Nuclei are as essential for crystal formation as they are for dew, raindrop, or cloud formation. The surfaces on which frost accumulates depend on the presence of these nuclei. Nuclei can be dust particles, irregularities in the configuration of leaves, plant hairs, or a host of other features. It is difficult to conceive of a situation where an adequate number of nuclei would not be present.

Although the literature is sprinkled with terms related to frost such as frost-wedging, ice-wedging, frost-buckling, and others implying solid ice, under scrutiny many of these terms are not frost at all but gelification of water as a liquid. Innumerable citations imply that ice formed by sublimation in pore space and microcellular space in rocks, soils, and other material should be classified as frost. Again it is probably interstitial and interfacial water that has crystallized or solidified. There is no recognition in the literature that water vapor is found free in cellular or pore space of such consequence that sublimation could occur to form frost to the extent of creating expansion of material and the destruction of, for example, plant cells.

Frost as a hazard

Protoplasm in plants functions at varying temperatures for each plant within restricted ranges. Frost, as defined here, implies near 0°C temperatures, but some plants cease protoplasm functioning at temperatures higher or lower than 0°C. Thus a plant may suffer "chilling" injury but not as a result of frost or freezing.

It is conceivable in certain types of cavities and caverns that frost accumulates over a period of time and a repetition of the conditions may permit consolidation of this frost into ice masses. The condition is simulated in large cold-storage or deep-freeze rooms. Thus, large and small cavities opened to the

atmosphere and near the surface experience frost activities. The results are such phenomena as ice-filled sink holes or ice caves.

Whatever the process of formation or product, frost is a symptom of a climatic situation in which temperatures have been reduced through radiation or advection to the freezing stage. Thus frost, particularly hoar frost, is a symptom of or forerunner to plant or crop loss.

Because frost can freeze plant tissue, which marks the end of growth for the plant, it is significant that this can occur at either end of the growing season. Since destruction is involved, it is evident that frost is a natural hazard along with other climatic hazards such as excessive precipitation, tornadoes, hail, etc. Most citations to frost overlook this hazard factor, perhaps because it is not as spectacular or forceful as high winds, high water, large hailstones, or heavy snowfalls. The agriculturist could well proclaim the facts by playing the game and trying to produce a crop that fits in between the last killing frost of the growing season in spring and the first killing frost at the end of the growing season in fall. In doing so, the farmer recognizes frost as a hazard.

The accumulated experiences of frost as a hazard leads to a considerable discussion in many climatology texts of techniques for frost or freeze prevention. These are generally beyond what the botanist and geneticist have already done to produce plants that mature in shorter periods of time, or by the climatologist who has defined the perimeters of frost incidence for any particular area. Indeed the greatest incidence of activity in frost prevention is in the marginal or fringe areas where, for reasons of possible economic gain, the farmer or orchardist is willing to take a chance on planting in the hope of being able to produce a crop.

Frost damage prevention techniques can be classified into several groups by procedures and practices:

1. Identification of the critical and perhaps typical physical site of low or high frost incidence in a general region. These can be defined as wind shelters, topographic favorable regions, or shore position, etc.
2. Development of physical equipment such as fans, heaters, brushes, sprinklers, and plant shields to modify temperatures or reduce radiation.

Whatever method or combination of methods is chosen to prevent destruction by frost, the choice is usually to modify temperatures a few degrees, usually not more than four or five. The techniques involve reducing radiation, improving wind circulation, discouraging sublimation, or creating a fog or smoke cover. The physical modification of the environment in the immediate situation of a frost or freeze hazard does not represent all that can be done.

Long before agriculture is considered for a particular area or crop, a climatic record or history would reveal the probabilities of frost or freeze incidence and the chance of success if the correct plans and methods are used. Additional terrain analysis helps to identify local microclimatic conditions in basins, alluvial fans, slopes, plains, or other topographic conditions. Peri-shore or valley sites could and should be evaluated.

In the competition for the early harvest-high price crop, farmers for many years have tried to protect young plants with shields of plastic or paper. Commercial outlets have provided the devices in large numbers. As is true of other procedures, the shield protects within limited temperature ranges. The shield in addition may speed growth and thus "harden" the plant against chill.

Another shield device is the drowning or flooding of crops, especially cranberries, to prevent low temperatures from damaging tender berries near the end of the growing season.

G

GENTILLI, JOSEPH

Dr Joseph Gentilli was born in the small Italian village of San Daniele de Friuli in 1913 and died in Australia in August 2000. Educated in Italy and the United States Dr Gentilli had a long and distinguished career of over 60 active years at the University of Western Australia. He was an outstanding scholar, teacher and researcher and he contributed over 150 works across a range of areas in geography including: migration studies, economic development in arid lands, regional planning, biogeography and refugees in Australia. His greatest contribution was in the field of climatology, and for this he was made a fellow of the Royal Meteorological Society and the Royal Geographical Society; and a member of the American Meteorological Society. Dr Gentilli's distinguished research career saw him prepare the first accurate climate and rainfall maps for Australia, Western Australia and Tasmania. He was also the first to recognize that a regional or "pseudo-monsoon" system operated over northwestern Australia and that there were summer heat lows with mean positions over the Pilbara region of Western Australia and Cloncurry in Queensland. These features are now recognized as crucial for understanding climate patterns across northern and central Australia, but their impact extends further. Indeed, when troughs form along the west coast these bring moist humid air and high humidity into the otherwise dry hot conditions generally experienced in Perth, for example, over summer.

The prominent ocean current called the Leeuwin brings warm water in winter south along the west coast of Australia and into the Southern Ocean. Dr Gentilli was the first to describe this and comment on its significance for marine life and fisheries in Western Australia. He also pointed out that its width and distance offshore made it unlikely that it had major climatic significance. In 1972 he wrote about the importance of factors in the Indian Ocean leading to the onset of weather patterns in other parts of the world. Joe was one of the first to begin looking for evidence of the "enhanced greenhouse effect" in climate records. While he was unable to demonstrate any clear signal it is typical that he was a trendsetter in this most modern areas of climatic work.

His synthesis work on climate is particularly well known. His *Climates of Australia and New Zealand* was published in 1971,

yet it remains a major work in the field. In preparing this he was led toward comparative work on climate systems of the southern continents, and from this he was able to show that the southern hemisphere was not a simple analog of the northern hemisphere. He took this further by asking questions on why even in the southern hemisphere there were interesting differences across the continents, and he began, and one might say pioneered, in this region the search for teleconnections of climate patterns.

In looking back over Dr Gentilli's work it must be remembered that all this was done by carefully comparing published observations of rainfall and daily weather maps. It took a finely honed mind to search for patterns visually across seasons, years and geography.

Australia and New Zealand, Climate of

GEOMORPHOLOGY AND CLIMATE

The driving forces that influence climate act as significant agents in the exogenic processes that operate at or near the Earth's surface. "The landforms of the earth are the result of the interplay between internal, or endogenetic processes, and surface, or exogenetic, processes" (Derbyshire, 1997, p. 89). The exogenic processes are driven by gravity and by solar radiation, therefore the climate of a region and the variability of climate in a region contribute to geomorphic variability.

Scale is a factor to be considered when examining climate and geomorphologic relationships. Surface variability interacts with atmospheric variables and results in energy movement and transfers. Five topoclimatic variables that affect incoming radiation are:

1. aspect – the direction an object faces;
2. slope – influences the temperature characteristics that will develop;
3. relief – direct radiation of the sun on a surface area;
4. color – impact on albedo; and
5. texture – smooth versus rough impacts heat transfer through the surface.

Each of these variables influences the geomorphic mechanics of a locale allowing for microclimates to be monitored and small anomalies to be accounted for within a given region.

Climatic geomorphology assumes that the geomorphic mechanics of a locale vary in type and rate according to the particular climatic zone in which they function. Classical climatic geomorphology is rooted in the investigation of landforms as products of particular climatic environments. Agassiz (1840) identified distinctive suites of landforms, such as moraines, as unique products of glaciers that existed in contemporary glacial environments and also beyond that climatic regime. Davis (1899, 1900, 1905) identified distinctive landforms characteristically associated with arid climates and additional features uniquely associated with humid, midlatitude regions. The landforms serve as indicators of dominant climatic influence in a region; in the past and/or present. In 1950 Peltier proposed his concept of "morphogenetic regions" (Figure G1). Climatic morphogenesis is the approach to geomorphology that emphasizes the shaping of landforms in response to various climatic conditions (Birot, 1960, 1968; Tricart and Cailleux, 1965, 1972; Andrews, 1975; Budel, 1982). The more acceptable terminology for areas characterized by landforms associated with a particular climatic environment are morphoclimatic zones (or regions). Tanner (1961) proposed a model that used potential evapotranspiration instead of temperature (Figure G2) to convey erosion rates as a function of effective precipitation. Tanner's model identified a total of four classes: arid, selva, moderate, and tundra-glacial. Wilson (1968) introduced a morphogenetic classification called the climate–process system (CPS). This system identifies sets of temperature–precipitation values that tend to drive (or dominate) geomorphic processes under those climatic conditions (Figure G3). The climate–process system considers climatic seasonality as well as air mass dominance as factors in defining the dominant geomorphic processes. Landscape characteristics (both erosional and depositional)

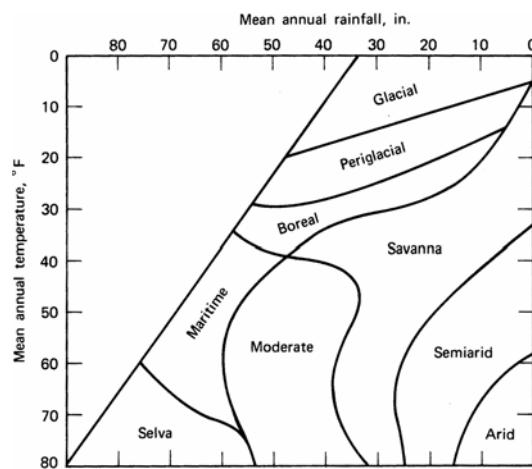

Figure G1 Morphogenetic regions distinguished by Peltier (after Peltier, 1950).

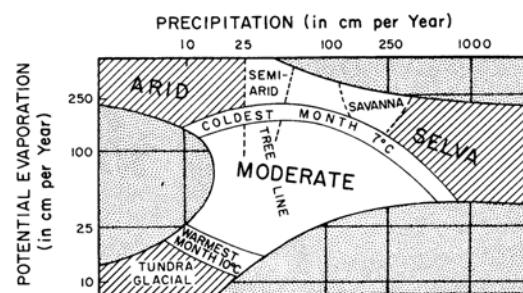

Figure G2 Tanner's morphogenetic regions (after Tanner, 1961).

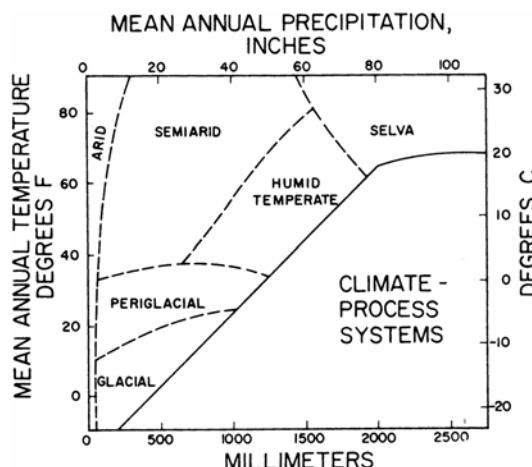

Figure G3 Wilson's climate-process systems (after Wilson, 1968).

Table G1 Simple morphogenetic systems and their landscapes (after Wilson, 1968)

System name	Dominant geomorphic processes ^a	Landscape characteristics ^b
Glacial	Glaciation Nivation Wind action (freeze-thaw)	Glacial scour Alpine topography Moraines, kames, eskers
Periglacial	Frost action Solifluction Running Water	Patterned ground Solifluction slopes, lobes, terraces Outwash plains
Arid	Desiccation Wind action Running Water	Dunes, salt pans (playas) Deflation basins Cavernous weathering Angular slopes, arroyos
Semiarid (subhumid)	Running water Weathering (especially mechanical) Rapid mass movements	Pediments, fans Angular slopes with coarse debris Badlands
Humid temperate	Running water Weathering (especially chemical) Creep (and other mass movements)	Smooth slopes, soil covered Ridges and valleys Stream deposits extensive
Selva	Chemical weathering Mass movements Running water	Steep slopes, knife-edge ridges Deep soils (laterites included) Reefs

^a Processes are listed in order of relative importance to landscape (not in order of absolute magnitude). List is abbreviated.

^b Both erosional and depositional forms are included. List is neither comprehensive nor definitive; merely suggestive.

Source: Wilson (1968).

Table G2 Earth's major morphoclimatic zones (after Summerfield, 1991, based on various sources)

Morphoclimatic zone	Mean annual temperature (°C)	Mean annual precipitation (mm)	Relative importance of geomorphic processes
Humid tropical	20–30	>1500	High potential rates of chemical weathering; mechanical weathering limited; active, highly episodic mass movement; moderate to low rates of stream corrosion but locally high rates of dissolved and suspended load transport.
Tropical wet-dry	20–30	600–1500	Chemical weathering active during wet season; rates of mechanical weathering low to moderate; mass movement fairly active; fluvial action high during wet season with overland and channel flow; wind action generally minimal but locally moderate in dry season.
Tropical semi-arid	10–30	300–600	Chemical weathering rates moderate to low; mechanical weathering locally active especially on drier and cooler margins; mass movement locally active but sporadic; fluvial action rates high but episodic; wind action moderate to high.
Tropical arid	10–30	0–300	Mechanical weathering rates high (especially salt weathering); chemical weathering minimal; mass movement minimal; rates of fluvial activity generally very low but sporadically high; wind action at a maximum.
Humid midlatitude	0–20	400–1800	Chemical weathering rates moderate, increasing to high at lower latitudes; mechanical weathering activity moderate with frost action important at higher latitudes; mass movement activity moderate to high; moderate rates of fluvial processes; wind action confined to coasts.
Dry continental	0–10	100–400	Chemical weathering rates low to moderate; mechanical weathering, especially frost action, seasonally active; mass movement moderate and episodic; fluvial processes active in wet season; wind action locally moderate.
Periglacial	<0	100–1000	Mechanical weathering very active with frost action at a maximum; chemical weathering rates low to moderate; mass movement very active; fluvial processes seasonally active; wind action rates locally high
Glacial	<0	0–1000	Mechanical weathering rates (especially frost action) high; chemical weathering rates low; mass movement rates low except locally; fluvial action confined to seasonal melt; glacial action at a maximum; wind action significant.
Azonal mountain zone	Highly variable	Highly variable	Rates of all processes vary significantly with altitude; mechanical and glacial action become significant at high elevations.

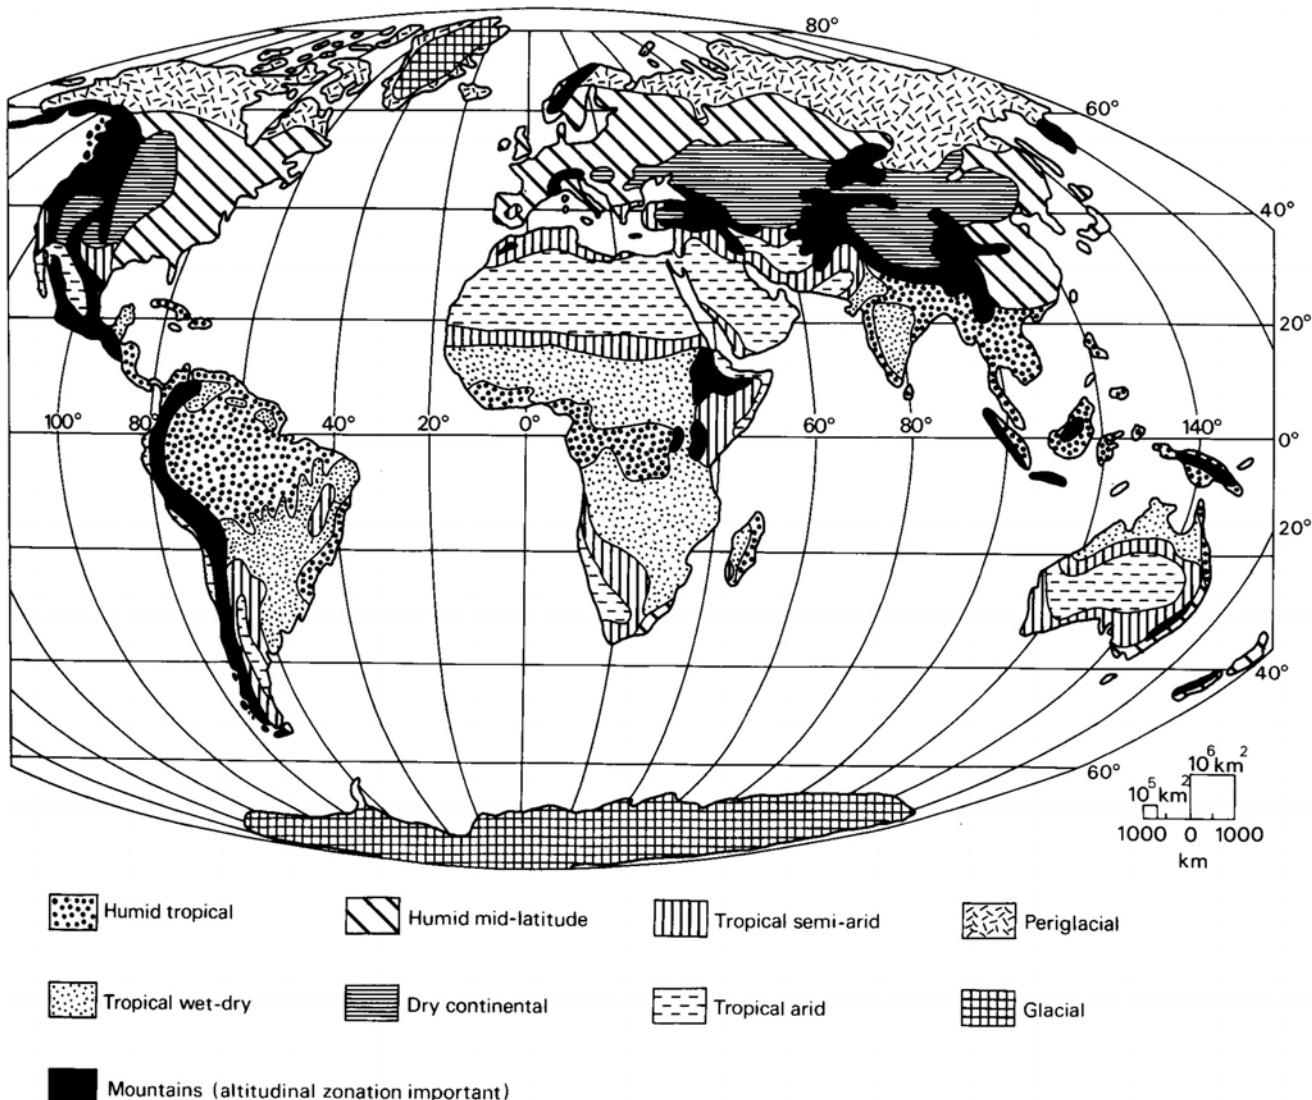

Figure G4 Global distribution of morphoclimatic zones (from Summerfield, 1991, after Tricart and Cailleux, 1972). See Table G2 for descriptions.

may be classified using this system (Table G1). Summerfield (1991) has revised the morphogenic classification to incorporate the Earth's major morphoclimatic zones as defined by mean annual temperature, mean annual precipitation and relative importance of geomorphic processes (Table G2).

In every proposed morphoclimatic analysis solar radiation is considered the most fundamental input to the Earth's climate system. A change in solar radiation input results in responses in the atmosphere, oceans, hydrologic cycle, vegetation cover, and glaciers and ice sheets (Benn and Evans, 1998). The rate of geomorphic activity, when taken into consideration with climate and landform morphology, seems to be a more dominating element in determining whether or not a landscape is formed by the prevailing climate or, in areas with a generally low rate of geomorphic activity, are dominated by relict

landforms developed under quite different climates from the current regime (Summerfield, 1991).

GLOBAL ENVIRONMENTAL CHANGE: IMPACTS

In preparing the entry “Bioclimatology” for this volume, the authors found that many of the articles they wished to cite appeared in literature pertaining to the impacts of global environmental change on humans and the biosphere. To provide a guide to that literature it was decided that a separate entry would prove of value. However, the literature relating to the impacts of global environmental change on humans and the biosphere is developing so rapidly (probably due to the beneficial influence of the IPCC on the world community of environmental scientists) that it would be quite impossible to survey the field in a few pages. Instead, an extensive Bibliography is given.

“Global environmental change” has become a widely discussed topic in recent years. Of particular concern is the issue of climate change (commonly referred to as global warming), which has become a priority policy question, both nationally and internationally. However, there are other kinds of global environmental change (e.g. land-use changes), some of which have feedbacks into the global climate system. Table G3 lists several important types of global environmental change.

The environment is constantly changing, of course, but the changes are now occurring at an accelerating pace. Examples include the continuing urbanization in many parts of the world,

Table G3 Types of global change that may affect climate, and thus, the health and welfare of humans, and the resilience of ecosystems

Increasing concentrations of greenhouse gases:

- Warming, especially in polar regions
Melting of glaciers and of polar snow and ice cover
Increasing evaporation, leading to increasing water shortages and desertification

More frequent air pollution stagnation episodes

Sea level rise

Spread of tropical diseases (e.g. malaria) into the temperate zone

Destruction of the stratospheric ozone layer

Disruption of the global biogeochemical cycles:

- Acid rain, leading to forest dieback and fish kills in sensitive lakes
Nitrogen overload, leading to increasing pollution loadings and changes in biodiversity

Land-use changes:

- Urbanization and industrialization
Irrigation, diverting water from rivers and causing salinization and waterlogging
Soil erosion and desertification
Habitat loss and changes in biological diversity

Over-consumption of renewable and non-renewable resources:

- Over-consumption of fresh water
Deforestation
Over-fishing
Increasing energy consumption, due to, e.g., increasing numbers of automobiles
Population growth in some developing countries accelerating the consumption of natural resources and desertification

New technology:

- Historical examples include the invention of the automobile; and development of chlorofluorocarbons (causing stratospheric ozone depletion)

Environmental consequences of war:

- Destruction of ecosystems
Nuclear winter

the increasing emissions of greenhouse gases and, since about 1970, growing evidence of human-induced greenhouse-gas warming (e.g. pronounced winter and spring warming over most of the northern high latitudes, a decrease in the extent of sea ice in the Arctic Ocean and a northward extension of the tree-line (Serreze et al., 2000)). By the end of the twenty-first century the world's environment is likely to be quite different from that of today.

For articles on global climate change, the main overview references are Volume 1 of the *Encyclopaedia of Global Environmental Change* (2001) and the *Third Assessment Report of the Intergovernmental Panel on Climate Change* (IPCC, 2002). Additionally, appropriate volumes in the *Encyclopedia of Earth Science Series* provide an important source.

Among the journals that deal particularly with global change issues are *Climatic Change*, *Global Change Biology*, *Global Change and Human Health*, *Global Environmental Change*, *Mitigation and Adaptation Strategies for Global Change*, *AMBIO*, and *Science of the Total Environment*. Nevertheless, it should be noted that research papers on global environmental change are dispersed across these and many other scientific journals. This makes it difficult for research bioclimatologists to keep abreast of the field.

Impacts of global environmental change: general

The main impacts of global environmental change on humans and on the biosphere can be classified as physical/chemical, physical/biological, demographic, economic and sociological. In the physical/chemical and physical/biological domains, the environmental impacts are direct, e.g. increased frequency and intensity of heat waves or air pollution episodes lead to increased rates of morbidity and mortality. In other cases the environmental impacts may be indirect, e.g. war may lead to a decline in agricultural production or to a closure of trade routes, in both cases causing malnutrition and even migrations of affected peoples.

When environmental stress factors are considered one at a time, the effects on humans and on ecosystems are reasonably well predicted. But in the case of the boreal forest, for example, where many different factors are likely to change over the next 50 years (climate, frequencies of forest fires and pest outbreaks, increasing nitrogen overload downwind of cities, and changing forest management practices), predictions of the net effects on a forest contain considerable uncertainty. Furthermore, trends in the socioeconomic drivers of environmental change are uncertain (rates of change in emissions of greenhouse gases, rates of human consumption of water, etc.). In summary, single-species and/or single-stressor models are useful diagnostic tools but they are often poor predictors of the behavior of whole ecosystems. See, for example, Fleming (2000) and Fleming et al. (2002).

Thus scenarios must be constructed, usually for several possible futures, and policy-makers must adopt the *precautionary principle* whenever the net losses of not taking action are very great (O'Riordan, 2001). A problem with this approach is that estimates of the benefits of taking action and the disbenefits of not taking action are both subject to uncertainty.

Impacts of global environmental change on humans

Table G4 provides a list of the research fields in which the impacts of climate change/warming on human health and welfare are currently being studied. Some of the major references in these fields are:

Human health:

General: Hancock (2001), Hammad (2002), IPCC (2002), McMichael (2001).
Infectious diseases: Epstein (2001), Guest (2001), NRC (2001), Pimentel (2001).
UV-B: UNEP (1998).

Socioeconomic impacts:

Tourism: Burger (2001), Lise and Tol (2002), Stadelbauer (2001), Unis (2001), Wong (2001).
Economics: Goodstein (2001), Mendelsohn (2001), Norgaard (2001).
Global land use: Douglas (2001a).
Sea-level rise: IPCC (2002).

