, in 33 years, lightning had struck 386 church towers and killed 103 bell-ringers. Conversely, in the year 1360, when his army was battered by an incredible hailstorm that killed 1000 soldiers and 6000 horses, English King Edward III, sensing apparent divine displeasure with his army, turned to the Cathedral of Chartres and "vowed to the Virgin that he would conclude a treaty".

Even after the industrial revolution, weather myths persisted. By the mid-nineteenth century the weather gods and goddesses of early cultures, for example, had morphed into the heroic superman myths of the American West – the Great Lakes' Paul Bunyan, Texas's Pecos Bill or the more obscure Febold Feboldson of Nebraska. These characters tangled with, and normally tamed, the violent weather of the Great Plains and Midwest in a manner reflective of the tough character of the people of that time and place. When Pecos Bill needed a stronger beast than a wild horse to break, he saddled up a tornado and rode it into submission. It was so cold in Paul Bunyan's logging camp one bitter winter that people's words froze and they had to be stored until the spring thaw to hear what had been said. Febold Feboldson once had to hire English fog-cutters to come and cut a Nebraska fog, which he then laid in strips along the dirt roads where it continues to drip out even today, especially in spring. These stories served to re-enforce and strengthen the "can-do" spirit of pioneers of the west.

Do weather-related myths still exist today? Many people would immediately answer no, citing that today's civilization is too scientific to still cling to old-fashioned weather myths and folklore. Yet many modern people still believe that washing their cars will somehow lead to the appearance of a thunderstorm or that a groundhog's shadow in Pennsylvania on February 2 in some way forecasts the coming of spring. And elements of weather, such as the still-elusive "ball lightning", are still linked in popular society to supernatural causes, such as extraterrestrial aliens and "UFOs".

As our human history has shown, because of their unique personal impact on every individual of the planet, weather and climate continue to hold a fascination. That enthralment has led to their prominent positions in our myths, folklore and legends, and helped to form the basic foundations and cultures of our societies.

 Literature and Climate

FROST

Frost may be considered as (1) a form of mineral; (2) a climatic condition; and (3) an economic situation. Each of these is dealt with sequentially.

Frost as a mineral

Frost is a solid phase of water. As a mineral it crystallizes according to the hexagonal system featuring six-sided plates, needles, clusters, and columns. The crystals are subject to innumerable variations of twinning and dendritic or arborescent growth. None of the variations is unusual in the mineral world, but the melting point of water limits observations, whereas similar crystallization can be found in commonly seen metallic and non-metallic minerals. The complex crystals are the object of a variety of platialdinal visual imitations in the forms of snow crystals drawn by artists and in reality as seen by frost on the windows.

Climatology of frost

From the climatologists' point of view, the frost of specific interest is *hoar frost* or white frost that accumulates on surfaces in places with appropriate temperatures. The white color is a

product of small air bubbles in the ice, cutting down on the transparency of the ice crystal, the reaction of poor sky light and the lack of sunshine. At the critical temperature at which frost forms, sunshine would prove disastrous in a very short time. The "hoar" implies a gray or grayish tone often seen on objects covered with frost. Hoar frost or the veneer of ice crystals is indicative of three conditions:

1. Surfaces on which the frost forms must be 0°C or below.
2. The surrounding air is saturated at 0°C or slightly below.
3. Nuclei are present so that the process of sublimation can take place.

Each of these three conditions is part of the natural environment from time to time.

Surfaces suitable for the accumulation of frost are cooled by outward radiation and advection, so that the ambient temperature of 0°C or less is reached. The temperature of the atmosphere has already been reduced to the near-freezing condition by normal processes. The loss of heat to or below the freezing level by the atmosphere and surface objects in dry air and without reaching saturation creates a frost known as *black frost*. Vegetation, when exposed to freezing conditions, upon thawing will turn dark or black. The water that is part of the cell structure of the plant solidifies, cell walls burst, and the plant materials deteriorate.

Saturated air at the appropriate temperature begins to give up its moisture. If this is in the range above 0°C, the product is dew and, should the temperature drop, the dew particles solidify to coat the object with a veneer of ice, which is amorphous. Thus the saturation-level temperature is most critical in the formation of frost.