Impacts of global environmental change on the biosphere

Table G5 lists the root causes of global change, and the resulting impacts on climate, and gives a summary of the types of

Table G4 Current research fields relating to the impacts of global change/climate warming on human health and welfare

Direct impacts on health of climate warming

Summer: increasing frequency and intensity of heatwaves
Winter: decreasing frequency of extreme cold and wind chill episodes
Increasing UV-B, causing more frequent cases of melanoma
More frequent weather disasters

Indirect impacts on health of climate warming

More frequent stagnation episodes generally in valleys, and in temperate zones and the Arctic, causing greater air pollution potential
Spread of tropical diseases into temperate zones
Fresh water shortages
Regional disparity in food yields and incidence of malnutrition
Increasing abundance of aeroallergens, particularly pollen

Socioeconomic impacts of climate warming

Impacts on fisheries
Impacts on forestry
Impacts on agriculture
Impacts on transport
Impacts on tourism
Impacts on the energy sector
Coastal zone damage from sea-level rise

Table G5 Causes of global change, resulting impacts on climate, and types of biosphere responses

Increases in human consumption and in human population leading to:

Increasing concentrations of greenhouse gases, leading to climate warming
Land-use changes, e.g. deforestation and other losses of habitat
Increasing pollution (e.g. acidic deposition, nitrogen overload, persistent organic pesticides, stratospheric ozone destruction)

Types of climate change:

Warming at the Earth's surface, particularly in polar regions
Decay of glaciers and polar ice
Increasing evaporation
Increasing frequencies of weather-related extreme events, e.g. droughts and floods
Rising sea level
Changes in the atmospheric general circulation, producing changes in the behavior of the Asian monsoon, El Niño, the Gulf Stream and possible "rapid" large-scale climate flip-flops to new regimes

Types of biosphere responses:

Longer growing seasons in polar and temperate zones
Poleward shifts of biomes
Changes in biodiversity regimes, e.g. nitrogen overloading may cause a severe decline in the Boreal forest
Oceanic shifts in the migration patterns of fish
Biological invasions and increasing numbers of species extinctions

biosphere responses to these impacts. Some of the major references on biosphere responses to global change are:

GREENHOUSE EFFECT AND GREENHOUSE GASES¹

The greenhouse effect is a natural phenomenon that warms the Earth by about 33°C. It is caused by greenhouse gases in the atmosphere (Table G6). The natural greenhouse effect is currently being enhanced through human activity via the release of additional greenhouse gases into the atmosphere. The consensus of the scientific community, voiced through reports written by the Intergovernmental Panel on Climate Change (IPCC), is that this enhancement of the natural greenhouse effect has caused global warming over the last 150 years and that this warming is very likely to accelerate in the future.

A simple explanation of the greenhouse effect is straightforward, although the full mechanics, processes and feedbacks that exist within the climate system are extremely complex. All things with a temperature above –237.16°C (known as absolute zero) emit electromagnetic radiation. A key property of electromagnetic radiation is that the wavelength of this radiation is related to the temperature of the emitting object. This relationship, described by Planck's Law, means that relatively cool objects emit radiation at longer wavelengths than relatively hot objects.

The sun has a temperature of about 6000°C and thus emits shortwave radiation (also known as solar radiation). Figure G5 shows a curve (known as a Planck or black-body curve) for the sun's emissions (dashed line, left-hand side). The actual wavelengths of radiation emitted by the sun vary across a wide range

Table G6 List of major greenhouse and non-greenhouse gases in the atmosphere

Gas	Concentration
<i>Non-greenhouse gases</i>	
Nitrogen	78.1% volume mixing ratio
Oxygen	20.9% volume mixing ratio
Argon	0.93% volume mixing ratio
<i>Greenhouse gases</i>	
Water vapor	Variable – of order 1% volume mixing ratio
Carbon dioxide	Trace gas
Methane	Trace gas
Nitrous oxide	Trace gas
Ozone	Trace gas
Hydrofluorocarbons	Trace gas
Perfluorocarbons and sulfur hexafluoride	Trace gas

¹ This entry is sourced primarily from Working Group 1 of the 2001 report (Houghton et al., 2001) of the Intergovernmental Panel on Climate Change (IPCC) which provides the scientific basis for greenhouse-related science. This entry therefore represents the consensus opinion of 122 lead authors and 515 contributing authors. The substantive information reported below has been reviewed by several hundred scientists from expert groups, governments and non-government organizations. In writing this entry I have had to simplify and condense the IPCC report and I would strongly recommend that interested readers refer to the Summary for Policy Makers and Technical Summary of Working Group 1 reports available at <http://www.ipcc.ch/pub/spm22-01.pdf> and <http://www.ipcc.ch/pub/wg1TARtechsum.pdf>.

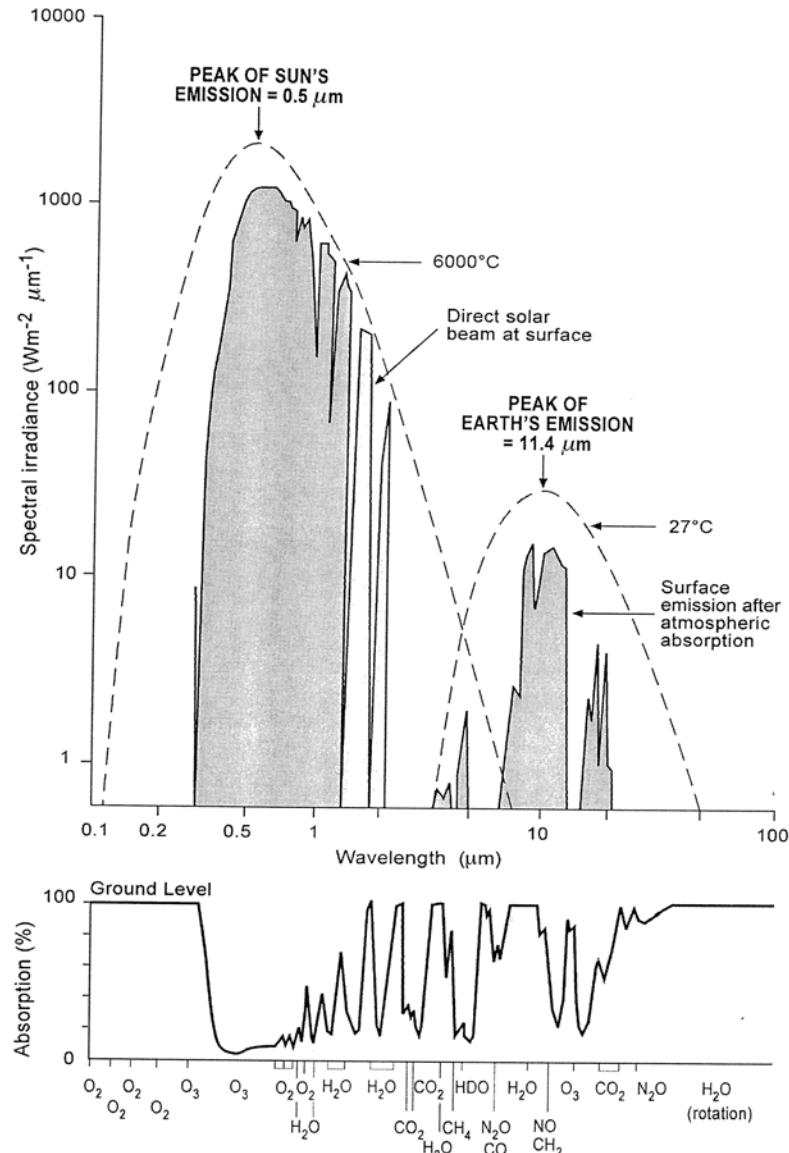

Figure G5 The top pane shows the Planck curves (the range and amounts of electromagnetic radiation) emitted by the sun and Earth's surface (dashed lines). The shaded areas show the amount of the sun's radiation the reaches the Earth's surface and the amount of the longwave (terrestrial) radiation the escapes to space through atmospheric windows. the lower panel shows the percentage of electromagnetic radiation absorbed at these wavelengths. Note the horizontal scale on both panels is the same.

but most is between 0.15 and 5 micrometers. Radiation at these short wavelengths can pass through the atmosphere relatively unimpeded as shown by the lower panel in Figure G5 where the percent of absorption of wavelengths around the peak of the sun's emissions (0.5 micrometers) is close to zero. Figure G5 shows a second curve (solid line, left-hand side) which shows the radiation from the sun that actually reaches the Earth's surface. With the exception of wavelengths shorter than about 0.3 micrometers and wavelengths above about 2 micrometers, the amount of radiation emitted by the sun that reaches the top of the atmosphere is very similar to the amount that reaches the

Earth's surface. The substantial difference in the sun's emissions of wavelengths of less than 0.3 micrometers and the receipt of this radiation at the Earth's surface is critical to life on Earth, since these wavelengths are known as ultraviolet radiation and are highly dangerous. The relative lack of this radiation reaching the Earth's surface is the result of absorption in the upper atmosphere principally by ozone (Figure G5, lower panel).

As the solar radiation passes through the atmosphere, some is reflected by clouds and atmospheric aerosols and some is absorbed by the atmosphere. Of the 342 W m^{-2} of shortwave solar radiation received at the top of the atmosphere, 198 W m^{-2}

reaches the Earth's surface. Since the overall Earth's surface is relatively non-reflective, only about 30 W m^{-2} is reflected and thus 168 W m^{-2} is absorbed at the Earth's surface.

To maintain a surface energy balance, the Earth's surface emits some of this absorbed energy as longwave or terrestrial radiation. Figure G5 shows the overall emissions by the Earth and includes emissions by the atmosphere. Since the Earth's surface is very much cooler than the sun, it emits radiation at longer wavelengths (mainly 3–50 micrometers, see Figure G5, right-hand side). The atmosphere is relatively more opaque (it has a higher absorptivity) to this terrestrial radiation because of greenhouse gases. Thus a significant fraction of the radiation emitted by the Earth's surface is absorbed in the atmosphere and re-emitted. This is particularly clear in Figure G5 (right-hand side) where the difference between what the Earth should emit to space (dashed line) is very different from what is actually emitted (shaded region). It is the presence of greenhouse gases in the atmosphere that causes this difference. As a result of this increased opacity (Figure G5, lower panel) more longwave radiation is absorbed and re-emitted, and this acts to warm both the atmosphere and the Earth's surface. The various greenhouse gases absorb longwave radiation at particular wavelengths (Figure G5, lower panel). If a greenhouse gas is released that happens to absorb radiation at a wavelength that is already strongly absorbed in the atmosphere then the impact of increasing this gas is likely to be relatively small (but not zero). In contrast, the release of a greenhouse gas that absorbs in a wavelength region poorly absorbed is likely to have a much larger effect. These wavelength regions, where the atmosphere is a poor absorber of longwave radiation, are known as atmospheric windows, and several of these windows are being partially "closed" through the emission of key greenhouse gases.

This role of greenhouse gases in the atmosphere is a very ancient natural process. The greenhouse effect is the main mechanism to explain how the Earth remained non-frozen during the Archean period (2.5–3.8 billion years ago) when the sun's luminosity is believed to have been 30% less than present (this is known as the faint-sun paradox). It is currently believed that methane generated a sufficiently strong greenhouse effect to counteract the faint sun. Through geological time the amounts of greenhouse gases in the atmosphere have varied, driven by long timescale changes in the sources and sinks of the natural greenhouse gases. For example, over the last 160 000 years carbon dioxide has varied naturally from below 180 parts per million by volume (ppmv) (some 40 000 years ago) to above 300 ppmv (some 140 000 years ago).

Human activity began to affect the Earth when humans began to use fire. However, the impact of humans began to accelerate when large-scale burning of fossil fuels began in Europe at the beginning of the Industrial Revolution (around 1750). Burning carbon-based fossil fuels in an oxygen-rich atmosphere releases carbon dioxide (CO_2), and since the 1750s the concentration of CO_2 has increased from about 280 ppmv to 375 ppmv (2003) at the Mauna Loa observing station which provides a very high quality and continuous data set (see Figure G7) (<http://cdiac.esd.ornl.gov/trends/co2/sio-mlo.htm>). Similarly, methane, nitrous oxide and a suite of human-made chemicals (the chlorofluorocarbons (CFC) and hydrofluorocarbons (HFC)) have increased in the atmosphere. At the same time industrial activity releases sulfate aerosols into the atmosphere.

Before examining the details of the greenhouse effect, some details on these greenhouse gases will be provided, since these form one of the foundations for the concerns over the

enhancement of the natural greenhouse effect by human activity. Basic data on major greenhouse gases are provided for particular greenhouse gases compared to an emission of a kilogram of carbon dioxide. The global warming potentials calculated for various time periods show the effects of the atmospheric lifetime of the different gases. Note that the global warming potentials are on the basis of kilograms of each greenhouse gas. While billions of tonnes of carbon dioxide are released annually, the amount of HFC and CFC released is far smaller: HFC-134a is of order $3.2 \times 10^{-5} \text{ Gt yr}^{-1}$ or 1/170 000 of the amount of carbon dioxide. Thus, even 500 years into the future, carbon dioxide will remain far more important than the HFC or CFC for net impact on radiative forcing.

Greenhouse gases and aerosols

Carbon dioxide has increased in the atmosphere by 32% between 1750 (280 ppmv) and 1998 (365 ppmv) (Figure G6a and Table G7); this increase is due to human activity. The current level of CO_2 has not been exceeded during the past 420 000 years and it is unlikely that it has been exceeded in the past 20 million years. The current rate of increase over the last century is unprecedented, at least over the last 20 000 years. Most of this increase in CO_2 (about 75%) comes from fossil fuel burning; the rest is largely the result of deforestation (Table G8). The sinks of CO_2 into the land and ocean currently take up about

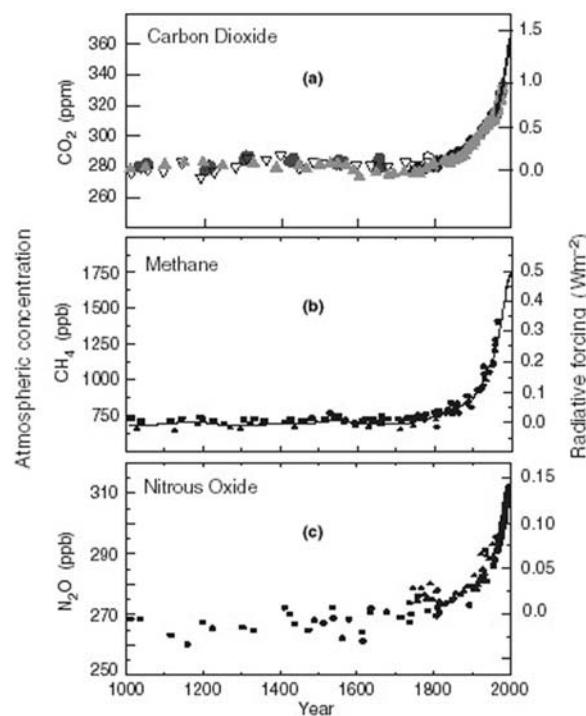

Figure G6 The variation in (a) carbon dioxide, (b) methane, (c) nitrous oxide since AD 1000. These data are derived from a combination of measurements including ice cores. In the last few decades observations have been taken directly from the atmosphere. The left-hand scale shows atmospheric concentration and the right-hand scale shows radiative forcing. This figure is taken from the Summary for Policy Makers Report of the Intergovernmental Panel on Climate Change, available at <http://www.ipcc.ch/pub/spm22-01.pdf>

Table G7 Various data for key greenhouse gases

Greenhouse gases	Concentration (preindustrial)	Concentration (1998)	Approximate lifetime (years)	Radiative forcing (W m ⁻²)	Global warming potential (years into the future)		
					20	100	500
Carbon dioxide	270 ppmv	365 ppm	5–200	1.46	1	1	1
Methane	700 ppbv	1745 ppb	12	0.48	62	23	7
Nitrous oxide	270 ppbv	314 ppb	114	0.25	275	296	156
Hydrofluorocarbon-23 (HFC-23)	0 ppt	14 ppt	260		9400	12 000	10 000
Chlorofluorocarbon (CFC-11)	0 ppt	−1.4 ppt	45	0.34		4600	
Perfluoromethane (CF ₄)	40 ppt	80 ppt	50 000		3900	5700	8900

The global warming potentials are relative to carbon dioxide and are an index for estimating relative warming contribution due to an emission of a kilogram of a particular greenhouse gas compared to an emission of a kilogram of carbon dioxide. The global warming potentials calculated for various time periods show the effects of the atmospheric lifetime of the different gases. Note that the global warming potentials are on the basis of kilograms of each greenhouse gas. While billions of tonnes of carbon dioxide are released annually, the amount of HFC and CFC released is far smaller: HFC-134a is of order 3.2×10^{-5} Gt yr^{−1} or 1/170 000 of the amount of carbon dioxide. Thus, even 500 years into the future, carbon dioxide will remain far more important than the HFC or CFC for net impact on radiative forcing.

Table G8 Global carbon dioxide budgets. Positive values are fluxes to the atmosphere, negative values represent uptake from the atmosphere (from table 3.1 and associated text in Prentice et al., 2001). See also Figure G7

Carbon dioxide	Size (1980s)
<i>Sources</i>	
Fossil fuels emissions	5.3 ± 0.3 Gt C yr ^{−1}
Cement production	0.1 Gt C yr ^{−1}
Land-use change	1.7 (0.6 to 2.5) Gt C yr ^{−1}
<i>Sinks</i>	
Oceans–atmosphere exchange	−1.9 ± 0.6 Gt C yr ^{−1}
Atmospheric increase	3.2 ± 0.1 Gt C yr ^{−1}
Terrestrial sink	−1.9 (−3.8 to 0.3) Gt C yr ^{−1}

Table G9 Major anthropogenic sources and major sinks for the global methane budget, derived from table 4.2 and associated text in Prather et al. (2001). See also Figure G7

Methane (CH ₄)	Size (1980s)
<i>Sources</i>	
Energy production	75–110 Tg CH ₄ yr ^{−1}
Landfills	35–73 Tg CH ₄ yr ^{−1}
Ruminants	8–150 Tg CH ₄ yr ^{−1}
Rice production	25–100 Tg CH ₄ yr ^{−1}
Biomass burning	23–55 Tg CH ₄ yr ^{−1}
Total (anthropogenic)	300–500 Tg CH ₄ yr ^{−1}
<i>Sinks</i>	
Soils	10–44 Tg CH ₄ yr ^{−1}
Tropospheric OH	450–510 Tg CH ₄ yr ^{−1}
Stratospheric loss	40–46 Tg CH ₄ yr ^{−1}
Total	460–580 Tg CH ₄ yr ^{−1}

50% of the CO₂ released by human activity, the other 50% is accumulating in the atmosphere. CO₂ contributes about 60% of the enhancement to the natural greenhouse effect of globally well-mixed greenhouse gases. This enhancement is measured

by the impact on radiative forcing (the amount of radiation available to drive the climate system). In the case of CO₂ the increase in radiative forcing is 1.46 W m^{−2}. A molecule of CO₂ released into the atmosphere remains for between 5 and 200 years (the lifetime or residence time), depending on the nature of the eventual sink.

Methane (CH₄) is also increasing in the atmosphere, by about 150% between 1750 (700 ppbv) and 1998 (1745 ppbv) (Table G7, Figure G6). CH₄ has an approximate lifetime in the atmosphere of 12 years. About half of the release of CH₄ is the result of human activity (mainly use of fossil fuels, agriculture, landfills etc) (Table G9). CH₄ contributes approximately 20% of the enhancement to the natural greenhouse effect of globally well-mixed greenhouse gases (an increase in radiative forcing of 0.48 W m^{−2}). Methane is removed from the atmosphere by chemical reactions. Table G7 shows the global warming potential of CH₄ relative to CO₂. A single kilogram of CH₄ emitted into the atmosphere will have a global warming potential of 62 times a kilogram of CO₂ 20 years into the future (Table G7). This global warming potential is reduced to 23 times at 100 years into the future and 7 times at 500 years into the future. This change in global warming potential reflects the atmospheric lifetime of CH₄ being quite short, while the overall greater global warming potential compared to CO₂ reflects the role of CH₄ in trapping longwave radiation in atmospheric windows. Note that, since the total anthropogenic emission of CH₄ is approximately 5% of the emissions of CO₂ (Figure G7), the actual impact of CO₂ will remain much larger than CH₄.

Finally, the large family of halocarbons are a group of very long-lived greenhouse gases. As a consequence of the Montreal Protocol, the concentration of some of these gases is falling (e.g. CFC-11) or increasing more slowly (e.g. CFC-12) than in the 1990s. The family of halocarbons contributes approximately 14% of the enhancement to the natural greenhouse effect of globally well-mixed greenhouse gases and adds 0.34 W m^{−2} to radiative forcing. These gases are removed from the atmosphere when the molecules are broken down in the stratosphere under the influence of ultraviolet radiation. Unfortunately, this leads to the release of bromine and chlorine, which contribute to the breakdown of ozone in the stratosphere. This breakdown of

these molecules is typically slow; and hence many of these chemicals have long atmospheric lifetimes. Typically, the HFC range between a few months (HFC-161) to a few centuries (HFC-23). Some gases (known as fully fluorinated species) have atmospheric lifetimes of thousands of years and perfluoromethane exceeds 50 000 years. This leads to very large global warming potentials for these gases (Table G7), both because they will remain in the atmosphere for long periods and because they commonly absorb longwave radiation at wavelengths where the atmosphere is presently relatively transparent.

In terms of the enhanced greenhouse effect, the key measure of the importance of a greenhouse gas is the role it plays in the

radiative forcing of climate (the energy available to drive the climate system). Very many factors have changed since 1750, and these all need to be considered as potential influences on the climate system. If radiative forcing increases, then warming is likely to occur, and conversely a reduction in radiative forcing is likely to cool the planet.

Figure G8 shows changes in radiative forcing between 1750 and the present. The main contribution to increases in radiative forcing is from the increases in globally well-mixed greenhouse gases (CO_2 , CH_4 , N_2O and the halocarbons) that combine to contribute about 2.5 W m^{-2} of radiative forcing. Figure G8 shows many other aspects of change within the climate system between 1750 and the present that contribute to radiative forcing. Most of these are unlikely to be a significant factor in future climate in comparison to the greenhouse gases. However, there are a series of issues worthy of note. The changes in ozone

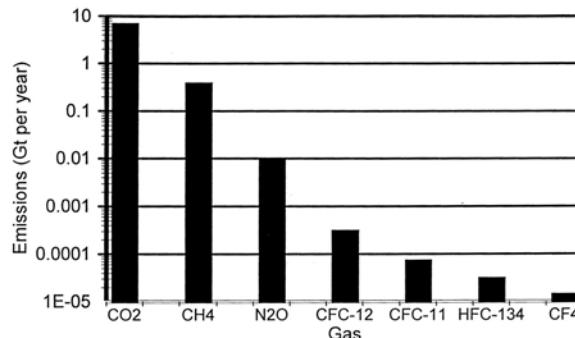

Figure G7 Total anthropogenic emission of various greenhouse gases (converted into Gt yr^{-1}). Note the log scale on the vertical axis. HFC-134 is hydrofluorocarbon-134 and CF_4 is perfluoromethane. These data are from various years in the 1990s.

Table G10 Major anthropogenic sources and all major sinks for the global nitrous oxide budget, derived from table 4.4 and associated text in Prather et al. (2001). See also Figure G7

Nitrous oxide (N_2O)	Size (1980s)
<i>Sources</i>	
Agricultural soils	$0.6\text{--}14.8 \text{ Tg N yr}^{-1}$
Biomass burning	$0.2\text{--}1.0 \text{ Tg N yr}^{-1}$
Industrial sources	$0.7\text{--}1.8 \text{ Tg N yr}^{-1}$
Cattle and feedlots	$0.6\text{--}3.1 \text{ Tg N yr}^{-1}$
Total (anthropogenic)	$2.1\text{--}20.7 \text{ Tg N yr}^{-1}$
<i>Sinks</i>	
Stratospheric loss	$9\text{--}16 \text{ Tg N yr}^{-1}$

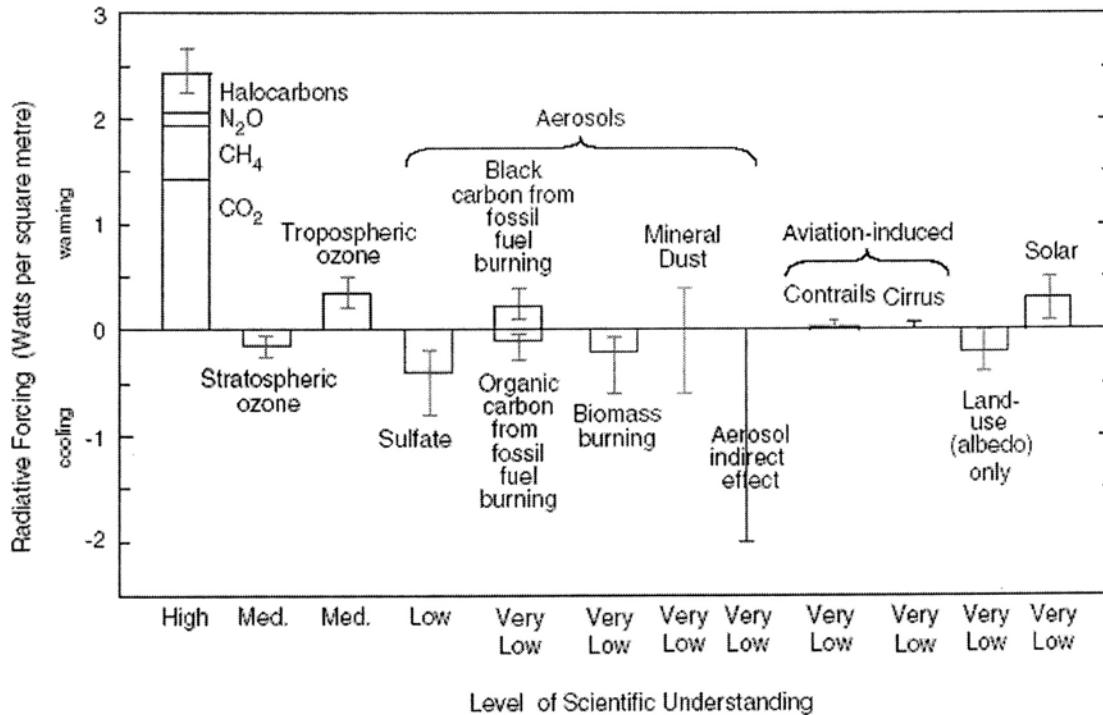

Figure G8 The global mean change in radiative forcing of the climate system between 1750 and 2000. Positive values imply warming and negative values imply cooling. This figure is taken from the Summary for Policy Markers Report of the Intergovernmental Panel on Climate Change available at <http://www.ipcc.ch/pup/spm22-01.pdf>

(O₃) have cooled the stratosphere (where the majority of ozone depletion has occurred), which may have lessened the observed tropospheric warming caused by greenhouse gases. The role of aerosols is also very important but quite poorly understood. There are two ways in which aerosols affect radiative forcing: (a) the direct effect, whereby aerosols scatter and absorb solar and thermal longwave radiation; and (b) the indirect effect, whereby aerosols modify the microphysical and hence the radiative properties and amounts of cloud. A major source of atmospheric aerosols are the emissions of sulfates by industry. These reflect incoming solar radiation and thus generate a negative radiative forcing that partially counteracts the effect of increasing greenhouse gases. It is believed that this may have led to a reduction in the amount of warming observed since 1860. This is not good news, however, since these sulfate aerosols affect air quality and are the cause of acid deposition. Overall, the best estimate of the role of the direct and indirect effect of aerosols is shown in Figure G8, but it should be emphasized that these estimates remain very uncertain.

In summary, the changes in the well-mixed greenhouse gases since 1750 are extremely well known. Their impact on radiative forcing is also very well known. The impact of the increases in CO₂, CH₄, N₂O and the halocarbons is to enhance the natural greenhouse effect. There is no doubt that this enhancement, as a direct result of human activity, will lead to ongoing climate change. There are questions, however, regarding how large these changes might be.

Impacts 1750 to present day

The Earth's surface is warming. The global average surface temperature (with measurements taken over land and ocean surfaces) has increased since 1861 (the earliest year where reliable measurements are available) (Figure G9). Over the twentieth century the global average surface temperature has increased by 0.6 ± 0.2°C. It is very likely that the 1990s was the warmest decade, and 1998 the warmest year, in the instrumental record since 1861. The global average surface temperature in 2002 was the second warmest since 1860, approximately 0.5°C above the 1961–1990 average. Remarkably, while the

warmest year since 1860 remains 1998, 2002 was the second warmest, 2001 the third warmest and the 10 warmest years since 1860 have all occurred since 1987. However, it is not just the amount of warming that has concerned climate scientists. It is likely that the rate and duration of warming over the twentieth century is larger than any other time during the last 1000 years, even if uncertainties in data are taken into account.

It is also possible to explore the warming trend geographically decade by decade. An analysis of annual trends in the observed temperature record highlights an apparent acceleration in warming in recent decades. Between 1901 and 2000 most of the Earth shows warming of approximately 0.2°C per decade. Warming was more rapid between 1910 and 1945. A mixed pattern of warming and cooling was apparent between 1946 and 1975 followed by very rapid warming, particularly over the continental surfaces of the northern hemisphere, between 1976 and 2000) (see <http://www.ipcc.ch/pub/wg1/TARtechsum.pdf>, Figure G7).

This pattern of regional change is one piece of a vast collection of evidence showing that the Earth is warming. Measurements of ocean heat content, measurements from weather balloons, observations of precipitation, atmospheric moisture, snow cover, land-ice, sea-ice, sea level, changes in terrestrial ecosystems and observed changes in some ocean circulation patterns and possibly climate variability and extreme weather and climate all point to a warming world. No single piece of evidence is safely taken in isolation; however, when taken collectively, looking at the spatial and temporal evolution of all these aspects of the climate, the evidence is genuinely convincing that the enhanced greenhouse effect is leading to significant climate change.

Thus, convincing evidence exists that the Earth is warming and theoretical evidence that the changes in greenhouse gases lead to an increase in radiative forcing also exists. Can we put these two pieces of evidence together and *attribute* the observed warming to human activity? An alternative question is, can we explain the observed changes in climate in other ways; ways that do not involve the observed increases in radiative forcing caused by greenhouse gases?

The process of demonstrating that an observed change in the climate system is statistically significantly different from

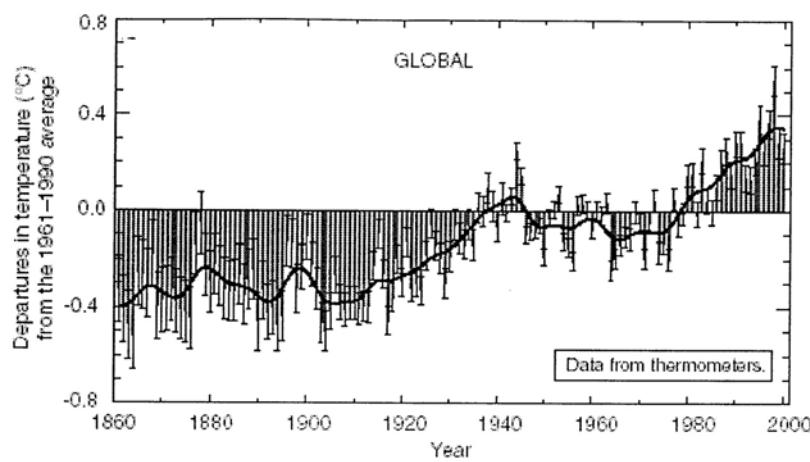

Figure G9 Combined annual land-surface air and sea surface temperature anomalies (°C) 1861 to 2000, relative to 1961 to 1990. Two standard error uncertainties are shown as bars on the annual number. This figure is taken from the Technical Summary of the Working Group 1 Report of the Intergovernmental Panel on Climate Change available at <http://www.ipcc.ch/pub/wg1/TARtechsum.pdf>

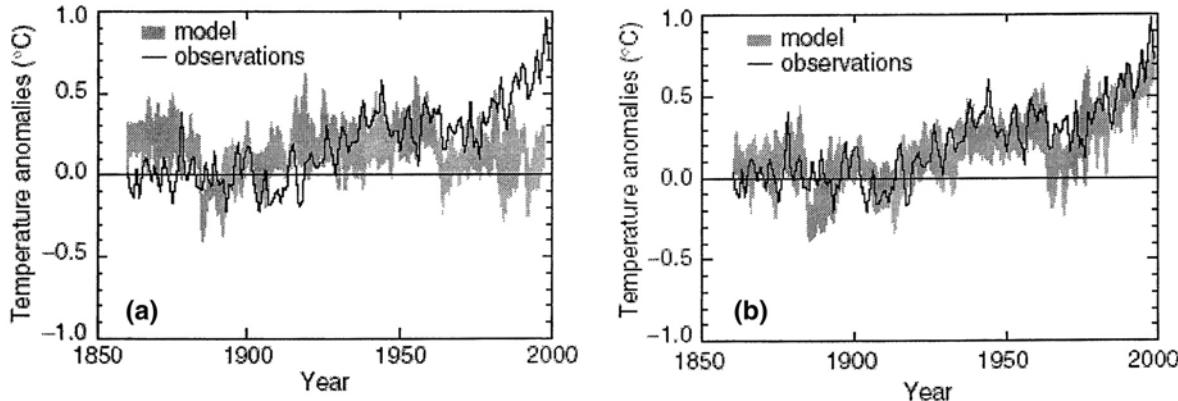

Figure G10 Simulating the Earth's temperature variations using a climate model without including the effects of greenhouse gas increases (a) and including these effects (b). Both simulations include the effects of solar variation and volcanic activity.

natural changes is called *detection*. The process of linking a cause (say the enhanced greenhouse effect) to an effect (say climate change) at a defined level of confidence is called *attribution*. A substantial effort has been invested in the past 5 years in attempts to detect the fingerprint of human activity on climate, and to then attribute these observed changes in climate to human activity.

The climate varies naturally, and has done so for billions of years. This natural climate variability is commonly called “noise”, and the key question is whether the currently observed changes in climate are just “noise” or whether they are a human-induced “signal” that is statistically unusual. It is also important to show that any “signal” is caused by human-induced changes, and that the signal is the approximate size expected given the changes in greenhouse gases in the atmosphere.

At the present time (2003), it appears that the temperature changes observed over the last 100 years are unlikely to be entirely natural in origin – recent globally averaged temperatures exceed reconstructions of temperature over the last 1000 years, even taking into account the uncertainties in those reconstructions. Evidence from climate models also shows that the warming observed since 1850 is very unlikely to be due to natural variability – because climate models do not warm at the rate that has been observed since 1860 for the length of time the observations show the Earth has warmed. This is illustrated in Figure G10a, where a climate model is used with no changes in greenhouse gases or aerosols. Under these circumstances the climate model responds to natural variability (forced by solar and volcanic activity) and shows no trend in temperature, in contrast to the observed record (Figure G10a) which shows the same upward trend seen in Figure G9. If, however, these natural processes are combined with changes in greenhouse gases and aerosols, the climate model shows a remarkable ability to simulate the observed changes in temperature since 1850 (Figure G10b). Climate models never show a warming trend which matches the observed since 1850 *unless* greenhouse gases are increased within the model. This is not proof that observed warming is caused by the increase in greenhouse gases, but it is another piece of strong supporting evidence that it is human activity that has caused the increase in surface temperature.

In summary, no one piece of evidence is totally convincing that humans have caused the observed changes in climate. However, when taken together the case is becoming convincing

that most of the observed warming over at least the last 50 years is likely to have been due to the increase in greenhouse gas concentrations caused by human activity. A further piece of evidence is worthy of note. It is very hard to dispute the reliability of the observed record, which is derived rigorously from many independent sources. Our understanding for the enhanced greenhouse effect can largely explain this record. We do not have an alternative explanation for the changes that have been observed. There is no known explanation for all the changes that are taking place in the terrestrial ecology – sea level, glaciers, snow extent, temperature, rainfall, etc. – *except* the enhanced greenhouse effect. It is valid scientifically to critique the impact of the enhanced greenhouse effect, but if we are to replace the enhanced greenhouse effect as the cause of the observed changes in climate, then an alternative theory that explains the observed phenomenon will have to be developed.

H

HADLEY CELL

In 1735 George Hadley proposed a cellular model to explain the primary circulation of the atmosphere. Based upon pressure differences produced by uneven heating of the earth, Hadley postulated that cold air sinking at the poles would flow equatorward to be replaced by warm air rising at the equator and flowing poleward aloft. This would result in two large Hadley circulation cells in each hemisphere (Figure H1a). This model was shown to be greatly oversimplified and to disregard the Earth's rotation, but it offered a very important first approximation and is reproducible in dishpan experiments. Hadley's model was refined over time and gradually altered to a three-cell model for each hemisphere as in Figure H1b.

Today, the low-latitude circulation between the equatorial low-pressure and the semipermanent high-pressure belts is referred to as the Hadley Cell, although now it is considered more complex than a simple thermal cell.

John E. Oliver

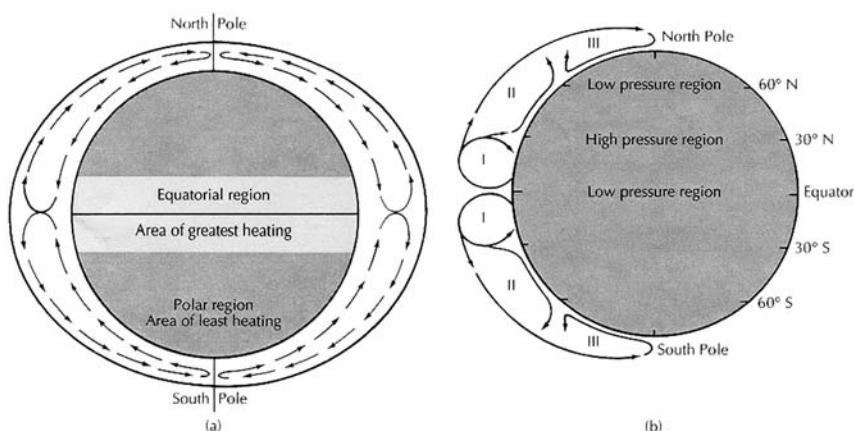

Figure H1 (a) A single cell in each hemisphere provides the fundamental air flow based upon temperature differences. (b) A three-cell model, for each hemisphere, that results from differential heating and Earth's rotation. The Hadley Cell is labeled 1.

HADLEY, GEORGE, 1685–1768

George Hadley was born in London, England, and educated at Oxford University where he trained in law. He also developed an interest in atmospheric physics and produced meteorological observations for the Royal Society of London. Hadley built on the 1686 work of Edmond Halley, who presented basic ideas about the rising of heated equatorial air and its replacement with cooler air flowing in from higher latitudes. Halley had not been able to describe a cause for the tropical easterlies, or tradewinds, however.

Hadley's key publication, "Concerning the cause of the general trade winds", appeared in 1735. In this paper he described variable speeds of rotation with latitude and deflection of airflow dependent on differences in Earth circumference between the equator and the tropics. Hadley combined this with an understanding of rising warm air in the tropics and sinking cold air in higher latitudes to explain the easterly direction of the tradewinds. He also described upper air motion in the opposite direction, from the equatorial region toward the higher latitudes, sinking and moving as westerlies beyond the tropics. Hadley described tropical circulation as two huge cells of tropical rising air caused by solar heating, poleward-moving air higher in the atmosphere, sinking cooled air, and return flow to the tropics at the surface. In doing so, he also attempted to explain the westerlies, as well as the northeast tradewinds in the northern hemisphere and southeast trades in the southern hemisphere. Although his understanding of circulation and deflection were incomplete, his view was generally accepted until better wind measurements in the mid-1800s led to modifications, with some authors showing two or three circulation cells in each hemisphere. Tropical circulation, however, follows the general pattern suggested by Hadley, and continues to bear the name "Hadley Cell".

HAIL

Hail is a type of precipitation often composed of concentric spheres of alternating clear and opaque ice, having a diameter of up to 50 mm or more. The largest single hailstone on record

to fall in the United States struck Coffeyville, Kansas, on 3 September 1970; this hailstone weighed 1.7 lb (766 g), was 5.7 in (144 mm) in maximum diameter and fell with a calculated velocity of over 100 mph (see Figure H2).

Three forms of hail have been recognized: graupel, small hail, and true or severe hail. *Graupel*, commonly called "soft hail", is composed of loosely compacted ice crystals, and is roughly spherical with a tendency to fracture upon striking the ground. Having a diameter of 5 mm or less, it is common for graupel to melt before it reaches the Earth, especially if it falls during the summer. *Small hail* is about the size of graupel, but is semitransparent with a translucent or milky-white center. Frequently, graupel serves as a nucleus for small hail, allowing a thin layer of ice to form around it. This ice sphere gives small hail a glazed appearance and causes it to be less compressible than graupel. When small hail strikes hard surfaces, often in conjunction with rain, the hailstone remains intact. *True hail* or *severe hail* is composed of hailstones greater than 5 mm that often cause extensive damage.

It is not known for certain how hailstones form. Traditionally, multiple-incursion theories had wide acceptance. According to these theories, ice embryos form as liquid water droplets from the warmer, lower portion of a cloud by being carried aloft by strong vertical currents, and subsequently freezing upon encountering the subfreezing temperatures associated with the upper portion of the cloud prior to falling out of the freezing portion of the cloud. Where a raindrop may require a million cloud droplets to form, a hailstone the size of a golfball needs approximately 10 billion cloud droplets to form. Additional water is acquired from the warmer, lower portion and, with each repetition of the process, a sphere of transparent ice is added to the embryo. Repeated circulation from the non-freezing to the freezing level of the cloud contributes to the onionlike structure of the concentric spheres of the hailstorms. As many as 25 concentric rings have been identified on some hailstones. Serious questions have been raised, however,

Figure H2 Photograph of the largest officially recognized hailstone to fall in the United States (© National Center for Atmospheric Research/University Corporation for Atmospheric Research/National Science Foundation; used with permission).

regarding the attempts of the multiple-incursion theories to account for the frequency and velocity of the essential updrafts required to create the concentric banding of the hailstone.

Gaining wider acceptance are theories that attribute growth of the hailstone to steady nonviolent updrafts within the cloud. According to these theories, the structure of the ice in the hailstone depends on the rate of deposition. If the hailstone acquires water too quickly to freeze completely, the resulting ice will be transparent, as dissolved air diffuses and escapes from the relatively slow-forming ice surface. If, however, multitudes of air bubbles become trapped as small droplets and freeze rapidly on impact, milky-white opaque ice will form. Hailstorms may, therefore, be a product of two different modes of growth, specifically "wet" growth resulting in a sphere of clear ice and "dry" growth depositing the opaque layer. The freezing level for hail in a cumulonimbus is often 3 miles (5 km) above the ground.

Large clouds, particularly the cumulonimbus, experience subsiding cold air from high levels that later create an intense, violent squall with rapid updrafts immediately ahead of the cold air. These updrafts pick up small protohailstones and carry them aloft. Most of these hailstones fall from the cloud and melt upon descent. Some of these hailstorms fall from the clouds, whereas others may fall back into the clouds. The size of those re-entering the cloud may be large enough to be slowly uplifted by the updraft and thus grow at a rate sufficient to almost match the speed of the updraft. Eventually these hailstones move forward near the cloud top and fall from the cloud. Occasionally, they may briefly pass through the updraft on their descent. Thus, in the same cloud, hailstones may be growing and rising while being very close to the condition in which hailstones are just becoming wet. Following these theories, slight variation in either the cloud-water concentration or in the velocity of the updraft may cause fluctuation back and forth between wet and dry growth stages, also resulting in opaque or clear ice being formed even in nearly-steady updrafts. Since these updrafts may be tilted in the cloud, the hailstone may traverse the cloud "sideways", experiencing wide variation in the irregular distribution of humidity with height.

Analysis of the structure of hailstones has provided insights concerning the environmental conditions under which they form. The interpretation of the process involved in hail formation is ambiguous and still a matter of controversy.

Distribution of hail

Hail occurs most often in deep continental interiors within the midlatitudes and occurs less frequently toward the poles and the equator. Hail is frequently associated with large, highly developed clouds, most notably the cumulonimbus. Clouds found in cold climates are seldom well developed enough to produce hail or are lacking water–ice concentrations necessary to facilitate the growth of large hailstones. Hailstones are rare in tropical regions because the steep horizontal temperature gradients and vertical wind shears conducive to hail formation fail to adequately develop. Likewise, hail seldom falls over temperate oceans, due in part to the absence of intense surface heating.

Maximum frequency of hail often occurs on the drier leeward side of high mountains. Representative of this distribution are the hailstorms in the pampas of western Argentina, the Po Valley of Italy, southern France, eastern New Zealand, South Africa, and the Caucasus regions of Russia. North America's principal hail area exists on the leeward side of the Rocky

Mountains from New Mexico to Alberta. Probably the stronger vertical currents associated with the mountains enhance hail formation. No portion of the United States is immune from hail but frequently hail occurs only once per year along the Atlantic–Gulf Coastal Plains.

More is known about the climatology of hail in the United States than in any other country. Across the United States the average number of days experiencing hail ranges from over 8 per year to less than 1 per year. The highest frequency region, known as "Hail Alley", is located where the borders of Wyoming, Nebraska, and Colorado meet. Great variability exists in the number of hailstorms experienced annually and varies considerably by size of hailstone: small (0.25–0.5 inches or 6–12 mm); moderate (0.5–1 inch or 12.5–25 mm); large (greater than 1 inch or 25 mm). In some years localized regions in eastern Colorado may record 20–30 days with hail. In the United States hail is recognized as a small-scale phenomenon with relatively infrequent occurrence at any specific site. Small hail is the most common classification recorded throughout the United States and often is correlated with regions experiencing relatively infrequent hail. Hail of moderate size is concentrated along the Rocky Mountains wedging through the Great Plains toward the Midwest. Large hail mostly falls in Wyoming and Colorado, comprising 20% of the number of days experiencing hail in this region (see Figure H3).

It is hail intensity that produces damage, and intensity is determined by the size and number of hailstones experienced, the velocity of their fall, and the accompanying winds. Wide variations in intensity likewise occur across the United States. Hail in the western Great Plains may be up to 18 times more intense than the hail falling farther to the east in the Midwest. The largest hailstorms in the United States tend to fall on the leeward side of mountains, whereas small hailstones are more representative of New England, Indiana, Illinois and the Pacific Northwest.

Hailstorms occur in any season and at any time of day. East of the Great Plains, hail activity is greatest in spring with the southern states being most vulnerable in March. The northern states are most susceptible to hailstorms in May. States located on the leeward side of mountains on the Great Plains record hail mainly in the summer, averaging over 25 episodes in July, whereas the west coast experiences maximum hail activity in late winter or spring. The Great Lakes region is the only area that records peak hail activity in the fall. Most hail occurs in the afternoon hours when the Earth's surface has achieved maximum ground heating. Regions close to the Rocky Mountains tend to experience most hailstorms between 3 and 6 p.m., whereas in areas farther east the peak hours for hail are between 6 and 9 p.m., suggesting a west-to-east storm sequence. Hailstorms that occur near mountains typically last 10–15 minutes, while those in the Midwest last 3–6 minutes. The average size of a *hailstreak*, the path of the ground completely covered by hail, is 5 square miles, and there may be several hailstreaks in a single storm. In the Midwest, half of the thunderstorms associated with warm fronts and low pressure produce hail, while 75% of cold fronts or stationary fronts associated with thunder produce hail. In Iowa, Illinois, and Colorado, hail is produced on 70% of the days during which thunderstorms occur.

Fourteen hail regions, based on meteorological origin, frequency, peak season, and regional intensity, have been delineated in the United States (Figure H4). Note that hail intensity differentiates the Rocky Mountain and Great Plains region from the upper Midwest region.

Hail damage

Accounts of devastation by hail have been recorded since ancient times. Hail has been known to kill cattle, horses, and even on rare occasion humans. One of the most deadly hailstorms to date occurred in India in 1888, killing 230 people at Moradabad and 16 others 50 miles away at Bareilly. The *South Carolina Gazette* reported, in what is likely the first recorded account of death by hail in the United States, that eight people died in Winnsborough, South Carolina on 8 May, 1784, from pieces of falling ice 9 inches in diameter. Even though hail has been cited as cause of death in Uvalde, Texas in 1909 and Windsor, North Carolina in 1931, the National Weather Service officially acknowledge only two deaths from hail during the twentieth Century. The first was on 13 May, 1939 in Lubbock, Texas, of a 39 year-old-farmer, and on 30 July, 1979, a 3-month-old boy (Jolene Kappelman) whose skull was crushed while in his mother's arm, resulting in his death from the injury 8 days later. Although fatalities from hail

are rare in the United States, the United States leads the world in total hailstorm damage.

Crops are most vulnerable to hail damage. In terms of total dollar value of damage sustained, the most susceptible crops in the United States are wheat, corn, soybeans, and tobacco. In 1997 hail destruction to crops was estimated at \$1.3 billion annually, representing up to 2% of the annual value of all crops in the United States. Property damage by hail in 1997 almost paralleled that of crop damage that approached \$1 billion. To lessen the economic consequences of hail, one out of every six farmers in the United States takes out hail insurance. In high-hail regions, insurance rates may amount to 30% of the crop value, with up to 6% of crops in the Great Plains experiencing loss. Annually, 25–30% of hail loss to crops annually in the United States is covered by hail insurance, with wide regional and temporal variations.

Hail suppression

One potential means of reducing losses due to hail is to reduce the fall of damaging hail. With cloud seeding an attempt is made to increase ice nuclei as a means of increasing the number of hail embryos competing for the supercooled water. The object of such seeding is to reduce the accumulation of large amounts of supercooled water by supplying the cloud with numerous freezing nuclei capable of converting water to ice, thus preventing the growth of large hailstones. It is thought that, as a result of these efforts, the hail reaching the Earth will be smaller and hence less damaging or that, under favorable conditions, the hail will melt completely during descent.

Hail suppression programs have been undertaken by over 15 nations in the past 40 years. Of the early projects the most ambitious were those of Russia, focusing on regions near the Caucasus Mountains. Russian scientists claimed a 50–80% reduction in crop hail losses by using rockets and artillery shells to supply the clouds with silver iodide nuclei. Statistical evaluation of Russian projects has not been possible, leaving their claims open to interpretation.

Stimulated by the Russian claims, the United States initiated the National Hail Research Experiment (NHRE) in 1972, eventually monitoring about 30 hailstorms (15 used as control storms) near the Colorado–Nebraska border. In 1975 an analysis of the observations of the NHRE failed to support statistically significant increases in the number of hailstorms associated with small hail or an increase in rain. In the 18-year period from 1958 to 1975, 137 cloud-seeding projects were attempted in the United States, and of these approximately 17% (61) dealt with some aspect of hail suppression. Controversy continues in assessing the possibility of significantly reducing hail. Cloud-seeding may increase the number of small hailstones under certain atmospheric combinations of temperature, velocity of updraft, and amount of supercooled water available, whereas other combinations may yield an increase in the number of large hailstones as well. Although there has been much interest and activity in hail suppression, controversy continues, since no adequate standard exists to determine the degree of success. Research into hail suppression has resulted in much additional information on hail formation, but with suspension of most of the federal funding research for suppression in the 1980s, and with declining public interest as to its effectiveness, investigations focusing specifically on hail suppression have declined. The formation, distribution, and suppression of hail continues to be a major topic of interest to climatologists and meteorologists.

HARE, F. KENNETH (1919–2002)

In his as-yet-unpublished autobiography, Ken Hare concludes with:

two conflicting self assessments... my students, colleagues and collaborators have done most of the real work.... I should have concentrated on a narrower range of subjects. I diffused my efforts – partly because of the strange cocktail of opportunities that I had to capitalize, but mainly because I am like my own pet beagle: I can't resist following any interesting scent that crosses my path.

The first comment hints at two key attributes of an individual who made important contributions during key times for the evolution of climatology – his typical self-deprecation, and his personally inspiring and enabling nature. The second self-assessment is poignant – it hints at a person who has left this world feeling his contributions could have been more substantive, and given greater recognition. But his contributions were not only substantial but also pioneering and perceptive. As a result of Hare's many and diverse contributions to climatology, and its cognate disciplines, the world is decidedly the better off for the somewhat eclectic (but far from esoteric) nature of his interests and contributions. The evidence is summarized in the paragraphs that follow. Ken Hare did deserve greater recognition, though in truth that was never his motivation. But the reality is that the world is more willing to recognize the innovative work of the reductionist scientist than the equally important contributions of the interdisciplinary researcher who explodes our understanding of policy-relevant science. Hare is a relatively unsung hero of climatology, but in 1989 he was awarded the International Meteorological Organization Prize from the World Meteorological Organization. He held 11 honorary degrees and was a Companion of the Order of Canada, recipient of the Order of Ontario, a Fellow of the Royal Society of Canada and President of the Royal Meteorological Society. Bailey, Oke and Rouse chose to dedicate their book *The Surface Climates of Canada* to Ken Hare, and accorded him the fitting honour of writing the opening chapter (see Bibliography, below). Ken Hare's important contributions to the University of Toronto were recognized by his prestigious appointment as University Professor. For several years Hare was Chairman of the Canadian Climate Planning Board for Environment Canada.

After graduating from the University of London (UK) with a first-class honours BSc, (Special) in geography, and with geology as a subsidiary subject, Hare's further studies and early career were disrupted by the Second World War. He was called up to join the British Meteorological Office, where he was trained and served as a weather forecaster. Thus began a distinguished career which linked many disciplines and continents. Hare's initial interests in landforms, landscapes and land-use were married with his expertise in dynamic meteorology, to forge an enduring interest in global climate and its stability. This in turn was often manifest by his studies into the exchanges and equilibria between the Earth's surface and its atmosphere, in order to understand the mutual interactions between soil and vegetation patterns and micro- and macro-climates. Hare's first postwar position was as an assistant professor of geography at McGill University, a formative start to an illustrious academic career that straddled the Atlantic, including

Dean of Arts and Science at McGill, Master of Birkbeck College, University of London, President of the University of British Columbia, Director of the Institute for Environmental Studies at the University of Toronto, Provost of that University's Trinity College, and Chancellor of Trent University.

Much of Hare's lifetime research focused on relating the characteristics of the northern boreal forest to the physical, dynamic and micro climates of the Canadian Arctic and sub-Arctic. Inspired by the work of such luminaries as Thornthwaite, Penman and Budyko, one of Ken Hare's major interests and research thrusts was heat and water balance climatology. Influenced also by the work of Lettau, he showed that all the familiar annual balance parameters of the hydrologists and climatologists – including the Bowen and run-off ratios, the Thornthwaite indices, Priestley–Taylor's alpha, and Budyko's dryness index – are simple linear or logarithmic transforms of one another, provided there is no change in annual water storage. Moreover, any three or four of these hydroclimatological measures form a conjugate set, definable for any locality, thereby characterizing uniquely the mean annual heat and water balance regime. Applications were many, including contributing to the debate on desiccation of the Sahel, and arid and semiarid climates more widely, by clarifying the parameterization of aridity. But perhaps the most seminal contribution was demonstrating that the depictions of mean annual precipitation and runoff for Canada were irreconcilable, to the extent that in some places mean annual runoff exceeded precipitation. This resulted in a comprehensive revision of the fields for precipitation, runoff and lake evaporation. Hare's specific and wider contributions on these topics are captured in such contributions as *Climate Canada* and *The Climate of Canada and Alaska* (see below).

In his later years, and again on both sides of the Atlantic, Hare was involved in numerous policy-related enquiries, reflecting not only his stature as an interdisciplinary scientist but also his integrity, objectivity, diplomacy and ability to think holistically, laterally and creatively. The enquiries covered such diverse themes and issues as nuclear waste disposal, trans-boundary air pollution and acid deposition, nuclear winter, global climate change, lead pollution, nuclear reactor safety and asbestos hazards.

But Ken Hare's most lasting legacy to climatology is the large number of his students who now lead and inspire others in their climatological and related investigations and other endeavors, throughout the world.

HEAT INDEX

High moisture content in the air adds to human discomfort when the temperature is high. Many indices have been developed over the years that are intended to approximate how hot it feels when both temperature and humidity are high (Quayle and Doebring, 1981). For example, when the temperature is 35°C and the dewpoint is 25°C, the air feels oppressively hot; whereas if the dewpoint is only 5°C, a temperature of 35° can seem almost tolerable.

The index that finds current favor in the U.S. is the Steadman heat index or simply heat index. It stems from the work of R.G. Steadman (1979a,b), who investigated the perception of heat under a variety of meteorological conditions using extensive data on human physiology. Steadman's tables give apparent temperature as a function of air temperature and relative humidity (Table H2) or, equivalently, air temperature and dewpoint (Table H1). The US National Weather Service quotes the heat index each summer.

Steadman's calculations assume standard sea-level barometric pressure (101.3 kPa, where kPa is kilopascal, given that 1 Pascal is a force of 1 Newton applied over an area of 1 square meter), a vapor pressure of 1.6 kPa (equivalent to a sea-level dewpoint of 14°C), a wind speed of 2.5 m s⁻¹, and no direct solar radiation. The person experiencing the heat is assumed to be walking.

In the table, note that if the dewpoint is less than 14°C, the apparent temperature is less than the actual air temperature. The reason is that evaporating sweat causes cooling on the surface of the skin and gives the sensation that the air is somewhat cooler than the actual temperature would suggest. If the dewpoint is greater than 14°C, sweat evaporates less readily, collects on the skin, and makes the subject more uncomfortable than the air temperature alone would suggest.

Steadman (1979b) notes that wind greater than 2.5 m s⁻¹ generally lowers the apparent temperature because of the increased evaporation of sweat. An exception occurs, however, when the air temperature approaches or exceeds body temperature (37°C) and the humidity is low. A hot, dry wind of 15 m s⁻¹ can raise the apparent temperature by 1–4°C. Finally, exposure to direct sunlight can raise the apparent temperature by as much as 7°C.

The US National Weather Service has guidelines for the following ranges of heat index:

32–40°C Heatstroke, heat cramps, or heat exhaustion are possible with prolonged exposure and/or physical activity.

41–53°C Heat cramps or heat exhaustion are likely, and heatstroke possible with continued exposure.

≥ 54°C Heatstroke is highly likely with continued exposure.

HEAT LOW

A heat low is a region of low barometric (atmospheric) pressure caused by intense local heating of the earth's surface. These systems are not frontal in nature. The air in direct contact with the heated surface will warm, become more buoyant, and rise. Rising air causes atmospheric pressure at the surface to decrease, and a "low" is created. This upward movement will eventually create an upper-level outflow (a "high" aloft) that induces more air to flow into the surface low. Heat lows (also called thermal lows) are commonly found over tropical and subtropical continental regions during the summer months. If moisture is available the thermal low may enhance convective rainfall or thunderstorm activity. Thermal lows are, at least, partially responsible for the movement of certain monsoonal winds.

Pressure, Surface

and Canada melting away, and sea levels rising to within a few meters of their modern elevations in most parts of the world. By contrast, during the second half of the Holocene, human impact has become an increasingly important agency in the modification of natural environments. A critical point in this endeavor was when *Homo sapiens* began the domestication of plants and animals, a process which began in regions such as the Near East and Mesoamerica very early in the Holocene, and which then spread progressively to almost all areas of the globe. For short histories of the Holocene, see Roberts (1989) and Bell and Walker (1992). Although there are different schools of thought about how the Holocene should be formally defined (see Watson and Wright, 1980), the most common view, and one which is supported by INQUA, is that the Holocene began 10 000 radiocarbon (^{14}C) years ago. But ^{14}C chronologies count AD 1950 as being the "present day" and also underestimate true, or calendar, ages by several centuries for most of the Holocene. None the less, there is evidence of a global climatic shift remarkably close to 10 000 ^{14}C yr BP (years before present), often involving a sharp rise in temperature (see Atkinson et al., 1987).

Various attempts have been made to subdivide the Holocene, usually on the basis of inferred climatic changes. Blytt and Semander, for instance, proposed a scheme of alternating cool-wet and warm-dry phases based on shifts in peat stratigraphy in northern Europe. Some researchers believe there is evidence of a "thermal optimum" during the early-to-mid part of the Holocene. During the 1980s the Cooperative Holocene Mapping Project (COHMAP) members established a comprehensive paleoclimatic database for the Holocene (Wright et al., 1993), and showed that variations in the Earth's orbit were the principal cause of differences in climate between the early Holocene and the present day. For this reason the early Holocene is unlikely to provide a good direct analog for a future climate subject to greenhouse-gas warming (Street-Perrott and Roberts, 1993).

Neil Roberts

HOLOCENE EPOCH

The Holocene, or "wholly recent", Epoch is the youngest phase of Earth history. It began when the last glaciation ended, and for this reason is sometimes also known as the postglacial period. In reality, however, the Holocene is one of many interglacials which have punctuated the late Cainozoic Ice Age. The term was introduced by Gervais in 1869 and was accepted as part of valid geological nomenclature by the International Geological Congress in 1885. The International Union for Quaternary Research (INQUA) has a Commission devoted to the study of the Holocene, and several IGCP projects have been based around environmental changes during the Holocene. A technical guide produced by IGCP Subproject 158B (*Palaeohydrological Changes in the Temperate Zone*) represents one of the most comprehensive accounts so far of Holocene research methods (Berglund, 1986). Since 1991 there has also existed a journal dedicated exclusively to Holocene research (*The Holocene*, published by Edward Arnold).

During the Holocene, the Earth's climates and environments took on their modern, natural form. Change was especially rapid during the first few millennia, with forests returning from their glacial refugia, the remaining ice sheets over Scandinavia

HORSE LATITUDES

Horse latitudes is a term used to describe north and south Subtropical High atmospheric pressure belts. The term is now used only rarely in modern studies. Marked by dry sinking air, these Subtropical High atmospheric pressure belts are centered around 35°N and 30°S, extending approximately 25° to 40°, respectively, N and S, and shifting seasonally – to the north in the northern summer and to the south in the southern summer. Characterized by light winds and fine, clear weather, where not modified by continental factors, they are sometimes known as the *Calms of Cancer* and *Calms of Capricorn*. In the northern Atlantic the Calms of Cancer include the Sargasso Sea, the lack of wind combining with the gyrotatory current system to make this an exceptionally difficult region to cross in the days of the sailing ships. According to the *Oxford English Dictionary*, the origin of the name “horse latitudes” is uncertain. However, it has been suggested that sailing ships carrying horses to the West Indies, if becalmed unduly in the Sargasso Sea, occasionally had to jettison their live cargo as fodder ran out.

The two belts merge equatorially into the belts of the Northeast Trade Winds and the Southeast Trade Winds. Poleward they merge into the westerly, zonal wind belts. Over the oceans the horse latitudes correspond approximately to the areas of maximal evaporation. Over land the air is exceptionally dry.

HOWARD, LUKE (1772–1864)

Luke Howard was born in 1772 in London, England. Although by profession he was a manufacturing chemist and pharmacist, he was also an amateur meteorologist who is credited with the first successful and logical classification of clouds based on appearance. Howard was educated at a Quaker school in Burford, Oxfordshire and became a devout Quaker and family man – Mariabella (Eliot) Howard, his wife, and three children. Although his professional life was that of a chemist, he stated that “meteorology was my real penchant”.

In his attempt to classify clouds, Howard believed that the terms should describe the appearance of the clouds and use a

common language that Europeans and non-Europeans could understand – Latin – rather than the vernacular which was attempted by Jean-Baptiste Lamarck of France. Lamarck's classification of clouds was not unlike Howard's basic idea that clouds have distinct appearances. However, there were three reasons that Lamarck's scheme failed – first, the use of the scheme which did not use the Linnaean style of nomenclature; second, the language was French not Latin, which would only be useful to French-speaking people; and third, it was too difficult to understand. Howard's success of classifying clouds came about when he used a similar method of classifying plants and animals by the Swedish taxonomist Carl von Linné (Linnaeus). The style of nomenclature used identified the genus and further specified the species. Howard's scheme was widely accepted for two reasons: similar clouds occur globally, which allowed the use of an internationally accepted language, and the proper use of nomenclature.

In his book, *On the Modification (classification) of Clouds* (1804), Howard presented three distinct basic forms of clouds: *stratus* meaning layered, *cumulus* having a stacked appearance, and *cirrus* regarding the appearance of an angel's hair. In addition, four cloud forms were introduced: *cirro-cumulus*, *cirro-stratus*, *cumulo-stratus*, and *cumulo-cirro-stratus*. Howard believed, from his study of cloud formations, that one could predict the weather through observing clouds.

Howard's classification scheme and detailed descriptions from republished essays inspired a few Romantic painters such as John Constable and Joseph M. W. Turner in the accuracy of illustrating clouds in their works of art (Thornes, 1984; Heidorn, 1999).

In addition to Howard's book, *On the Modification of Clouds*, he further presented a range of papers and lectures on meteorological topics, including *Average Barometer* (1800), and *Theories of Rain* (1802). In 1806 Howard began a register of meteorological observations, which were regularly published in the *Athenaeum Magazine* in 1807. A series of *Seven Lectures in Meteorology* (presented in 1817) that Howard gave were later published as a textbook on meteorology in 1837. Howard began a study of London's urban climate that culminated into two volumes, *The Climate of London* (1818–1819). In 1821 Howard became a member of the Royal Society, an organization of scientists and inventors, and later published his final work, *Barometrographia* (1847).

Although not much has been written about Howard's life and his classification of the clouds, Richard Hamblyn's book, *The Invention of the Clouds: how an amateur meteorologist forged the language of the skies*, provides a history into the life of Luke Howard and his creation of the classification of clouds. On 17 April 2002 English Heritage of England awarded a plaque to be placed on the home of Howard to honor his achievements to the study of meteorology and climatology. Although Howard's original classification has been modified and further cloud types added, such as *cumulus congestus*, *cumulus fractus*, *cumulonimbus calvus*, and *stratocumulus undulates*, his concept is still used around the world in meteorological and climatological studies.

Cloud Climatology

HUMAN HEALTH AND CLIMATE

The impact of climate on human health has commanded increasing attention in light of growing research indicating a strong relationship and because of the very real possibility of a global-scale climate change. Human physiological adaptive responses, such as sweating, are largely determined by climatic factors. Even though modifications of the indoor environment, such as heating and air-conditioning, may influence considerably the atmospheric conditions to which humans are exposed, it is still clear that the human population is significantly impacted by the vagaries of weather. In addition, individual lifestyles, such as behavioral modifications and clothing habits, also influence the exposure levels of people, even if they live in the same habitat.

Climate also acts on human health indirectly through its effects on ecosystems, on the hydrologic cycle, on food species, and on disease agents and vectors. Studies on climate's indirect effects upon human health are less intensive than on direct effects, but it is clear that many causes of illness and death occur through climate's impact on ecosystem modification.

Climatic thresholds

Within certain ranges of tolerance, human biology can handle most variations in climate, whether these relate to rate of change or degree of change. But large short-term fluctuations in weather can cause acute adverse effects, often indicated by increased death rates, upswings in hospital admissions, and increases in the number of individuals complaining of mental stress, such as depression (WHO/WMO/UNEP, 1996). In fact, the notion of a "temperature threshold", which represents the temperature beyond which human health declines precipitously, is common in numerous studies, and in many midlatitude cities in summer it is apparent that elevated mortality occurs only during the hottest 10–15% of days with temperatures above the threshold (Auliciems et al., 1998). Even more interesting is the notion that these threshold temperatures are *relative* rather than *absolute*; they actually vary from locale to locale, depending upon their frequency. For example, the temperature exceeds 36°C in St Louis with approximately the same frequency that it exceeds 32°C in Detroit, values which represent threshold temperatures for these cities (Mills, 2004). This strongly suggests that the notion of a "heat wave" is relative on an interregional scale, and is dependent upon the frequency of times that the local threshold is exceeded.

A most interesting finding related to heat- and cold-induced mortality which potentially could have a profound influence on such deaths in a warmer world is the large degree of variation in response on an interregional level. Recent studies on summer mortality demonstrate that many cities in temperate regions, where hot weather is severe but irregular in occurrence, show a sharp rise in total mortality during unusually hot weather conditions (IPCC, 1996; Kalkstein and Greene, 1997). In some cases daily mortality can be more than double baseline levels when weather is oppressive (Figure H5). Conversely, cities in more tropical locales seem less affected by hot weather. One possible explanation for this interregional disparity may involve the variance in summer temperatures across regions. In the cities of the northern and midwestern US, for example, the very hot days or episodes are imbedded within periods of cooler weather. Thus, the physiological and behavioral "shock value" of very high temperature is considerable. In tropical cities the hottest periods are less unique, as they do not vary much from the mean. Low variability in the fluctuation of thermal meteorological variables seems to lead to a diminishing impact of a very hot episode on human health. Thus, less people die in Phoenix when the temperature is 45°C than in New York City when the temperature is 35°C. Although the concept is not intuitive, weather variability thus plays as important a role in affecting human health as does the intensity of individual weather events.

Similar findings occur with cold-related mortality and morbidity, but the prevalence of infectious agents in the winter, and their rapid spread because of indoor confinement, renders winter health research a more daunting task. However, there is evidence that the impact of weather on human health in winter is also relative in nature, and weather variability also plays a large role in creating winter weather health problems (Keatinge et al., 1997).

Direct weather-related health problems

Clearly, direct exposure to hostile weather elements, such as lightning strikes and hurricanes, can kill large numbers of people very rapidly. However, the largest direct weather-related killer is extreme heat and cold. The combination of temperature, wind, and humidity produce an "apparent temperature", which is the perceived temperature to the human body (Steadman, 1984). Healthy persons have efficient heat-regulatory mechanisms which cope with increases in apparent temperature up to the threshold condition. When exposed to heat the body can increase radiant, convective, and evaporative heat loss by methods such as vasodilation (enlargement of blood vessels) and perspiration (Diamond, 1991). In addition, acclimatization to oppressive conditions can occur during several days with continuing exposure (Kilbourne, 1992). However, there are obvious indications that the body cannot cope with oppressive conditions indefinitely, as indicated in Figure H5 (Kalkstein and Smoyer, 1993). The rapidity of deteriorating conditions beyond the threshold is startling (WMO, 2003).

Some recent studies have utilized a "synoptic climatological approach" to identify meteorological conditions which exceed the threshold. The synoptic approach identifies "airmasses" which comprise the entire umbrella of air affecting individuals. Thus, the interaction of numerous meteorological factors is evaluated simultaneously, and their impact on human health can be assessed (Kalkstein, 1999). Each day is assigned to a particular airmass, allowing for the identification of "offensive airmasses", which contain days with mortality that exceeds the

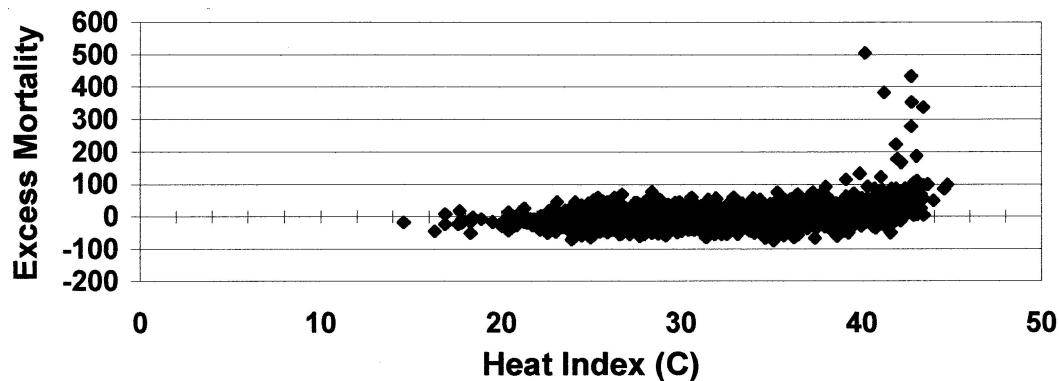

Figure H5 Shanghai daily mortality.

baseline for a locale. For example, in Shanghai, an airmass which included days with high afternoon temperatures, low wind speeds, and low humidity was deemed offensive (Tan et al., 2004).

The elderly and very young appear to be disproportionately affected by offensive airmasses, as they possess a limited ability to adapt to stressful conditions. There is evidence that individuals living in poverty, as well as urban populations in developing countries such as China and northern India, are particularly vulnerable to heat stress. Poor housing conditions, the exacerbation of stress because of the “urban heat island”, and the lack of access to air-conditioning are frequently cited as primary causes (Kilbourne, 1989; Mestel, 1995).

Although the most direct impact of heat stress on the human body is the onset of heat exhaustion or heat stroke, it appears that morbidity and mortality increases associated with hot weather are related to a variety of causes. For example, deaths from cardiovascular, respiratory, and immune system disorders, as well as accidents, appear to increase during stressful weather conditions and; surprisingly, heat stroke and heat exhaustion represent only a small proportion of the mortality increase (IPCC, 1996).

The relationship between weather and cold-related mortality is less clear, and disagreements appear in the literature. In many countries the death rate in winter is 10–25% higher than during the rest of the year. However, the existence of a threshold temperature is less evident in winter than in summer (Jendritzky, 1995). Although deaths from cardiovascular disease are important in both seasons, influenza, pneumonia, and increased mortality from a variety of accidents appear to be of greater significance in winter than in summer (Langford and Bentham, 1995). In some cold-weather locales, such as Montreal and Minneapolis, the increase in mortality with decreasing winter temperature is slight (Frost and Auliciems, 1993). However, in less extreme climates, such as those in Europe, mortality rates seem to rise linearly with decreasing wintertime temperatures (Keatinge et al., 1997). People in temperate environments may be less accustomed to extreme cold, while in colder climates, behavioral responses such as cold avoidance may be a dominant thermoregulatory process when very cold temperatures occur.

There is a major discussion among biometeorologists who are exploring the possibility that a global climate change might exacerbate health problems from direct causes. The IPCC clearly expects that a climate change including increased warming will produce increases in direct weather-related summer mortality, primarily because of the existence of greater

numbers of days above threshold conditions and the inability of the population to adapt to the increased heat (IPCC, 1996, 2001). Although most research points to worsening conditions for direct weather-related human health problems if the globe warms, there are large question marks. First, will possible decreases in cold-related mortality compensate for increases in hot-weather mortality in a warmer world? Some authors believe that this will be the case, especially in moderate European climates (Langford and Bentham, 1995). Others believe that the increased respiratory infections in winter will not be decreased significantly in a warmer world, since such infections partially depend on aerosol transmission in poorly ventilated places. The relatively small rise in winter temperatures will probably not encourage outdoor activities to a level where risk is reduced (Mills, 2004), and to support this stand, there appears to be a poor correlation between winter temperature and annual influenza outbreaks (CDC, 1994).

However, it is not certain how much summer mortality will increase, even if the world warms (Davis et al., 2004). For example, if climate change is accompanied by a decrease in summer temperature variability, it is possible that heat-related mortality will not increase substantially, even in a warmer world. However, if variability is similar to the present, or if it increases, the likelihood of increased summer mortality is much more likely (WHO/WMO/UNEP, 1996; Mills, 2004).

Mitigating measures to lessen direct-weather-related health problems

A number of strategies are possible to reduce the impact of weather on present and future weather-related mortality. For example, the introduction of protective technologies (e.g. improving insulation, extension of air-conditioning use) would be helpful (WHO/WMO/UNEP, 1996). In addition, there are a number of cost-effective options to lower summer temperatures in dwellings while saving billions of dollars in energy costs. Widespread use of reflective paint and innovative roofing materials might decrease in-home temperatures sufficiently to lessen heat-related mortality (WMO, 2003).

A pressing requirement is for an adequate surveillance system to alert the public and city agencies responsible for public health that dangerous weather is predicted. Such a system is in place at a number of municipalities around the world, and recent forecast improvements have probably saved many lives (Kalkstein et al., 1996; Tiesberg et al., 2004). The present

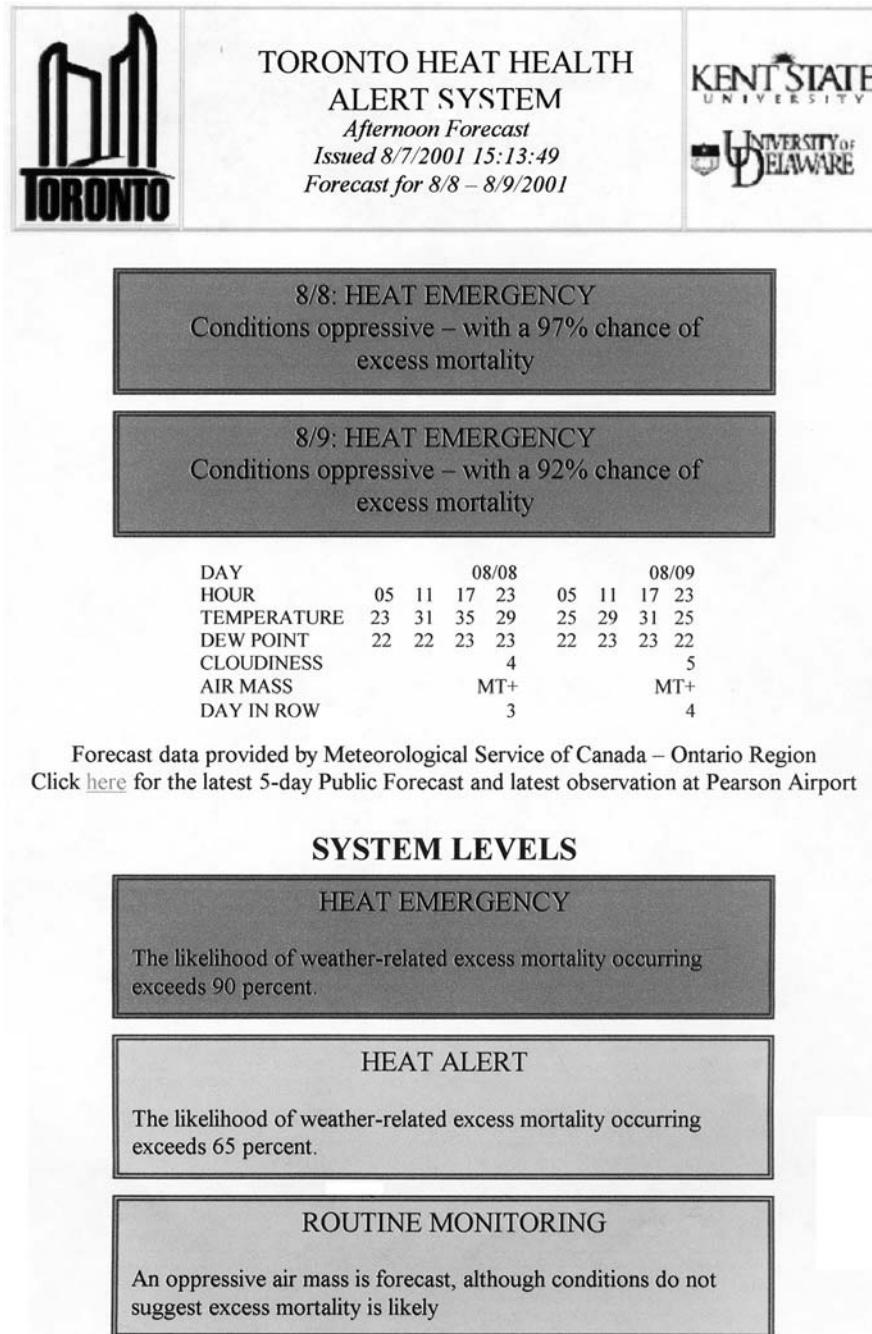

Figure H6 The Toronto heat health alert system.

systems in Philadelphia and Toronto are considered by many as state-of-the-art (Figure H6). Besides possessing a high degree of accuracy, these cities have instituted a large number of intervention techniques that are novel, including the use of numerous city volunteers to deal with vulnerable citizens within their community. The number and sophistication of these systems are increasing rapidly, especially in the US, where a nationalization of standardized systems is presently under way.

Infectious disease and climate

Since the introduction of vaccines and improved nutrition and sanitation, such once-devastating infectious diseases as influenza are no longer among the leading causes of death in developed nations. However, other infectious diseases, once considered to be in broad retreat, are now resurgent in many parts of the world. This situation reflects a global convergence of a number of factors, including rapid population growth and

density, greater human mobility, inappropriate use of pesticides and antibiotics, and regional climate disturbances (WHO/WMO/UNEP, 1996). Many of the biological organisms linked to the spread of infectious diseases are especially influenced by fluctuations in climate, notably thermal and moisture variables. A majority of these fluctuations are part of normal climatic variability, as indicated by the seasonality of the diseases. For example, onchocerciasis (river blindness), an important vector-borne disease in tropical countries which is transmitted by a small black fly, is largely tied into the monsoonal climates of these regions. Wet conditions during the high-sun season increase transmission dramatically, while dry conditions initiate great reductions (Mills, 1995).

Climate affects the vector biology in many ways. For example, warmer temperatures accelerate vectors' metabolic processes, consequently affecting their nutritional requirements. Blood-feeding vectors need to feed more frequently. Their biting rate therefore increases, which can lead to increases in egg production. Temperature changes can also affect the distribution of many arthropod vectors, since this is limited geographically by ranges of tolerance of the organisms (Dobson and Carper, 1993). High humidity prolongs the survival of most arthropods, while low humidity might cause some vectors to feed more frequently to compensate for dehydration. Precipitation is important, especially for insects that have aquatic larvae and pupae stages, as it is precipitation that determines the presence or absence of breeding sites. In short, climate is a major factor in vector development and subsequent disease transmission.

Of a number of infectious diseases which are closely tied to climate, there are at least three that may become particularly troublesome if the climate warms. One of them, malaria, presently kills millions annually, and is transmitted by a number of species of *Anopheles* mosquitoes. The infectious agent of malaria is any of four species of parasitic microorganisms of the genus *Plasmodium*. The malarial parasite requires a temperature of at least 15°C to complete its development within the mosquito, while the mosquito vector requires a temperature of at least 16°C and prefers a relative humidity above 60% (WHO/WMO/UNEP, 1996). The parasitic agent develops much more quickly with elevated temperatures; at 30°C its reproductive rate is more than twice that at 20°C. Thus, abundance of both the parasite and the vector could increase considerably under warmer conditions. Moreover, increased use of irrigation, which is possible if moisture stress increases under climate change, has the potential for creating numerous new breeding grounds for mosquitoes. Malaria is already showing a range increase; whether this is due to climate change is uncertain, but the potential is great for more widespread appearances of this dangerous disease (Carcavallo et al., 1996).

Trypanosomiasis (sleeping sickness) is a major disease of humans and their domestic animals in Africa. It is particularly important because its presence may preclude human habitation from areas where wild animals act as a reservoir for the disease. Its agents are various species of parasitic microorganisms of the genus *Trypanosoma*, which is transmitted by an insect vector, the tsetse fly. Research has indicated that mortality rates of the tsetse fly are closely related to humidity, and to a lesser extent to temperature. Information on the climatic requirements of the insect has been used to construct a possible distribution, given a 2°C increase in temperature in sub-Saharan Africa. The analysis suggests that the tsetse fly would become less frequent near the north edge of its range (because of drier conditions adjacent

to desert landscapes) but would become more frequent toward the south (Rogers and Williams, 1993). Studies show that a very small change in temperatures can alter the range of the tsetse fly significantly.

Dengue fever is widespread in Asia, Oceania, Australia, tropical America, and the Caribbean. It is caused by one of four distinct viruses (known as "arboviruses", because they are transmitted by arthropods) which are transmitted by a mosquito, *Aedes aegypti* or *Aedes albopictus*. The current range of these insects is limited by cold weather, which kills both larvae and adults. Dengue is a particularly insidious disease that is characterized by the abrupt onset of fever, severe headache, muscle and bone pain (the disease is commonly called "breakbone fever"), and sometimes hemorrhaging of blood vessels. Some forms can be fatal if treatment is not available.

One of the unique challenges to climatologists involving dengue is that the insect vector breeds frequently in old tires and containers. Thus, many climatologists have taken a water-budget approach to evaluate the likelihood that the vector is prevalent (Cheng et al., 1998). At present a number of models are available to evaluate and estimate mosquito populations that transmit dengue, and are being used to control pesticide application. However, this disease is a major menace, and can continue to spread if the climate warms.

There are a number of vector-borne and water-borne diseases that are sensitive to climate. Until the recent past, research on these diseases was limited to the medical community, and finally, climatologists are becoming more involved in modeling the spread and transmission of these diseases.

Other weather-related/health issues

The relationship between climate and human health is multi-faceted and complex beyond any potential discussion here. However, some other key issues of interest include:

1. *The potential synergism between weather/pollution/human health.* It is clear that pollution has a sizable negative impact on human health, but the synergistic impacts of oppressive weather and unhealthy pollution episodes are still not fully understood. Some research indicates that weather is a confounding factor in strengthening the impact of pollution on human health (Samet et al., 1998). Other studies indicate that, when the weather is already oppressive (especially in summer), many extra deaths will occur no matter what the pollution concentration (Kalkstein, 1995). Studies of this type acknowledge that high pollution concentrations are dangerous to humans, but the real acute impact of these concentrations is generally noted when the weather is benign. However, there seems to be general agreement that weather and pollution can combine synergistically to create a negative environment for asthma sufferers. With this in mind, there are attempts to develop asthma warning systems, to advise sufferers that the combination of meteorology, pollution, and aeroallergens is such that there is a high likelihood of discomfort among asthma patients (Jamason et al., 1997).
2. *Stratospheric ozone depletion.* Although not exactly a weather/health issue, there has been considerable research describing the impacts of ultraviolet exposure on the human body. These analyses assume that the thinning ozone layer over parts of the Earth has created environments where humans are more vulnerable to direct sun exposure. Some of

the most common conditions associated with extended exposure to UV-B radiation include skin cancers, cataracts and eye damage, a reduction of immune system function, and large negative impacts to terrestrial and aquatic species of animals and plants (WHO/WMO/UNEP, 1996).

3. *Sea level rise.* Many climate change advocates have developed extensive research on how sea level rise can negatively impact human health. Some of these assume that a long-term climate warming can increase sea level by up to a meter over the next 100 years (IPCC, 2001). The potential impacts of sea level rise on human health are multifaceted, and include population displacement, increase in vector-borne diseases, lessening of food availability, and greater probabilities of coastal flooding (WHO/WMO/UNEP, 1996).

Considering the numerous links between meteorology and human health, the World Meteorological Organization, the World Health Organization, and the United Nations Environmental Programme have developed an initiative to encourage interdisciplinary collaboration to achieve greater integration between the human dimensions and biophysical dimensions of this issue. Some of the recommendations include: expansion of electronic data exchange to enhance climate–health researchers, development of integrated process-oriented models to understand the complex linkages, strengthening the role of international agencies (such as the WMO, WHO, and UNEP) to provide technical support and policy advice to various governments, and creation of multidisciplinary scientific advisory boards to address long-term environmental and health issues. The heightened awareness of climate-induced health problems should permit meteorological and health practitioners to move aggressively in meeting these ends.

VON HUMBOLDT (BARON), FRIEDRICH HEINRICH ALEXANDER (1769–1859)

Alexander von Humboldt was born in Berlin in 1769 and died there in 1859. He is widely regarded as a scientific “renaissance man” who was able to observe and integrate a variety of natural phenomena. He attended the universities of Göttingen, Frankfurt-on-Oder, and Freiburg, with fieldwork emphasizing botany and geology. His travels with botanist Aimé Bonpland to South America, Mexico, Cuba, and the United States (1799–1804) led to development of 30 volumes, *Voyage de Humboldt et Bonpland (Personal Narrative in the English edition)*, published from 1807 to 1817. He sought to understand the interaction of natural forces, the influences of geography on living things, and “the unity of nature”.

In 1817 Humboldt became the first to use temperature observations to construct an isothermal map, evidently based on earlier isogonic maps by Edmond Halley. During his travels he had identified the Peruvian current, which sometimes is called the Humboldt current. Humboldt’s isotherm maps were adjusted to sea level, depicting the effects of latitude, but also showing ocean current effects. Although his isothermal map removed the effect of topography on temperature, his experiences in South America, particularly the Andes, led to recognition of the similar effects of altitude and latitude on vegetation.

In 1829 Humboldt spent time in Russia, with 6 months of exploration funded by Tsar Nicholas I. Humboldt was able to use extensively collected temperature data to develop the idea of continentality. He worked with mathematician Karl Gauss to establish a worldwide network of weather and magnetic observatories. A number of European countries were convinced to do so, including Russia; this created “the first large-scale international collaboration”.

Humboldt’s second great series of volumes, *Kosmos*, was published 1845–1862. In its five volumes Humboldt attempted to describe the universe as it was then known. He spent a quarter-century writing this series; the last volume was completed after his death, based on his notes. *Kosmos* was Humboldt’s attempt to present “the unity of nature”.

HUMID CLIMATES

Humid climates are commonly considered to be those that support forests as the typical vegetation cover (Huschke, 1970); thus the term forest climate often is applied. However, several alternate definitions, from broad generalizations to detailed specifications, also exist.

One alternate definition specifies that a humid climate is one in which annual precipitation exceeds evaporation. This definition encompasses all areas that are not desert or semiarid, although the icecap climates of Antarctica and Greenland, where annual precipitation is generally less than 130 mm, often are also excluded. According to this interpretation, humid climates cover approximately 74% of Earth’s land surface (approximately 64% if the icecaps are excluded).

Other approaches to delineating humid regions were developed by Thornthwaite (Griffiths and Driscoll, 1982; Oliver and Hidore, 2002; Thornthwaite, 1931, 1948), as part of general climatic classifications. A central assumption of Thornthwaite’s earlier (1931) classification is that to quantitatively determine whether a region is truly humid or not, the precipitation of the region must be compared with what has been termed the climatic demand for water. This concept was incorporated through the use of a moisture index. Humid climates have positive index values and dry climates have negative values. Table H3 shows the basic groups of the moisture index. Climate types A (perhumid) and B (humid) are generally referred to collectively as the humid climates. Together they comprise approximately 18% of Earth’s land. The generalized global distribution of the perhumid and humid climates is shown in Figure H7. The perhumid climate (group A in Table H3) is concentrated in tropical regions, such as Malaysia, southern Philippines and the west coast of India. It is also found on the coast of west-central Africa, throughout much of Central America, especially the eastern portion, on parts of the northern coast of South America, and on west coasts in higher middle latitudes, especially northwestern United States and southwestern Chile.

Group B climate (humid group in Table H3), which is slightly less wet than the perhumid group, is extensive in tropical and middle latitudes, particularly the Amazon Basin, southeastern Brazil, equatorial Africa, eastern and northwestern United States, Japan, southeast Asia, eastern Australia, New Zealand, and central and western Europe.

Interestingly, the extensive taiga (boreal) forests centered at about 60°N latitude are not included in Thornthwaite’s humid (groups A and B) climates. In this region, as well as in more poleward areas, temperature efficiency, rather than precipitation effectiveness, is the most critical influence on plant distribution; temperature provinces, instead of moisture groups, are the basis for Thornthwaite’s climatic divisions in these areas. Soil moisture is relatively abundant in the taiga zone, although it is often frozen for a portion of the year.

Because humid climates occupy such diverse global positions, there are few universally applicable characteristics. However, in comparison with arid areas, humid regions, which are generally dominated by forests, utilize a much larger portion of solar radiation in the process of evapotranspiration. Thus there is less energy available to heat the atmosphere; consequently humid regions are less likely to have the

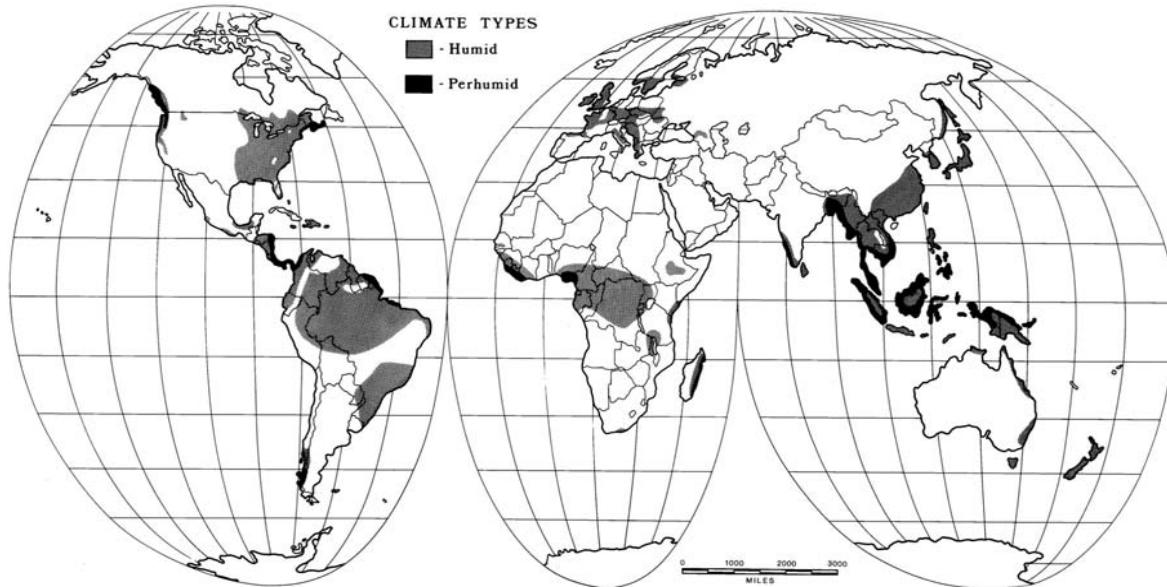

Figure H7 Thornthwaite's perhumid and humid moisture regimes (after US Department of Agriculture, 1941; Griffiths and Driscoll, 1982).

HUMIDITY

Humidity refers to the water vapor content of air. Several ways of expressing humidity are:

1. *Absolute humidity* (also known as vapor concentration or vapor density). For a moist parcel of air the ratio of the mass of water vapor to the volume of the parcel is called the absolute humidity, i.e. the density of the water vapor. It is expressed in grams of water vapor per cubic meter, or by engineers (as in air-conditioning) in grains per cubic foot (1 grain = 0.0648 g and 1 cubic foot = 28 317 cm³). For meteorologists the absolute humidity is not very useful since it neglects questions of pressure.
2. *Specific humidity*. This is the ratio of the mass of water vapor to the mass of air, expressed as grams of vapor per kilogram of air or as grains per pound (in air-conditioning). This figure may be quoted regardless of temperature and volume (related to the atmospheric pressure), therefore for meteorology it is a much more useful expression than absolute humidity. For most purposes the specific humidity may be approximated by the mixing ratio (the ratio of mass of water vapor to mass of dry air) thus:

$$q = \frac{w}{(1 + w)}$$

where q is specific humidity and w the mixing ratio. The terms specific humidity and mixing ratio thus are used interchangeably because the amount that they differ by is less than the error involved in measuring either one of them.

3. *Relative humidity*. This is what is commonly meant by "humidity". It is the dimensionless ratio of vapor that a given quantity of air can contain for a given temperature,

expressed as a percentage. Perfectly dry air has a relative humidity of 0%; totally saturated air, 100%. Thus:

$$r = \frac{w}{w_s}$$

where w_s is the saturation mixing ratio.

Humidity measurement, hygrometry and hygrometers

The techniques of humidity determination are known as hygrometry and the class of instruments as hygrometers. The term hygroscopic pertains to a substance altered on contact with water vapor. In certain clouds, fog, and haze, condensation may be initiated on hygroscopic nuclei (NaCl) even when relative humidity may be only 75%. Of the hygrometric instruments there are several types, operating on varied principles:

1. *Hair hygrometer* and related devices depend on the absorption of moisture and change of physical dimensions of a particular substance. This substance may be a strand of human hair or other animal hair, which may be appropriately treated so that it varies in length (it increases approximately logarithmically) with a relative humidity increase of 20–100%. Its lag time at low temperatures is serious and essentially infinity at -40°C . The torsion hygrometer is simply a variety where the hair is twisted to cause a rotation (indicated on a dial) during expansion or contraction. Another is the goldbeater's-skin hygrometer, using the expansion characteristics of a length of skin from the large intestine of the ox, such as is used in goldbeating.
2. *Electrical absorption hygrometers* depend on change of electrical properties during absorption of water vapor. A simple form, electrically operated, uses a film of carbon black dispersed in a hygroscopic binder on a plastic strip. Another, called the humidity strip, often used in radiosondes, uses the electrolytic principle on a plastic strip coated with lithium chloride or other hygroscopic compound. Absorption of moisture changes the resistance of the circuit, thus indicating humidity.
3. *Diffusion hygrometer* measures the diffusion of water vapor through a porous membrane, to be absorbed in a container by a hygroscopic medium, the drop in pressure in the container being measured by a manometer.
4. *Spectral hygrometer*, an electronic-optical class of instruments that measure the absorption spectra of water vapor, i.e. the attenuation of radiant energy due to the absorption bands of water vapor.
5. *Psychrometer or wet- and dry-bulb hygrometer*, the most widespread and generally useful instrument, a thermodynamic procedure, utilizing two matched mercury thermometers, one of which has damped muslin wrapped around the bulb, the muslin being wetted in distilled water before making the reading. A psychrometric chart is a nomograph for graphical determination of relative humidity, absolute humidity, and dewpoint from wet- and dry-bulb thermometer readings. Alternatively, a circular slide rule may be used as a psychrometric calculator.

Humidity in climatology

Humidity is one of the basic concepts of climatology, essential for considering comfort, the habitability of a region, the

agricultural potential, and the pedologic characteristics. It has to be considered alongside an aridity index.

Humidity coefficient, proposed by A. J. Angstrom to indicate the precipitation effectiveness of a region, recognizes the exponential relationship of temperature to plant growth, and is expressed as $P/(1.07)^t$, where P is precipitation in centimeters and t is mean temperature in degrees Celsius for the period.

Humidity index, devised by C. W. Thornthwaite (1948) as a measure of water surplus over water need at a given point, and given by $100s/n$, with s being water surplus (the sum of monthly differences between precipitation and potential evapotranspiration for those months when the former exceeds the latter, and n being water need, determined by the sum of monthly potential evaporation for those months of surplus). The humidity index is used as a component in Thornthwaite's moisture index and as a basis for classifying climates in general.

Humidity province, a regional unit in Thornthwaite's classification of 1931, characterized by climax vegetation (rainforest, tundra, etc.). Five classes of humidity province were proposed (bounded by values of precipitation effectiveness index): (A) wet or rain forest; (B) humid or forest; (C) subhumid or grassland (D) semiarid or steppe; (E) arid or desert. In his 1948 system Thornthwaite removed the biologic consideration (vegetation climax) and used values of the moisture index for identifying rather similar regions: (A) perhumid; (B) humid; (C) subhumid; (D) semiarid; (E) arid. Moisture index can be calculated by the formula:

$$I_m = \frac{(100 \times \text{water surplus}) - (60 \times \text{water deficit})}{\text{potential evapotranspiration}}$$

which becomes

$$I_m = \frac{100s - 60d}{n}.$$

where I_m is the moisture index, s the water surplus, d the water deficiency, and n the water need.

HYDROCLIMATOLOGY

Hydroclimatology was defined by Langbein (1967) as the study of the influence of climate upon the waters of the land. It includes hydrometeorology as well as the surface and near-surface water processes of evaporation, runoff, groundwater recharge, and interception. The total hydrologic cycle, then, is the basis for a discussion of hydroclimatology.

The water budget equation based on conservation of mass is given as:

$$P = R + ET + U \pm \Delta S_s \pm \Delta S_g + I$$

where P is precipitation, R is streamflow, ET is evapotranspiration, U is subsurface underflow, ΔS_s is the change in soil moisture, ΔS_g the change in groundwater storage, and I is interception. When the equation is evaluated using annual mean data, the changes in groundwater storage, soil moisture and subsurface underflow are assumed to be zero; and if the interception is sufficiently small, all four terms may be deleted. Although the components of the total budget are easy to list, quantification of each of the components over various time scales is always difficult, and sometimes impossible to measure or to estimate correctly.

Observations of the standard meteorological parameters have been made continuously since the late 1880s at some 250 National Weather Service (NWS) First Order Stations (major airports in the US). Daily observations of temperature, precipitation and snowfall are routinely made at about 6000 NWS so-called Second Order sites. These provide the necessary means for the study of climate and climate change. During the last 20 years or so many states have inaugurated networks of automated observing sites where the standard parameters are continuously sensed and recorded. In addition, these data are generally on line and hence available on a near real-time basis.

Measurement of water budget components

Precipitation

Measurement of precipitation is typically accomplished by catching the rain or snow in a flat-bottomed, vertically sided canister, and simply measuring the depth, either after each precipitation event or continuously by an automatic sensor and recorder. Catchment of solid precipitation (particularly under windy conditions) often underestimates, in that snow is easily blown over the gauge opening rather than falling in. Liquid precipitation and the water equivalent of freezing precipitation, too, are subject to depletion by wind.

A different, but equally important problem, relates to the measurement of the spatial distribution of rainfall rates and amounts. Low-latitude and most warm-season precipitation in summer is convective in nature, i.e. precipitation emanating from cumuliform clouds. Individual clouds typically exhibit a horizontal extent of only a few kilometers. Therefore the spatial distribution of precipitation, even over flat terrain or the ocean, can be quite variable. In the extreme case, rainfall at the rate of a few tens of millimeters per hour can occur in one location with no precipitation occurring only a few kilometers distant.

Rain gauge densities sufficient to measure small-scale anomalies of, say, 1-km scale have only been maintained for research, rather than for operational networks. Changnon (1979) describes 14 meso-networks or rain gauges in Illinois operated by the Illinois State Water Survey during the last three decades. The networks ranged from 0.03 km^2 (18 gauges) to 3800 km^2 (250 gauges). The former was operated during 20 warm seasons, the latter for four. Some of the precipitation anomaly patterns are discussed by Changnon and Vogel (1981).

The spatial distribution of precipitation is typically determined from measurements made at several rain gauges within a given area. On scales of a few tens of kilometers, spatial correlation of rainfall is directly related to latitude, and it is greater during the cold season. For example, summer rainfall for sites with 5 km separation typically correlates about +0.2 to +0.3 in Florida, and about +0.4 to +0.6 in Illinois (Jones and Wendland, 1984).

Although the spatial distribution of precipitation can be inferred from radar imagery, the calibration of the radar echo intensity to rainfall rate can only be fulfilled if rain gauges are sufficient in number and appropriately located, a condition not always possible (Browning, 1979). However, Browning foresees precipitation data from gauges, overlapping radars, and geostationary satellites contributing to a meso-scale numerical model to produce areal precipitation forecasts up to c. 6 h. Currently, the decrease in precipitation data quality from gauges to radars to satellites will require much human interaction to integrate the complex data sets.

Surface runoff

Runoff is composed of several potential components: immediate runoff from rainfall and snow-melt, lagged runoff from snow- and ice-melt, and runoff contributed for interflow if reentering a stream. Each of the above lags the precipitation event by substantially different intervals, the lag being a function of the rate of liquid precipitation, depth of snowpack-ice layer, slope and aspect of the hydraulic conductivity and its vertical variation in the subsurface material, and the presence of ground frost. The length of time that runoff lags the precipitation event varies inversely with the rate of liquid precipitation, and may increase greatly if the precipitation is of a solid form; it is substantially diminished when the underlying soil is relatively porous. From monthly observations from several Illinois sites streamflow and shallow groundwater responded to anomalous precipitation within the month following the event (Wendland, 2001). The response of soil moisture, however, was not as clear, in that wet months were followed by either increases, decreases or no change depending upon the season (growing or fallow) and the magnitude of evaporation, whereas dry months were either followed by declining soil moisture or no change.

The severe drought in the Upper Midwest during the growing season of 1988 drew down all surface and groundwater resources, delaying any recovery until fall and early winter. The heavy precipitation of the growing season of 1993 was of sufficient magnitude so that none of the hydrologic responses showed any decline through the usually desiccating growing season.

Interestingly, infiltration of liquid precipitation or snow melt into essentially frozen soil under a snowcover can represent in excess of 95% of the precipitation (Price et al., 1978). Runoff from surface ice and snow is substantially reduced if ablation (i.e. snow or ice loss through either melting or evaporating) occurs via sublimation during clear sunny days with temperatures less than 0°C .

The rate of runoff largely determines the degree of erosion from a surface, although erosion also depends on surface cover, slope, aspect, etc. Sediment yield in a stream (including eroded material) has been found to be highly related to the coefficient of variation (standard deviation/mean) of precipitation (Harlin, 1978).

Evapotranspiration

The rate of evaporation from a surface into the air is a function of the availability of an energy source, the vapor pressure gradient between the soil or vegetation surfaces and that of the ambient air, and windspeed. Evapotranspiration is the total moisture loss through the soil-air interface, and that which transpires through the vegetation.

In the United States, evaporation is measured by the water loss from a Class A evaporation pan (25 cm deep, 1.2 m diameter) initially filled with water to 5 cm from the rim. Because of turbulence to air flow caused by the structure itself, and heat transfer through the sides of the container, pan evaporation tends to be greater than that over an open water surface (Budyko, 1974). This difference from actual evaporation can be reduced by sinking the pan so that the evaporating surface is near the level of the undisturbed ground surface (World Meteorological Organization, 1971). Reasonable estimates of evaporation from a cropped surface can be obtained from a lysimeter (a container several meters in diameter and 1 or 2 m in depth), filled with soil and growing vegetation. Water loss is usually determined by noting weight loss of the lysimeter. That water loss can vary greatly is seen from the observation that evapotranspiration over a pine forest was found to exceed that from a water surface by about 10% over six warm seasons (Holmes and Wronski, 1981).

Estimates of evaporation and evapotranspiration can be calculated. For example, Thornthwaite (1948) presented an equation to calculate potential evapotranspiration (evapotranspiration from an unlimited supply of water) as a function of daily mean air temperature and day length. Penman (1963) related evapotranspiration to vapor pressure, wind speed, surface temperature, and the shortwave radiation available at the surface. Estimates in Illinois using Penman's method are typically greater than those calculated by the Thornthwaite equation (Jones, 1966). Monteith (1965) suggested an improved evapotranspiration calculation, whereby evapotranspiration is determined as a function of energy (usually radiation), temperature, humidity, wind speed, leaf resistance, and the number and distribution of stomata. Bavel (1966) derived a relationship between potential evapotranspiration and net radiation, ambient air properties, and surface roughness. Priestley and Taylor (1972) demonstrated that latent and sensible heat fluxes could be closely estimated using parameterizations of energy over land and of bulk aerodynamic type over the sea. The latter three relationships, based on a greater number of physically related independent variables, yield good estimates of evapotranspiration under varying conditions. However, the greater number of independent variables limits their use to sites where sufficient observations are available, i.e. primarily micrometeorological research sites.

On a larger scale, Rasmusson (1966) presented the spatial distribution of mean monthly water vapor transport over North America, determined from 2 years of twice-daily aerological data. These analyses exhibit a reasonable pattern of flux divergence and inferred evapotranspiration. On the whole, however, calculated evaporation rates without corroborating observations must be considered suspect.

Groundwater

Groundwater includes two components: subsurface underflow and groundwater storage. These two components are difficult to measure separately and are therefore often treated as one quantity and evaluated as a residual in the water budget equation, i.e. groundwater recharge, that quantity representing the change to subsurface underflow and groundwater storage. Rehm et al. (1982) review methods to estimate groundwater recharge: calculations based on hydrograph records, Darcy flux calculations (where vertical flow is a function of permeability, hydraulic gradient, and porosity), and flow partitioning from an analysis of groundwater flow. Two examples of the first method are found in Schicht and Walton (1961) and O'Hearn and Gibb (1980). Depth to shallow groundwater is relatively easy to measure, but is routinely done at only a few locations due to cost of infrastructure and continued measurements.

Soil moisture

Soil moisture is moisture in the unsaturated zone, originating from surface water that enters the soil through percolation. Soil moisture can be measured by physically removing a soil column. It is then weighed, heated, and weighed again. The weight difference is attributed to water from the soil mass. Obviously, disturbing the soil precludes further measurement at the same site.

In-situ measurements of soil moisture can be made with a calibrated neutron probe. A neutron source/sensor is lowered into a pipe extending downward from the soil surface, obtaining measurements at any level. These sites can be remeasured as necessary.

Other than "casual" observations of soil moisture in terms of "adequate", "short", etc., quantified observations were few and far between in the US until the late 1980s, when routine observations began at several locations. Even today, however, soil moisture is routinely observed at only a few score sites, e.g. on a bi-weekly basis during the growing season and monthly thereafter at some 18 sites in Illinois.

Models have been developed to estimate the change in soil moisture from an earlier time, that time often being saturated conditions in early spring. Soil moisture estimates are updated as a function of temperature and precipitation. Dale et al. (1982) describe a budget technique that estimates soil moisture under different field and drainage conditions.

Interception

Interception is that quantity of precipitation that impinges on vegetation and other structures above the soil surface, some of which is either assimilated into the intercepting medium or evaporated prior to reaching the surface. In long-term determinations interception is usually assumed to be minimal. However, interception can be a significant moisture source to vegetation. For example, in coastal Peru where precipitation is minimal, vegetation obtains moisture by interception from surface-based clouds that drift through the vegetation. Cloud droplets settle on the leaves, drip to the soil surface and are available to the tree roots. Interception in an Australian plantation forest with closed canopy was found to be 1.8 mm by Holmes and Wronski (1981).

Worldwide distribution of evaporation and runoff ratios

Maps of annual and seasonal measured or (as necessary) estimated precipitation and evaporation are presented in most

climatology texts and are not reproduced here. The mean annual distribution of the above two variables and runoff are given in Sellers (1967), and Budyko (1974).

Two parameters helpful in delineating hydroclimatological regions are evaporation ratio and runoff ratio. Evaporation ratio is the heat consumed by evaporation (E) during a given time interval expressed as a percent of the total net radiation (R_n) received during the same interval. Runoff ratio is the total runoff (RO) during a given time interval expressed as a percent of total precipitation (P) accumulated during the same interval. The raw data required for these ratios (i.e. heat expended for mean annual evaporation, net radiation, and precipitation) were obtained from Barry (1969), Budyko (1956), and Geiger (n.d.), respectively. Additional heat budget detail from tropical oceans was determined from data presented by Hastenrath and Lamb (1978, 1979). Runoff was calculated from precipitation minus evaporation estimates, and the appropriate ratios constructed. Resolution of detail is limited to distances of about 1000 km.

Evaporation ratio

Budyko (1956) and Sellers (1967) have discussed the concept of evaporation ratio. The ratio ($E/R_n \times 100$) differentiates between those areas where evaporation can be totally supported by net radiation (indicated by evaporation ratios less than 100%) and those where the energy required for evaporation comes in part from sensible energy sources, i.e. atmospheric advection, Earth's surface, etc. (indicated by values greater than 100%). Figure H8 shows the large-scale annual mean patterns of evaporation ratio over oceans and over continents.

Ratios greater than 100% dominate the midlatitude oceans of both hemispheres. Note the relatively large ratios along the western oceanic margins, where the sea surface is relatively warm, and diminished ratios over eastern oceans. Maximum values in excess of 250% are found over the Gulf Stream. The tropical oceans and eastern margins of the Atlantic and Pacific oceans typically exhibit evaporation ratios of 50–60%.

Ratios less than 50% dominate the continents, including the southwestern United States, southern South America, Africa, southwestern and central Asia, and Australia. Sizeable areas with evaporation ratios less than 10% are found over northern Africa and interior Australia, where minimal precipitation limits evaporation. Maximum ratios are found over northern hemisphere continents poleward of about 60°N, exhibiting values in excess of 150%. Midlatitude continental ratios are between 50% and 100%. For the continents as a whole, net radiation is sufficient to support estimated evaporation.

Evaporation and net radiation estimates are undoubtedly less accurate over oceans and high-latitude continents, as are therefore the evaporation ratios. However, it is unlikely that the estimates are sufficiently in error to significantly change the patterns of the evaporation ratio.

Runoff ratio

Budyko (1956) and Sellers (1967) have also discussed another hydrologic parameter, i.e., runoff ratio ($RO/P \times 100$) where runoff is defined as mean annual precipitation minus evaporation. The pattern of runoff ratio is shown over the continents as broken lines in Figure H9. Substantial areas of the continents exhibit ratios near

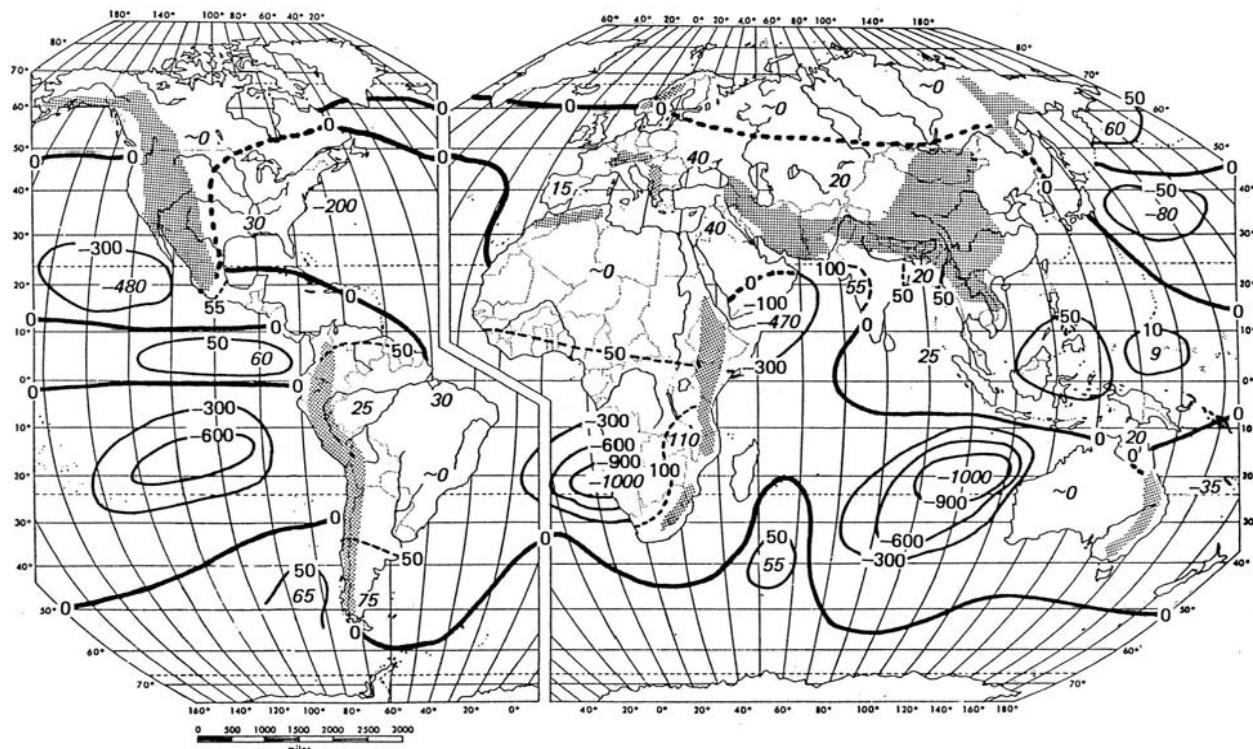

Figure H8 Mean annual evaporation ratios (evaporation/net radiation $\times 100$). High-altitude areas shown by shading; continental ratios analyzed by dotted lines; those over oceans by continuous lines. Maximum and minimum values are italicized.

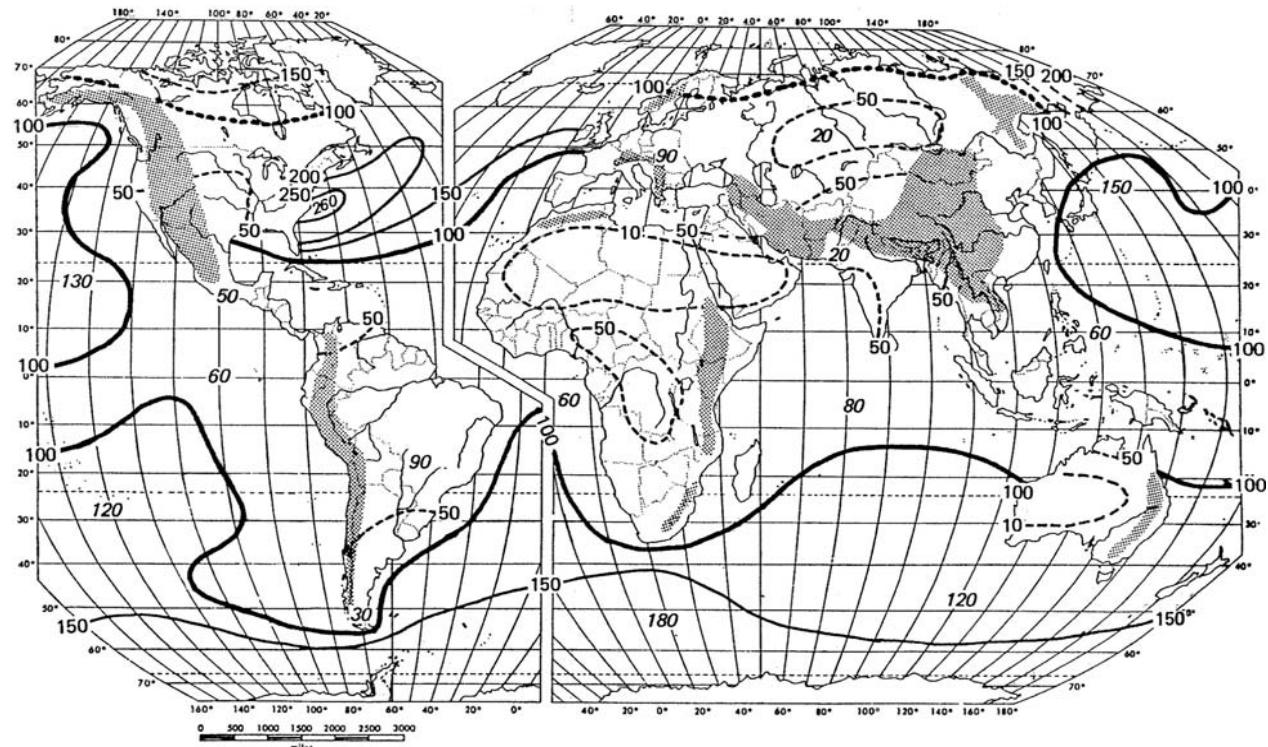

Figure H9 Mean annual runoff ratios ($\text{runoff}/\text{precipitation} \times 100$) over the continents, indicated by dotted analysis. Mean annual effective precipitation ratios ($\text{precipitation} - \text{evaporation}/\text{precipitation} \times 100$) are shown by continuous lines over oceans. High-altitude areas are shown by shading. Maximum and minimum values are italicized.

zero, including northern and western North America, east central South America, Australia, northern Africa, and northern Eurasia. Evaporation equals precipitation in these areas. The remainder of the continents typically exhibit ratios between 30% and 50% except southern South America and western India ($>75\%$), and southeastern Africa ($>100\%$). Only in these latter two areas does runoff exceed precipitation, at least at this scale of analysis.

The solid lines of Figure H9 (over oceans) show the distribution of effective precipitation ratio, i.e. $[(P - E)/P \times 100]$. Low-latitude oceans typically exhibit effective precipitation ratios less than zero, due to the considerable evaporation under subtropical anticyclones. The ratios tend to be slightly positive near the equator and over high-latitude oceans, where cloud cover tends to dominate due to the intertropical convergence and the subpolar cyclones, respectively. Lowest effective precipitation ratios are found over the eastern margins of southern hemisphere oceans.

Again, because evaporation and precipitation estimates are less likely to be accurate over oceans and high latitudes, runoff and effective precipitation ratios may be in error. However, it is unlikely that any errors are sufficiently large to change the patterns shown in Figure H9.

Human influences on hydroclimate

Purposeful and inadvertent impacts have been exerted on the hydroclimate in limited areas and times by human activity. The effect of large metropolitan areas on the urban and downstream precipitation distribution has been demonstrated by data from, and downstream of, St Louis, Missouri, by Changnon et al. (1981).

Reducing water loss by evaporation from lakes, and evapotranspiration from vegetation by the addition of monomolecular films to the surfaces, has been shown to be feasible (Roberts, 1961).

Atmospheric carbon dioxide concentrations have been increasing since observations began about 40 years ago. Though water vapor is a more effective greenhouse gas its atmospheric concentration is minimal and relatively stable, fluctuating only with changes in air mass and advection. The concentration of carbon dioxide, on the other hand, is increasing near-exponentially, generally attributed to the burning of fossil fuels and forest clearing, i.e. human activity. The presence of atmospheric carbon dioxide warms the lower atmosphere by reducing terrestrial longwave losses to space. It is anticipated that the present atmospheric carbon dioxide concentration will double by the mid-twenty-first century, resulting in mean annual warming of $1.5\text{--}3^\circ\text{C}$ (Schneider, 1990; Houghton et al., 2001). This warming may decrease atmospheric stability affecting precipitation, and will further modify the hydrologic budget since relative humidities are expected to remain constant, with a concomitant increase in absolute humidity (Watts, 1980).

The damming and channeling of the Mississippi River to improve navigation and flood control has changed the river's flow rate and sediment-carrying capacity. The change imposed on discharge and residence time of water on its journey to the Gulf of Mexico has impacted the local hydrologic budget. Reversing the direction of flow of the Snowy River in southeastern Australia modified local water budgets by draining regions that formerly received runoff and delivering water to others that formerly exported runoff.

On a larger and speculative scale, Borisov (1973) discusses changes that would result from diverting warm Pacific water to the Arctic Ocean, thereby freeing Arctic Ocean coastal areas from ice during much of the year. In addition to improving shipping opportunities for currently ice-locked ports during much of the year, the open ocean may lead to increased precipitation over nearby continental regions. This would increase runoff of fresh water to the Arctic Ocean, modifying the distribution of density and thus having an impact on ocean circulation.

The hydrologic budget may also be modified by purposeful cloud seeding, in which a nucleating agent is injected into a cloud. These agents promote ice crystal formation either by cooling cloud temperatures or by providing a crystalline structure conducive to ice crystal formation (briefly reviewed by Kerr, 1982). Positive results have been observed in some locations and in some cases, but cloud seeding does not produce consistent results, suggesting that the process is more/less efficient at some locations and times because of topography, ground cover, stability etc., or because of differences in application technique. Clearly, the process is not yet well understood and should not be adopted *a priori* as a strategy for drought mitigation.

Conclusions

The components of the water budget exhibit spatial and temporal patterns over the surface of the Earth in response to various climatic forcing functions and surficial constraints, e.g. components of atmospheric general circulation, atmospheric stability and moisture, radiation, topography, surface albedo, and surface water. As any one component changes, so does one or more component of the hydrologic budget.

The occurrence and frequency of unusual hydrologic events prompts interest in the concept of climatic change and what the future may hold. Recent examples of such events include the intensity and frequency of droughts in northern Africa. Lamb (1985) has shown that the sub-Saharan drought has persisted from 1968 through 1985, a relatively long string of moisture-deficient years relative to the *ca.* 45-year record. Recently, the upper Midwest experienced two substantial precipitation anomalies, a monumental drought in 1988 and massive flooding in 1993, events which exhibited 50–100-year recurrence intervals. The occurrence of extreme-magnitude events, or several such events in a relatively short time, may merely reflect natural variance or may signal a change from one stable climatic regime to another.

That climate, and the hydrological responses, change with time is clearly shown from the paleoclimatic record. Continued monitoring and research of atmospheric and hydrologic parameters will provide a database from which better dynamic relationships can be developed.

HURRICANES – DATA AND DATA SOURCES

The word hurricane is a regionally specific name for a strong tropical cyclone in the North Atlantic Ocean, the Northeast Pacific Ocean east of the dateline, or the South Pacific Ocean east of 160°E. A tropical cyclone is the generic term for a non-frontal synoptic scale low-pressure system over tropical or subtropical waters with organized cyclonic surface wind circulation.

The details of hurricane formation are provided in the item on “Tropical cyclones”. Given the enormous damage, human suffering and cost of the hurricanes season in Florida and the Caribbean, there is considerable interest in hurricane information. This entry provides some basic data and sources applicable to hurricanes.

ICE AGES

An ice age, in its broad sense, is any cold period in geologic history when glaciers extended over mountainous areas and, in high latitudes, covered continent-sized regions. At their maxima the land area covered by ice would exceed 45 million km² and its volume 80 million/km³. During the last 4 billion years of geologic time, ice ages have occupied less than 10%; at other times more equitable climates prevailed and major glaciation was absent, except in high mountains (John, 1979). During that history the movements of continents due to plate tectonic processes brought those land masses into paleolatitudes which at certain times favored ice-age initiation (Fairbridge, 1973). At other times, equatorial distribution of land areas made it unlikely (Schwarzbach, 1963).

Ice ages of the past have generally lasted 10–20 million years, and have a recurrence time of about 150–250 million years (Fairbridge, 1987; Williams, 1980). This “cyclicity” may be related to the passage of the solar system through the two spiral arms of the Milky Way galaxy. Within any ice age there is a powerful cyclicity with terms around 20 000, 41 000, and 93 000 years, which is related to the variations of orbital motions (the so-called “Milankovitch periods”, Berger et al., 1984; Milankovitch, 1941) of the moon around the Earth, and of the Earth around the sun, that change the eccentricity, the tilt angles and the precessional seasonality (Mörth and Schlamminger, 1979). These variables create an alternation of “glacial” and “interglacial” stages. Modern mankind is living in an interglacial (i.e. mild) stage, following a glacial interval that had its climax about 20 000 years ago. In popular use, it is the latter that is known as *the* Ice Age, a time characterized by Paleolithic (“Stone Age”) Man, and various extinct creatures such as the woolly mammoth, mastodon, saber-tooth tiger and Irish elk. (Only in science fiction did early man coexist with the dinosaurs, which became extinct some 65 million years earlier.)

The present ice-age condition has lasted about 2 million years, and is identified as the “Quaternary Period”. (The name is a survivor from an obsolete terminology, first introduced in 1750 with

“Primary”, “Secondary” and “Tertiary” for labeling divisions of geologic time.) All of the glacial and interglacial intervals have received local names in different regions, but there is little consensus on an acceptable international nomenclature. In deep-sea deposits, which contain the only continuously stratified record of the Quaternary Period, there is evidence of about 28 glacial-type climatic oscillations. In rare instances there is a land record, e.g. in 28 coastal dune ridges in South Australia; also, in the loess region of northwest China, there is a comparable record with desert-dust accumulation during the cold–arid phases, alternating with red soil layers marking the warm–humid interglacials.

Of the ice-covered areas of the present day, Antarctica is the largest (over 12 million km²), and it has been glaciated throughout the Quaternary. It displays signs of only minor interglacial melting from time to time. In contrast, the northern hemisphere landmasses of North America and northwestern Europe were repeatedly buried by ice and then “deglaciated”; each melting phase was completed within about 10 000–15 000 years. The melting ice left behind swaths of rock debris and piled-up soil (moraines) that marked the outer limits of “ice-push” or standstill episodes during the ice retreat. Giant boulders (erratics), some bigger than a house, are included in that debris and were the source of much speculation in the nineteenth century, before the modern glacial theory was developed (in the 1840s). One early theory attributed erratics to sea-ice flotation during the biblical flood. Discoveries of pre-Quaternary ice age indicators in the second half of the nineteenth century were to have a profound effect on geological thinking and philosophy. Most striking were finds in India, Australia, South Africa and Brazil in rocks, shown by the fossils, to be of Permian age (about 250 million years old), at latitudes so close to the present equator that various “nonactuarialistic” theories were proposed to account for them. The paradox was partially solved by the development of plate tectonics (Fairbridge, 1973; Tarling, 1978), but the overall problem of cycles of global cooling remains a scientific challenge. A still-earlier ice age of 450 million years ago (the Ordovician Period) was actually discovered (in 1970) in the middle of the Sahara Desert and later found to extend from West Africa to Saudi Arabia. Although predicted on paleontological evidence by Grabau (1940) and paleomagnetic data (Fairbridge, 1970a), it

was only later confirmed in the field (Beuf et al., 1971; Fairbridge, 1970b, 1973). After plate-tectonic closing of the Atlantic, the late Ordovician ice sheets may once have extended from Brazil to the Persian Gulf. In a review by Crowell (1999) it was largely ignored (see also Royer (2004)).

Ice ages that are still older, around 600, 750 and 900 million years, or even earlier, have introduced further paradoxical

problems that hint at changes in the Earth's spin axis (the "obliquity"). Such changes cannot be explained by ordinary astronomic variables, but might be caused during the early history of the Earth by catastrophic collisions with large asteroids which would be expected from the evidence of such impacts on the moon and Mars. Talk of a "snowball Earth" at one stage has not gained universal support.

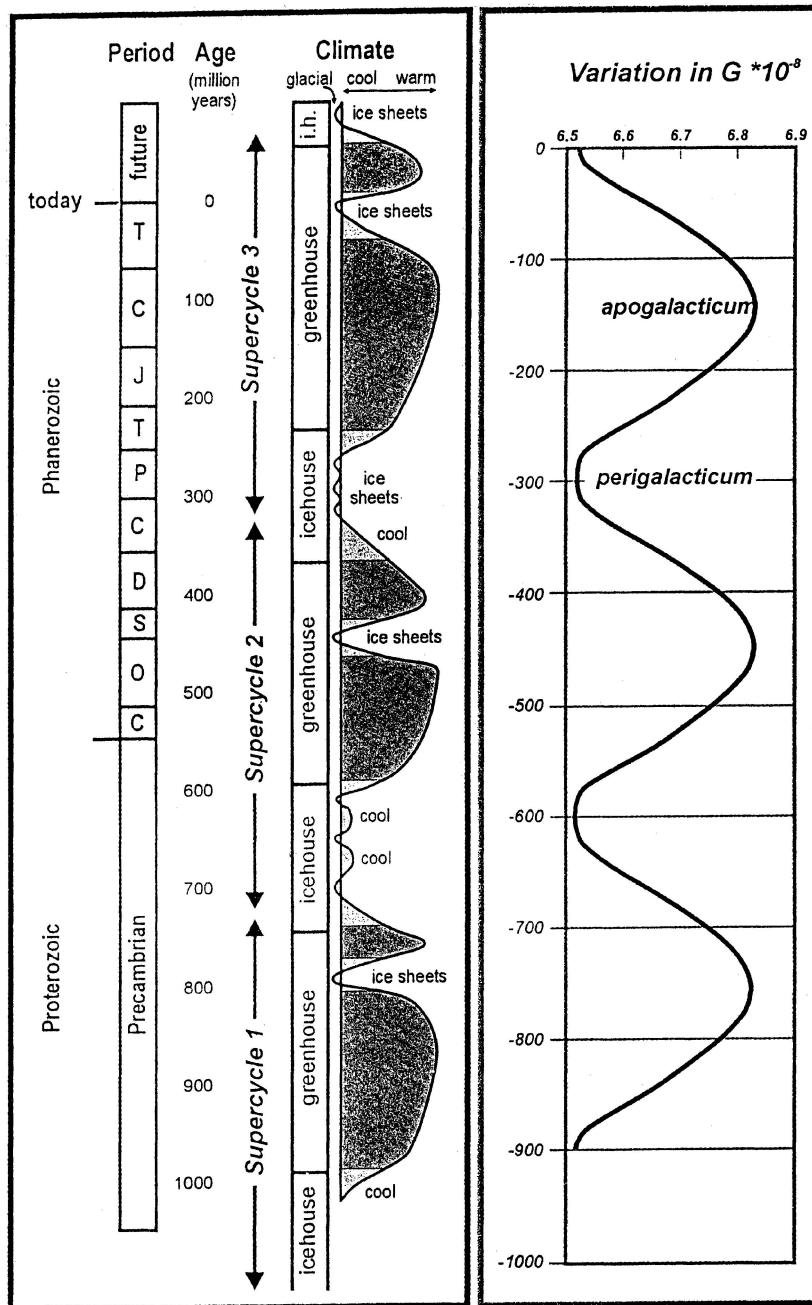

Figure I1 Steiner's concept of climate changes over the last billion years, as adapted by Veevers (1990) and others, postulating three supercycles, with "icehouse" to "greenhouse" alterations. These correspond approximately to a postulated variation of the gravitational constant \mathbf{G} in the Milky Way galaxy, where the "apogalacticum" matches peaks of greenhouse conditions, and "perigalacticum" the icehouse maxima. Additional cooling stages are presumed to match the "Simpson Effect". Over the same billion-year period the cosmic-ray flux shows the same broad cycles, but in an inverse relationship to temperature (Shaviv and Veizer, 2003).

The primary “driver” of ice ages is variously attributed to CO₂, solar dynamics and the rotation of the galaxy (Figure II). In general, temperature seems to be inversely related to cosmic ray flux (Shaviv and Veizer, 2003).

For the environmentalist, what important messages are contained in the history and dynamics of the Earth’s ice ages? To begin with they show that, although the mean history of the Earth has been “uniformitarian” and there is other evidence to show that the mean temperature of the Earth over the last 4 billion years has been in the order of 20 ± 5°C, this equable-to-subtropical world was sometimes seriously disturbed by intervals of multiple cold cycles that, individually, during their extreme phases, may each have lasted 5000–10 000 years (Budyko et al., 1987). Such episodes of climatic extremes would have been sufficient to trigger numerous evolutionary extinctions, so-called “punctuated evolution” (Clube, 1990). These concurrent hydrologic exchanges, of water to ice and back, also led to eustatic changes of sea level, themselves introducing several stress conditions that would also be liable to cause extinctions. By the same token, Darwinian adaptations to those stresses would accelerate positive (“intelligent”) changes; one such “nudge” may be modern human evolution to Homo sapiens sapiens from the Neanderthals, perhaps around 30 000–20 000 years ago.

Much speculation has appeared on the subject of “the next ice age”, meaning the next glacial stage of the Quaternary Ice Age (Imbrie and Imbrie, 1979). Close studies of the lat interglacial (about 100 000 ± 20 000 years ago) furnish a basis for modeling. An astronomically forced reduction of solar radiation can lower mean global temperatures by 3–5°C within a few decades (Pöhl, 1965). If events of this sort augment long-term trends (paleogeographic shifts, Milankovitch cycles), a glacial cycle is predictable. But when? Much more research is still needed.

ICEBERGS AND HEINRICH EVENTS

Icebergs are seasonal phenomena in modern oceans, but are commonly associated with cooling events during climatic history, as seen on 10³ to 10⁹-yr time scales (Hambrey and Glasser, 2003). However, when considered in century or decadal terms the facts are paradoxically opposite. Glacial erratics scattered about the landscape in northern Europe when first noticed were often attributed to iceberg transport during Noah’s Flood – another misconception doomed to be discarded.

From the geological record it is observed that around 2.7 Myr ago there was a sudden increase in bipolar sea-ice and ice-rafting of sedimentary debris (“IRD”, or ice-rafterd debris). This pattern fluctuated from glacial to interglacial stages, but at glacial extremes ice-rafting took the IRD, even large erratics, as far south in the Atlantic as 30° or even 25°S. In the Southern Ocean, ice transport reached the coasts of South Africa and Australia. As a biological proxy, various species of penguins, riding as “passengers” on the ice, were able to colonize the low-latitude Galapagos Islands, and their bones are found in Australian paleosols as far north as 28°.

The nature of IRD tends to reflect the source areas. Thus, the shale blocks with Paleozoic fossils, dredged up off the Canary Islands on a nineteenth-century oceanographic expedition, could be traced immediately to the British Isles. Granitic boulders found by Ewing near the northern edge of the Bahama plateau were mistakenly attributed to tree-trunk transport from Brazil, but eventually were traced to iceberg carriers from the Laurentian ice-sheet. An extensive literature now treats with the provenance of the North Atlantic IRD deposits. Besides the lithology, i.e. composition, of the debris, in the case of pebbles and small boulders it is sometimes possible to use shape as a guide (Middleton, 2003, p. 580). Following the Cailleux rule, those of ovoid shape reflect intertidal, planar abrasion (such as found in ice-foot or “glaciell”

coastal settings, while those of three-dimensional to subspherical form point to the tumbling dynamics of subglacial meltwater torrents (and therefore more likely to be carried by icebergs).

Actualistic, or “MAT” modern-analog, observations show that ice-shelf (tabular) bergs are typically developed in the Southern Ocean, off Antarctica, whereas the irregular blocky bergs are more likely to be generated at the valley-glacier snouts of Greenland, Spitzbergen, southern Alaska, New Zealand and southern Chile. The tabular bergs generated around 1985–2005 in the Weddell Sea or Ross Sea are often of giant size (as “big as the state of Connecticut”, i.e. 5000 miles², or 13 000 km²) before they disintegrate. The accelerating production of icebergs in recent decades is demonstrably related to two climatic variables, the rising MSL and rising SST, both aspects of twentieth-century “global warming”. The sea-level rise increases the glacier-ice buoyancy, thus its distal areas float rather than rest on the shelf. Secondly, the warming water leads to melting from below, even when atmospheric temperature is well below zero. Surface melting of the glacier during warm summers feeds meltwater into crevasses, thence to subglacial rivers, which further increases its general mobility.

Historically, the longest record of North Atlantic sea ice can be derived from Icelandic evidence, which began with the first Norse settlers in AD 865. Schell (in Fairbridge, 1967, p. 858) provides a century-by-century synthesis, expressed as weeks of coastal ice severity:

865–1100:	0.1–0.7
1101–1200:	zero
1201–1300:	7.5
1301–1600:	3.2–6.0
1601–1800:	22.6–25.3
1801–1900:	40.8
1901–1950:	8.6

From this evidence it seems that the Medieval Warming Period was indeed most favorable for the settlers, while the Little Ice Age is known to have brought great privations and the abandonment of many farms in Iceland and to the total loss of the Greenland colonies. However, it is curious to note that the maximum sea ice off Iceland was not reached until the nineteenth century (probably due to a shift in the Irminger Current). At the present time the ice cover of the Arctic Ocean may exceed 10 Mkm² in winter, calving and melting away to 800 000 km² or so in late summer. In the Pacific the winter ice cover of the Sea of Okhotsk today may even beset northern Japan, and the winter ice of the Bering Strait still links Siberia and Alaska, though all is gone by early summer. Closely associated with global climate, heavy ice years are often matched by a southerly shift of the jet stream over the North Atlantic (corresponding to the NAO). Even the monsoons are affected by these global cycles, as shown by the flood years of the Nile (Currie, 1995), as well as India’s succession of drought/flood years.

Icebergs and tides

The relationship of iceberg production to oceanic tides was first demonstrated by the Swedish scientist, Otto Pettersson (1914a), with respect to SST in the Norwegian Sea. Pettersson also recognized that the periodicity of the temperature and tidal oscillations were linked primarily to the luni-solar forcings. Normal fortnightly tidal cycles were greatly amplified by the long-term effects of internal waves coming in across the Continental Shelf, at times near the shore achieving amplitudes

in excess of 20 m. (A discussion of internal waves by Cucchiione and Pratson, 2004, treats some of the oceanographic and geological aspects involved.)

The master study of tidal dynamics by Wood (2001) brings out both short- and long-term tidal cycles which tend to have additive effects. Thus the perigee’s closest approaches to the Earth, enhancing the tides, he called the “proxigee”. Over the long term the proxigee–perihelion–syzygy precession tides return at only some 558-yr intervals; their last epoch was 1912. Around southern Greenland the SST was then 2–3°C above normal. Small wonder that “armadas” of icebergs were reported drifting out into the northwest Atlantic. It was just an incredible misfortune that this event in the early summer of 1912 coincided with the maiden voyage of the RMS *Titanic* and its disastrous fate (Wood, 2001).

Precisely one declination cycle earlier, in 1893–1894, coinciding with the apsides–perihelion cycle, there was a gigantic outburst of icebergs in the Antarctic, even reaching 40°N (Pettersson, 1914a,b), and forcing the Cape-Town to Australia shipping to shift from their usual (great circle) course. Five years previously no icebergs at all were sighted along that route.

The luni-solar tidal acceleration (or “slow-down”) of the 18.6-yr nodal and nutation (declination) cycles are a striking feature of all the geostrophic ocean currents. The two periodicities recur at 18.6 yr intervals but with a nodal lag of 4 yr, which is often disregarded (Currie, 1995). Thus not only the Gulf Stream and Kuro Shio are accelerated, but also the return flows of the Canaries and California currents, as well as those of the southern hemisphere. The 18.6-yr effect in the North Atlantic was discovered by Maksimov and Smirnov (1965) of the Russian Oceanology Institute in Saint Petersburg from the evidence of warming SST. This was confirmed by the Canadian workers in the Maritime provinces, and by MSL rise in New England (Kaye and Stuckey, 1973). On a global basis Currie (1987, 1995) recognized the 18.6-yr effect in MSL, SST, rainfall and other proxies in his lifelong researches.

Economic aspects were recognized by Pettersson (1914a, b) inasmuch as the incoming megatides brought tremendous catches of herring and cod to the Swedish west coast. In the Middle Ages these tides even reached into the southern Baltic, as shown by tax records in the Hanseatic League ports dating back to the fourteenth century. Fisheries are also affected in the western Atlantic, as reported by Currie et al. (1993).

Heinrich events

Evidence of extensive late Pleistocene sea-ice and iceberg transport of IRD was discovered during sediment coring operations in the northwest Atlantic, particularly around 45°N, but later to 60°N and beyond (Heinrich, 1988; Grousset et al. 1993), and notably in the Labrador Sea (Bond et al., 1994; Hillaire-Marcel, 1994). These crescendos here become known as “Heinrich Events” and are numbered from “H-0” back to “H-11”. The principal IRD provenance was the North American Laurentide ice sheet (Alley and MacAyeal, 1994), but Greenland and the Canadian Arctic also contributed. The IRD composition was particularly distinctive for its carbonate enrichment when derived from Arctic Canada, but almost devoid of carbonates in the northeast Atlantic. Unlike the IRD of the northwest Atlantic with its carbonates traced to the Paleozoics of “Canada”, cores in the northeast are non-calcareous, and the IRD can be associated with fluctuations of the Fennoscandian ice-sheet (Fronval et al., 1995).

From various temperature proxies covering the span of the late Pleistocene (oxygen isotope stages 2–4) a sawtooth pattern is evident. While not exactly cyclical they have a distinctive regularity (Bond et al., 1992, 1993, 1997, 1999) and are accordingly identified as “Bond Cycles”, with Heinrich Events following each nadir. Their association with ice-melting was shown by decrease in salinity.

Measured over the last 100 000 yr or so, Bond et al. (1993) showed that the fluctuations in 0–18 in the Greenland ice cores were indicators of temperature-cycle proxies in the sea-floor sediments of the northwest and northeast Atlantic. In a comparison of North Atlantic cores in general, it can be seen that the largest Heinrich/Bond oscillations were in core K 708-1 located at 25°W, a site due west of Ireland.

A secondary feature of the Bond Cycles with their asymmetric sawtooth pattern are the Dansgaard–Oeschger events that were first recognized in 0–18 trace in the Greenland ice cores (Dansgaard et al., 1993). These are abrupt warming events of 5–8°C, not associated with a sine curve of temperature proxies, but with abrupt rises and falls (sometimes likened to the pattern of skyscrapers on a city skyline). They can be matched with the pattern of the ^{14}C flux record in Holocene tree rings (Stuiver and Braziunas, 1988), with only 10–40 yr or so difference between the start of the rise and the irregular “plateau” at the top. After a

few centuries this is followed by an equally abrupt fall. They are much more prominent in Greenland than in Antarctica at Vostok.

Solar and lunar links

Global distribution of Heinrich Event teleconnections far away from the glacial regions has been suggested in several papers, but most clearly in a well-dated lake core from Florida (Grimm et al., 1993).

To calculate the ages of these events, as a working hypothesis, one can use the luni-solar tidal periodicities, established in the Santa Barbara Basin (Behl and Kennett, 1996; Berger et al., 2004), with AD 1943 as a convenient index year. (That year marks the continentality peak for Stockholm and summer temperature crescendo.) It is also a solar spin-rate minimum, which marks a weakening of the geomagnetic field, favoring a high influx of solar particles to the Earth. Behl and Kennett identified 17 anoxia horizons since 59.6 ka (see Table I1) which perfectly match the Greenland ice-core record of warming events of Bond et al. (1994). Resonance of two major planetary periodicities, 18.6134 yr (L_N) and 11.17 yr (SSC) occurs ideally at 156.392-yr intervals, respectively $15 \times L_N$ and $14 \times SSC$, the so-called “Libby Cycle” (Libby, 1955), but due to varying amplitude and length of the solar cycle, however, it is not

Table I1 Tentative chronology of Heinrich Events and climatic proxies

(a) following Mayewski et al. (1994), based on calcium and other ions in Greenland ice core “Summit”, in kyr BP; in parenthesis is suggested the 208.5/417-yr solar cycle based on tree-ring ^{14}C flux with an index year of AD 1943. (b) Following Bond et al. (1997) are shown estimates of the start (warmest) phase of “Bond Cycles” with prominent Dansgaard–Oeschger events in brackets. (c) Cyclic returns of 6672 yr period (337×18.0334 yr lunar tide cycle; 600×11.12 yr solar cycle; 32×208.5 yr ^{14}C flux cycle). (d) Notes. “ka” indicates chronology in kiloyears (kyr) BP, AD 1950. Oeschger events [in brackets]: e.g. $70.35 - 24.5$ ka = 45 850 yr ($208.5227 \times 220 = 45 875$ yr). OIS = oxygen isotope stage (also given as “MIS”).

always quite regular. Several other periodicities are found to cluster around AD 1900. The 31.01-yr lunar perigee syzygy extreme falls in 1900 with L_N in 1898. The SSC minimum came in 1901. Astronomically, it is interesting that 1900 marked the sun–barycentric radius maximum (greatest inertial swing of the sun from the system center of gravity) and minimum in its orbital velocity, a time characterized by fewer solar flares with their climatic impact. On Earth there was a spin-rate maximum, associated with global outbreaks of volcanicity.

The previous, closely calculated event of this nature was in 1340, some 558 yr before 1898, and also the largest tidal pulse during the past millennium (Wood, 2001). This value can be used for estimating the approximate ages of the various Heinrich events which at present are only stated in radiocarbon years that need to be calibrated to astronomic time in order to relate their iceberg outbreaks to tidal and climatic events. With the guidance of ice-core 0–18 values and the tree-ring ^{14}C values, both dated in sidereal time, it can be suggested that the Heinrich incidents can each spread over some 500 yr or somewhat more.

Analysis of calcium and other indicator ions in a Greenland ice core (“Summit”: Mayewski et al., 1994) show that their amplitude corresponds very closely during the late Pleistocene glaciation to a GCI or “general circulation index” for the Polar Vortex system. The larger the vortex, the colder the high-latitude climates. At such times stronger (easterly) winds would transport more dust particles to the ice sheet. In China and Mongolia such winds would be from the northwest (the Gobi and Maklakan deserts), producing gigantic loess deposits.

Massive iceberg discharges during Pleistocene cycles are not confined in their climatic effects to a single region, the North Atlantic, but appear to have global repercussions. Broecker (1994) has suggested they act as triggers for worldwide climate fluctuations, mediated by the thermohaline circulation. Very abrupt transitions are apparent. It is clear that the abrupt termination of each Bond Cycle is marked by a dramatic reduction of salinity over a broad surface of the ocean, which in turn is accompanied by the warming atmospheric temperature, a rise that must result in extensive melting of glacier ice. However, there will also be an increase in evaporation and thus the snowfall over the ice sheets, which accounts for the brief duration of the Dansgaard–Oeschger events. Where precise dating is available it is also evident that each Heinrich Event and its high IRD supply continues until the climax of the steep warming phase that follows each Bond Cycle. Iceberg production then decreases during the extended cooling phase that follows.

With its abrupt change following the Younger Dryas and during the Holocene to globally warm climates the GCI is inversely related to ^{14}C flux (which is high during cold intervals, e.g. during the Younger Dryas). Progressively over the last 10 kyr there has been a decrease in the amplitude, both positive and negative, of the ^{14}C flux (Stuiver and Braziunas, 1988) that has probably been related to the decrease in the extremes of the Earth–moon orbital cycles. Since about 6000 BP there has been also a progressive fall in the cold-cycle temperatures, reaching their nadir in the last stage of the Little Ice Age.

To sum up: water-level glaciers and grounded sea ice are made buoyant by rise of sea level such as at peak tides in AD 1912, an 18.6-yr cycle, with crescendos at 558-yr intervals. These events are marked by “armadas” of icebergs in both

hemispheres. Icebergs and sea ice increase generally during major cold cycles, but their production accelerates greatly during brief warming events marked by an abrupt rise in temperature and a rise in MSL. This rise is caused by outbursts in solar emissions, with the synergy provided by lunar cycles.

ICELANDIC LOW

The Icelandic Low is a semipermanent low-pressure cell or trough located in the North Atlantic between Iceland and southern Greenland at 60–65°N (Trewartha and Horne, 1980). This subpolar low is one of the major “centers of action” in the northern hemisphere.

Daily synoptic weather charts (i.e. weather maps drawn from observations taken simultaneously from a network of stations over a large area, thereby yielding a general view of weather conditions) for the northern hemisphere show many high- and low-pressure systems associated with the disturbances along the polar front between the cold and warm air masses. These moving disturbances can be eliminated cartographically by constructing mean charts that delineate rather clearly their semipermanent character (Rossby, 1945). Thus, the mean Icelandic Low is a result of numerous traveling depressions alternating with shorter periods of anticyclonic weather.

The center of the Icelandic Low has a January mean sea-level pressure of 996 mb (29.41 in), 17 mb (0.51 in) below the normal sea-level pressure of 1013 mb (29.92 in). By comparison, the center of the Aleutian Low has a January mean sea-level pressure of 1002 mb (29.59 in), 6 mb (0.18 in) higher than the Icelandic Low.

Although both the Aleutian and Icelandic Lows are considered subpolar in latitude, the latter is centered further poleward, tending to stretch along the poleward edge of the Gulf Stream. In contrast, the Aleutian Low is displaced somewhat equatorward by the effect of the Aleutian Islands in restricting the movement of warm Pacific waters to the Bering Sea (Willett and Sanders, 1959).

The Icelandic Low expands during the low-sun period (winter in the northern hemisphere) when the ocean is relatively warmer than the cold continents. The steady pressure gradient associated with this zone of converging cyclonic activity is largely responsible for the severe gales and winds common to the North Atlantic in winter (Ahrens, 2003). Winds of 88–121 km/h (55–75 mph) are common in winter cyclones. In the summer the low greatly decreases in size as the land temperature becomes warmer and the water relatively (but not actually) cooler.

During periods of strong circulation, both the Icelandic and Aleutian Lows cover large areas and form single well-formed centers. Conversely, the centers may be split into two separate cells of smaller size during periods of weak circulation, often due to blocking. At this time the Icelandic Low is often displaced westward and southward of Iceland.

The Icelandic Low is a major component of the North Atlantic Oscillation (NAO), a periodic fluctuation in the distribution of pressure between the low and the Azores High that strongly affects weather in Europe. Visbeck et al. (2001) note that the phase of the NAO has been shifting from mostly negative values to mostly positive values during the past three decades, a change that may be attributed to anthropogenic activities. Recent changes in Arctic Ocean sea ice motion appear to be related to the intensity of the Icelandic Low, as this center of action influences the sea-level pressure distribution over a large part of the Arctic Ocean and contiguous waters (Kwok, 2000).

INDIAN SUMMER

The term “Indian Summer” is applied in North America to an autumn period, usually in late October or November, when delightfully warm, but not really hot, weather dominates for a period of days. It occurs in the midst of cooler days after the first frost has occurred and the first signs of winter have made their appearance. While there is no formal meteorological definition of Indian Summer, it is usually assumed that, subsequent to a hard frost, warmer days, clear skies, and calm or light winds prevail for at least 3 days.

This late autumn warming period is also identified elsewhere. In some parts of Europe it sometimes may be referred to as “Saint Martin’s Summer”, a time of mild weather during late fall. In England it is also known as St Martin’s Festival, a time that coincides with “All-hallows Summer”.

A number of explanations have been given to account for the name Indian Summer. The most commonly accepted are those applying to American Indians. Early settlers in the United States noted that the Indians recognized this summerlike weather as a time for storing late crops and readying their lodges for the coming winter. Brooks (1924) suggests other versions including that “early settlers attributed the blue haze which is characteristic of the season to the smoke of fires set by Indians on the western prairies, and bestowed the name for that reason. Yet another suggested possibility is that the name was bestowed by some early traveler who, familiar with the dry, hazy weather of India, recognized a similar type of weather here.” The versions could go on, but, irrespective of its origin, the name Indian Summer is a beautiful description of a delightful weather event.

Indian Summer is a “weather singularity”, a weather event that recurs around a specific calendar date each year. The “January Thaw” is another well-established North American weather singularity.

The idea of Indian Summer dates back to the late eighteenth century and has been an oft-quoted literary subject. For example, in the 1855 poem *Hiawatha*, Longfellow wrote:

Brought the tender Indian Summer
To the melancholy north-land,
In the dreary Moon of Snow-shoes.

It is a most appropriate description.

INTERGOVERNMENTAL PANEL IN CLIMATE CHANGE (IPCC)¹

The work of the IPCC is guided by the mandate given to it by its parent organizations the World Meteorological Organization (WMO) and the United Nations Environment Programme (UNEP). IPCC Principles contain specific procedures for the preparation, review, acceptance, approval, adoption and publication of IPCC material. The three main classes of IPCC material are IPCC Reports, which include Assessment, Synthesis, Special and Methodology Reports; Technical Papers; and Supporting Material such as proceedings of IPCC workshops. The procedures provide also guidance on the tasks of authors and reviewers.

The IPCC has three working groups. Working Group I assesses scientific aspects of climate systems and climate change; Working Group II studies the vulnerability of human and natural systems to climate change and options for adapting to them; Working Group III assesses options for limiting greenhouse gas emissions and economic issues. Also, a task force studies national greenhouse gas inventories.

INTERTROPICAL CONVERGENCE ZONE (ITCZ)

The intertropical convergence zone (ITCZ) is an east–west-oriented low-pressure region near the equator where the surface northeast and southeast trade winds meet. As these winds converge, moist air is forced upward, producing cumulus clouds and heavy precipitation. These clouds occur in scattered masses about 100 km (60 miles) across. Among these randomly spaced clouds are synoptic-scale waves that move from east to west; they are known as the easterly waves. Within the ITCZ, winds are often light and variable in both speed and direction. It was known as the doldrums by sailors because of the lack of horizontal air movement.

The ITCZ is most clearly developed in the tropical oceans (in the eastern Pacific and Atlantic). It is the most prominent climatic feature in the tropics and plays principal roles in tropical climate by interacting with the planetary-scale circulations of the atmosphere and ocean.

¹ This account is drawn from www.ipcc.ch/ which is the home page of the IPCC. The site provides a wealth of information about organization and publications.

The positions of the ITCZ

The ITCZ is usually found within 350 km of the equator; about 80–300 km wide and 5° north and south from the equator. The position of the ITCZ varies seasonally (Figure I2), being drawn toward the areas of the most intense solar heating. The largest seasonal migration occurs over land. In January the ITCZ lies about at 15°S over South America and Africa. In July it lies at about 25°N over Africa and about 30°N over Asia. The ITCZ is less mobile over the oceans, where it holds a stationary position just north of the equator. It was discovered that the equatorial asymmetric sea surface temperature (SST) distribution and the ocean-atmospheric feedback mechanisms, including the Bjerknes feedback and wind-evaporation-SST (WES) feedback, cause the oceanic ITCZ to stay to the north of the equator (Xie, 1998).

Double ITCZ

The double ITCZ refers to two ITCZ, one at each side of the equator. Double ITCZ experience spatial and temporal variations. The most noticeable double ITCZ are usually found over the eastern Pacific during boreal spring. Over the western and central Pacific, signals of double ITCZ can be seen during June to September. Infrequent weak signals of double ITCZ are also observed over the Indian Ocean during November (Zhang, 2001). However, the QuikScat images show that the double ITCZ exist in the Atlantic and eastern Pacific all year round. For most of the time the south ITCZ is weaker than the north ITCZ. The stronger north ITCZ is created when the northeast and southeast trade winds converge over the warm waters, resulting in intense convection and formation of vigorous cumulonimbus clouds that produce heavy precipitation. The south ITCZ is formed when the southern trade winds blow over the cold upwelling waters near the equator, that cause decrease in vertical mixing and deceleration of surface winds (Liu and Xie, 2002). The south

ITCZ contains only the southern wind blowing to the equator, and does not have the cloud creation capability of the north ITCZ.

Models and theories for the explanations of the ITCZ

The ITCZ is commonly viewed as the ascending branch between the Hadley cells, that is a deep circulation pattern extending from the surface to the top of the troposphere (Figure I3a). Heating due to latent heat release in deep convection plays a crucial role in the tropical meridional circulation. Fletcher (1945) proposed a twin equatorial cell model (Figure I3b). Latent heat release first heats up the atmosphere. However, radiational cooling from the cloud top and evaporative cooling at the lowest layer of the cloud will create a directional reversal in the solenoidal field. Thus, the equator becomes a cold source from which air flows outward into the two hemispheres, resulting in two small new circulation cells and two convergence zones.

Asnani (1968) suggested another model with a single equatorial cell separating the two Hadley cells (Figures I3c and I3d). In the single cell the air flows toward the equator in the lower layers and flows away from the equator aloft, producing upward motion on one side and downward motion on the other. Near the equator, subsidence occurs. There are two regions of absolute vorticity maximum, one on each side of the equator; one coincides with the ITCZ that is an area of maximum absolute vorticity where a kinematic tough is formed.

Hastenrath (1968) stated that Asnani's three-cell model could be explained by varying the vertical distribution of absolute vorticity, frictional force and vertical zonal wind components in the vorticity equation. However, for Fletcher's twin equatorial cell model, the requirement of the eastward-directed frictional force in the lower layers to decrease from the equator poleward, within the subsiding portion of either of

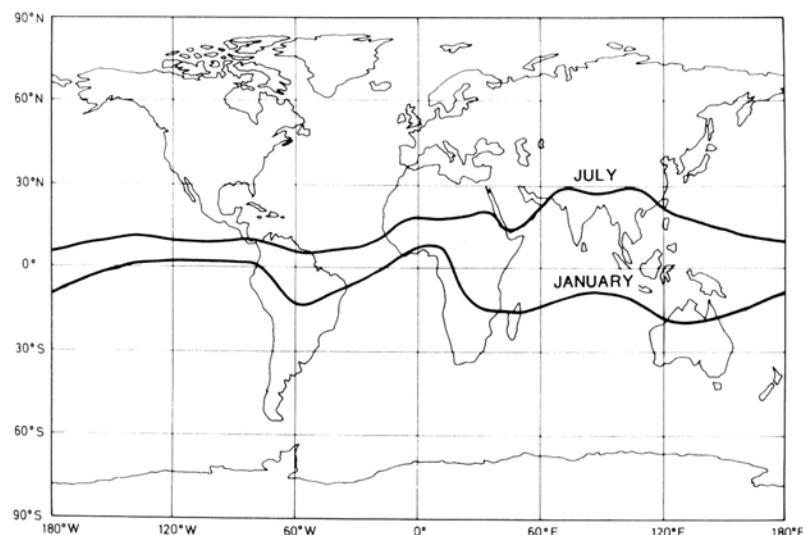

Figure I2 Mean positions of the Intertropical Convergence Zone (ITCZ) in January and July (after Henderson-Sellers and Robinson, 1991).

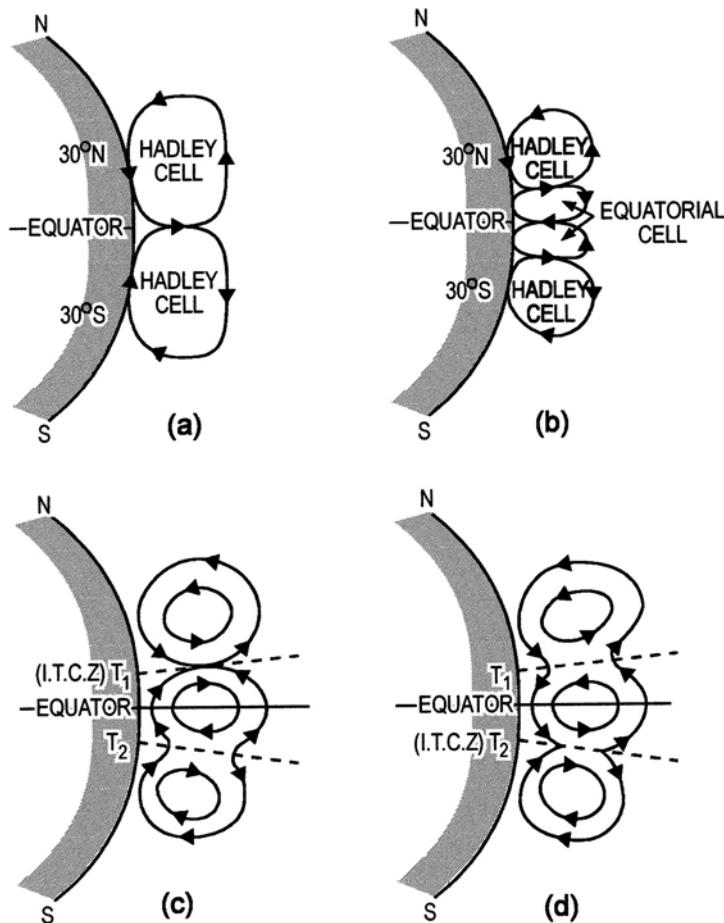

Figure I3 Models of tropical meridional circulation. (a) Hadley cells on two sides of the equator; (b) two equatorial cells separating the two Hadley cells (adopted from Fletcher, 1945); (c) and (d) a single equatorial cell separating the Hadley cells (adopted from Asnani, 1968). (Source: <http://orca.rsmas.miami.edu/~czhang/Research/ITCZ/research.itcz>).

the two equatorial cells, can only be met over the oceans but not the continents.

There are numerous theories and numerical modeling studies for the explanation of the ITCZ. Charney (1971) considered that conditional instability of the second kind (CISK) and stated that the position of the ITCZ depends on Ekman pumping efficiency and moisture availability. Holton et al. (1971) stated that the easterly waves were associated with the convergence at off-equatorial location of the ITCZ. Lindzen (1974) employed a wave-CISK argument to explain a convective maximum off the equator.

Schneider and Lindzen (1977) discovered that zonally symmetric convective heating was crucial in determining the location of the ITCZ. Tomas et al. (1999) stated that a zonally symmetric cross-equatorial pressure gradient would result in a convergent flow at the ITCZ latitudes. Some modeling studies reveal that the ITCZ follows the SST maximum. Goswami et al. (1984) discovered a steady ITCZ occurred over the SST maximum. Hess et al. (1993) and Numaguti (1993) found that the ITCZ location following SST maximum depended heavily on the cumulus parameterization used.

Attempts to address the ITCZ position have been conducted using coupled ocean–atmosphere models. Pike (1971) found that the ITCZ was displaced because of equatorial oceanic upwelling. Manabe et al. (1974) explained that maximum precipitation tending to occur off the equator was a consequence of oceanic upwelling at the equator. Xie and Philander (1994) argued that the processes such as mixing and evaporation were as important as dynamic oceanic upwelling.

There are many numerical modeling studies examining the association of the ITCZ with atmospheric internal dynamics (Waliser and Somerville, 1994), energy transport by transient waves (Kirtman and Schneider, 2000), moist static energy budget (Neelin et al., 1987), and radiative convective instability (Raymond, 2000).

Despite the many ongoing numerical modeling studies, no single theory can explain the formation and variations of the ITCZ as various competing mechanisms are involved.

INVERSION

An inversion occurs when there is an anomaly in the normal positive lapse rate. Such a condition may occur for the vertical

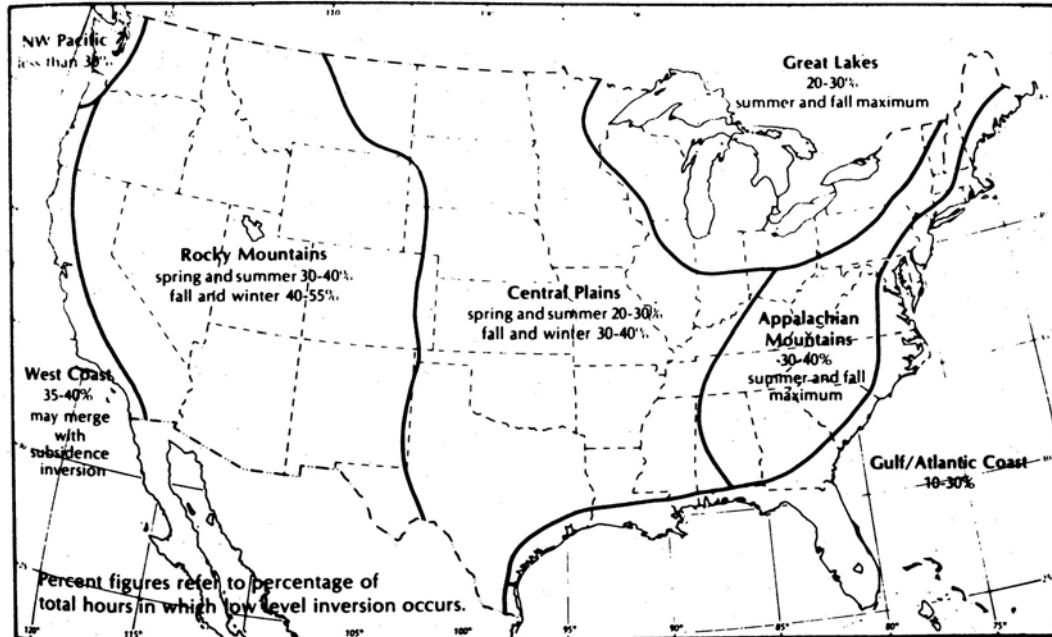

Figure 14 Frequency of low-level inversions over the United States.

variation of any atmospheric property, but the unqualified term usually implies a temperature inversion, i.e. a situation in which temperature increases rather than decreases with height. Temperature inversions can be found at or above the surface.

Surface inversions generally occur in highly stable air with minimum turbulence to allow the lower levels of air to be cooled. Such a situation often occurs during early-morning hours and gives rise mist and fog.

Inversions above the surface level occur as part of large-scale circulation systems in which subsiding air causes temperatures aloft to be higher than those closer to the surface. Such subsidence inversions are caused by the adiabatic heating of descending air that is often associated with anticyclonic circulation. Upper-level inversions can also result when cold anticyclones pass over warm surfaces. A winter flow of cP air over the Great Lakes is one case in point; if vertical mixing of air below the inversion level takes place, inversion stratus may form at the base of the inversion layer to give light snowfall.

Given the highly stable conditions under which inversions form, they are associated with poor ventilation conditions and a resulting propensity for adverse air pollution levels. Because of this, the spatial distribution of inversion frequency is of particular concern. Figure I4 provides a generalized map of the temporal and spatial distribution of low-level inversions in the United States. Note the high incidence of such inversions in the mountainous states.

Subsidence inversions are of particular importance in determining the climate of a number of locations. The aridity of coastal areas on the eastern side of the subtropical high-pressure cells (e.g. California in summer) is partly a response to stable maritime air, mTs. Similarly, the Trade Wind Inversion plays an important role in the climatology of locations in the trade wind belt.

"ISO" TERMS

"Iso" is the Greek prefix meaning equal; therefore, "iso" terms are usually applied to some sort of contoured map or diagram showing equal distributions. Stamp (1963) compiled a listing of

the many "iso" terms in use, and the following lists those used in climatic studies:

- Isallobar*: lines of equal pressure tendency, marking similar changes within a given time.
Isanomaly: lines or contours of equal anomalies, or departures from normal.
Isarithm: lines of constant value (of any sort); similar to isopleth (*q.v.*).
Isamplitude: lines of equal amplitude of variation of any feature or phenomenon.
Isobar: lines of equal barometric pressure.
Isobase: lines of equal land uplift.
Isobath: lines of equal depth (generally below sea or lake level).
Isobathytherm: lines of equal temperature at given ocean depths.
Isocheim: lines on a map through places of equal mean winter temperature.
Isochroine: lines on a map joining points that can be reached in equal time from a given origin. Isochronous also refers to anything related by equal time.
Isocryme: lines on a map connecting places of equal lowest mean temperature for specified periods, e.g. for the coldest month.
Isodynamic line: indicating points of equal intensity of terrestrial magnetism.
Isogeotherm: a surface within the Earth connecting points of equal temperature.
Isogram: lines of equal values of any sort (similar to isarithm and isopleth; not recommended, as of mixed derivation).
Isohaline: lines of equal salinity, in the ocean or lakes.
Isohel: lines of equal sunshine.
Isohydrics: lines or surfaces (within a water body) of equal pH or hydrogen-ion concentration.
Isohyet: lines of equal rainfall.
Isihyomene: lines of equal wet months.
Isohypse: lines of contour, generally of topography; also used for level of ground water.
Isoikete: lines of equal habitability.
Isokeraunic: lines of equal thunderstorm incidence.
Isokrymene: lines of equal minimum temperature in the ocean.
Isoline: lines of equal anything (not recommended, as a mixed derivation; better, see isopleth).
Isomer: lines of equal average monthly rainfall, expressed as percentage of annual average.
Isometric: lines of equal value, specifically applied to a method of projection, often used in block diagrams, the plane of the projection being equally inclined to the three principal axes of the object. Isometric is also a system in crystallography.
Isoneph: lines indicating equal degree of cloudiness.
Isonif: lines indicating equal snowfall.
Isophene/Isophane: lines of equal seasonal phenomena, e.g. in botany, flowering season.
Isophenomenal: lines on a map connecting places of equal phenomena of any sort.
Isophotic: lines or planes of equal light emission or penetration, e.g. in the ocean or lakes.
Isophyte: lines of equal height of vegetation.
Isophytochrone: lines of equally long growing season.
Isopleth: lines of equal values, a general descriptive term.
Isopone: lines of equal annual change in magnetic variation.
Isopotential: lines, levels, or planes to which artesian water may rise.
Isoryme: lines of equal frost incidence.

Isostasy: equilibrium within the Earth's crust and mantle obtained by vertical adjustment to mass and density.

Isotade: lines of equal significant dates.

Isotalantose: lines connecting places with equal range between the mean temperatures of the hottest and coldest months.

Isoterp: lines of equal comfort (bioclimatology).

Isothere: lines of equal mean summer temperature.

Isotherm: lines of equal temperature in air or sea.

Isothermombrose: lines of equal summer rainfall.

Isotope: term of chemistry, indicating elements of similar chemical character, but of differing electron numbers.

Isotype: a type of organism common to different regions.

JET STREAMS

The term jet stream primarily refers to concentrated, narrow atmospheric currents in the upper troposphere or stratosphere, associated with large wind shears and single or multiple velocity maxima. According to the World Meteorological Organization, the typical jet stream is “thousands of kilometers in length, hundreds of kilometers in width and some kilometers in depth”. The vertical shear of wind is of the order of 5–10 m/s per kilometer and the lateral shear is of the order of 5 m/s per 100 km. An arbitrary lower limit of 30 m/s is assigned to the speed of the wind along the axis of the jet stream. Ocean currents, such as the Gulf Stream and Kuroshio current, follow the same physical laws and could be considered jet streams, although their velocities are considerably less than atmospheric examples.

Formation of jet streams

The uneven distribution of available energy over the Earth's surface, marked by surplus solar radiation absorption at low latitudes and excessive radiative loss at high latitudes, necessitates a heat transport from equator to pole. If the Earth did not rotate, this transport would occur as a simple Hadley cell (Figure J1).

In a rotating system, in addition to heat, absolute angular momentum is transported poleward with the meridional circulation generated by differential heating. In the absence of external

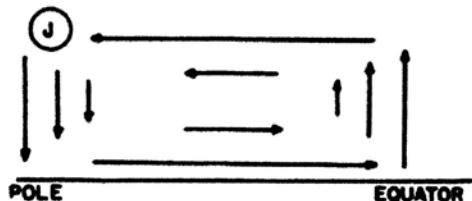

Figure J1 Hadley cell on a non-rotating Earth.

forces, absolute angular momentum is conserved along the path of displacement, resulting in an increase in westerly velocity.

According to Figure J1, air rising over the equator has been in frictional contact with the Earth's surface, acquiring angular momentum characteristic for these latitudes. As the air travels poleward beneath the tropopause it turns – under conservation of angular momentum, from a southerly into a westerly direction. At the same time its westerly velocity increases with the distance moved meridionally. Although relatively small displacements are sufficient to generate a strong westerly jets stream, wind velocities often fall short of those derived from angular momentum conservation because of the counteracting effect of friction and pressure forces.

In a slowly rotating system the meridional circulation extends close to the pole, accompanied by a high-latitude jet stream. This position is possible because only small amounts of absolute angular momentum need be transported at a slow rate of rotation. When rotation is more rapid, horizontal wind shear and turbulence near the pole (as jet velocities drop to zero directly over the pole) force the jet stream position to shift equatorward.

Beyond a critical rate of rotation the meridional circulation is no longer capable of transporting heat and angular momentum in required amounts. The jet stream breaks down into a series of symmetric waves or eddies. Figure J2 shows a simulated

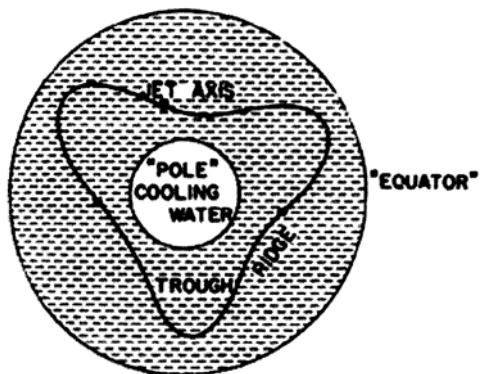

Figure J2 Three symmetric Rossby waves in a rotating dishpan.

three-wave arrangement in a rotating dishpan. Such waves were first theoretically described by Rossby. With still-increasing rotation rates the number of such waves increases. As the rotation rate continues relative to the magnitude of the surface heating imbalance within the system, irregular waves form, resembling those observed on daily hemispheric weather maps. These waves have a strong tilt of their axes (Figure J3) permitting more westerly momentum and heat to flow northward along the east side of troughs than southward on the west side of troughs.

Atmospheric conditions

Conditions in Earth's atmosphere are more complex than those considered in classical jet stream simulations (e.g. dishpan experiments). The Coriolis parameter (f) varies with latitude, rendering the deflection of airflow under conservation of absolute angular momentum greater in polar than in equatorial regions. As f increases with latitude, so does the maximum allowable anticyclonic wind shear, causing high-latitude jet streams to be more pronounced in terms of horizontal wind shear than their low-latitude counterparts.

In addition, the presence of large topographic disruptions to the depth of the troposphere, such as the Tibetan Plateau and the Rocky Mountains, cause deflections in the jet stream flow that form quasistationary planetary (Rossby) waves. The variable heating effects of land and ocean also exert a strong influence on planetary long-wave patterns. Superimposed on the long-wave patterns are migratory Rossby waves, observed in jet stream simulations under relatively high rotation rates.

Because of large momentum transports resulting from the relatively fast effective rotation rate of the Earth at high latitudes,

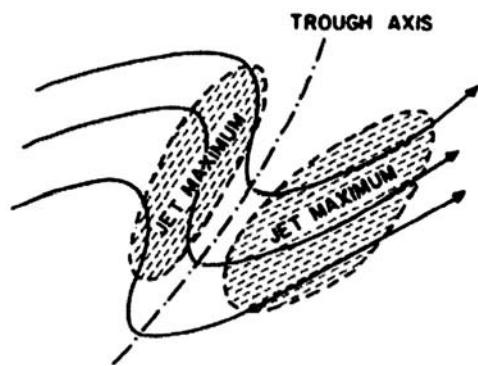

Figure J3 Streamlines and jet streams in a tilted low-pressure trough.

the Hadley cell of Figure J1 is confined to latitudes equatorward of 30°. Impossibly high wind speeds would result from a Hadley cell more meridionally extensive. Rather, the circulation model shown in Figure J4 is observed, revealing multiple jet streams.

Jet stream systems

Although absolute angular momentum is not strictly conserved in airflow because of external pressure and frictional forces, a tendency toward such conservation leads to jet streams in regions where considerable meridional circulation occurs. Such meridional displacements typically reach extreme values at characteristic atmospheric interfaces, prescribed by the thermal structure of the atmosphere and designated "pauses" (Figure J5). Jet streams are observed at the tropopause, stratopause and mesopause.

Tropopause jet streams

The Subtropical Jet Stream (STJ) is found near 30°N during the northern hemisphere winter as a continuous corridor around the hemisphere with three waves superimposed and jet maxima center near 70°W, 40°E and 150°E (Krishnamurti, 1959; Chen et al., 1988). The maximum at 150°E shows the strongest mean winds (e.g. >150 knots during the 1955–1956 winter). The STJ draws its high speeds from the meridional circulation of the Hadley cell. Momentum transfer is accomplished via both the meridional component of the mean circulation and horizontal eddy transport associated with the three-wave pattern. During the summer the STJ is less pronounced, particularly over Asia, where it gives way to an eastlery jet stream during the monsoon (see Riehl, 1962).

The core of highest winds in the STJ is located near the 200 mb level (about 12 km); the tropopause is disrupted on its poleward side. A zone of enhanced baroclinicity (horizontal temperature gradient on a surface of constant pressure) occurs beneath the STJ but does not extend below the 400 mb level. Below this shallow baroclinic zone the atmosphere is barotropic; wind shears and horizontal temperature gradients are small and naturally dissipated by the subsidence and surface divergence associated with the subtropical high-pressure zones.

The Polar Front Jet Stream (PFJ) is located above the polar front of the middle latitudes near the 300 mb level (about 10 km). The PFJ interacts strongly with developing extratropical cyclones, commonly inducing frontogenesis and precipitation via low-level convergence and upslope flow along the frontal zone. In addition to their occurrence above the baroclinic environment of the polar front, jet streams are also associated with continental and maritime Arctic fronts.

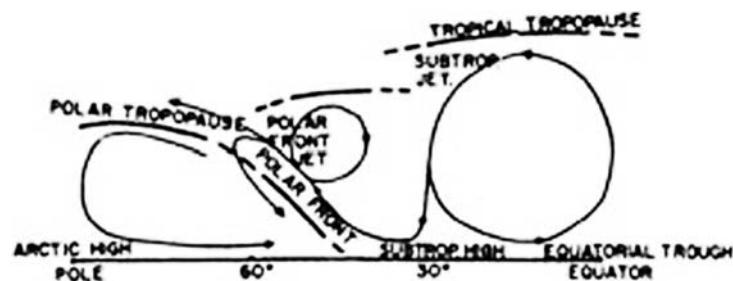

Figure J4 Schematic diagram of mean meridional circulation during winter, northern hemisphere (after Palmén, see Reiter, 1963).

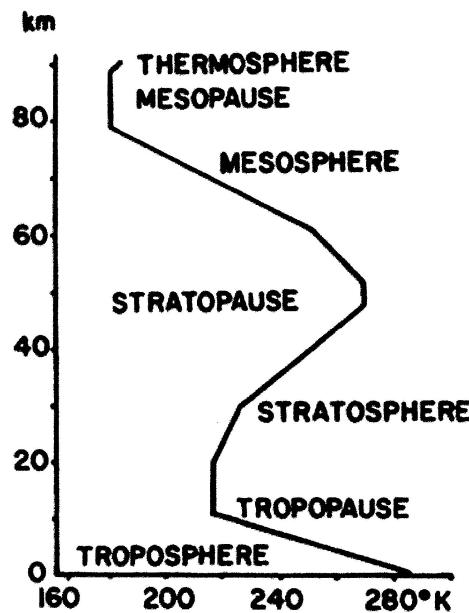

Figure J5 Thermal structure and nomenclature of the standard atmosphere.

Although diversion of air poleward along the polar front supports conservation of absolute angular momentum as a mechanism for jet stream formation, atmospheric conditions near the PFJ are more complex than those of the STJ. Individual jet maxima develop along the bases of deep low-pressure troughs, rather than at the crests of high-pressure ridges, as suggested by angular momentum theory and exhibited by the STJ. In the vicinity of jet maxima, pressure forces and potential energy released through sinking (rising) cold (warm) air exert considerable influence on the formation and maintenance of the PFJ.

Stratopause and mesopause jet streams

The stratopause located near the 50-km level harbors a strong westerly jet stream during winter, with winds in excess of 150 knots near 70° (Lee and Godson, 1957). A two-wave pattern dominates, with mean troughs centered over Siberia and Hudson Bay, suggesting the strong orographic influence of the Himalayas and Rocky Mountains, even at high latitudes. Large-scale horizontal and vertical transport processes induce anomalous seasonal ozone concentrations, which are not accounted for by the radiation budget of these latitudes. During the northern hemisphere warm season, continuous insolation over the pole reverses the hemispheric temperature and pressure gradients and the jet stream gives way to moderate easterly winds. Stratospheric flow patterns in the southern hemisphere show similar seasonal trends, although the summer easterlies are weaker than in the northern hemisphere.

The breakdown of the winter circulation may be rather abrupt. Whereas in the southern hemisphere it falls close to the period of the equinoxes, in the northern hemisphere large variations occur from one year to another. As the orientation and intensity of the stratospheric jet changes, stratospheric temperatures below the jet may experience “explosive warming” of more than 20°C within a few days. The transition to the warm

season solar radiation regime is marked by a shift from a prominent standing wave pattern in winter to summer easterly winds positioned symmetrically about the pole. According to Charney, planetary waves are trapped as they encounter an atmospheric layer in which the wind speed is equal to their phase velocity. In winter, with westerly winds (westerly velocity $u > 0$) in the troposphere and stratosphere, standing waves (phase velocity = 0) propagate freely into the stratospheric jet stream. During summer, standing waves will be trapped as they encounter easterly winds ($u < 0$) and are thus prevented from influencing the stratosphere.

Jet streams of the mesopause are still poorly understood. Because they occur in the ionosphere, and consist of drifts of charged-particle clouds, they are sometimes referred to as electrojets. Electromagnetic forces must be taken into account when considering air motions at these altitudes (>80 km).

Low-level jet streams

Low-level Jet Streams (LLJ) tend to form along *pauses* in the lower troposphere, i.e. along inversions on top of the planetary boundary layer. The precise depth of this layer is dependent upon convective mixing and nocturnal cooling and stabilization of air near the ground. Bonner and Paegle (1970) determined that the LLJ is influenced by differential heating along an inclined surface (e.g. the Great Plains between the Mississippi River and Rocky Mountains). The diurnal heating and cooling of the planetary boundary layer induce changes in the horizontal pressure field, to which the wind adjusts with a time lag dictated by the period of inertial oscillation. The inertial oscillation is contingent upon the Coriolis parameter, which varies by latitude. At 30° latitude the 24-h period of inertial oscillation matches the period of the diurnal temperature flux and it is here that LLJ develop most frequently.

LLJ phenomena are also associated with synoptic-scale forcing in extratropical low-pressure systems. In particular, LLJ have been observed imbedded within the southerly flow downstream from transient shortwave axes in northern hemisphere systems. Whether motivated by the diurnal heating and cooling cycle or the circulation with a midlatitude cyclone, LLJ can carry abundant moisture from adjacent seas (Gulf of Mexico, South China Sea) and thus contribute to severe weather.

Effects of jet streams

On a surface of constant pressure the vertical component of relative vorticity

$$\zeta = V/r - \delta V/\delta n$$

(where V is the velocity of the air current, r is the radius of curvature, n is the coordinate normal to the flow of direction) varies strongly to either side of the jet axis. These strong shears, coupled with the effects of curvature within the airflow, generate positive vorticity poleward and negative vorticity equatorward of a westerly jet maximum. Poleward of the jet axis, air flowing through this vorticity pattern will undergo convergence as it enters the jet maximum, then divergence as it passes downstream of the jet center. Equatorward of the jet axis, air diverges as it enters the wind maximum, then converges downstream of the center. Figure J6 shows schematically the divergence field around a jet maximum, superimposed on straight flow. Relative vorticity adjustments from curvature have been shown to modify

the divergence field as a jet maximum migrates through a geopotential trough.

Since divergence at tropopause level will result in a mass deficit in the vertical air column, surface pressure falls should result beneath the regions of divergence. If a frontal zone is present at low levels in the zone of pressure falls, cyclogenesis may occur, as shown by Pettersen, 1956; Newton, 1954, and others). Thus, stormy weather patterns, particularly cloudiness, precipitation and cyclones, are intimately linked to jet streams at tropopause level. These weather patterns in turn modify the kinematics of the jet streak environment (see Wolf and Johnson, 1995).

The divergence distribution at jet-stream level also forces significant vertical mass displacements that induce mixing of

tropospheric and stratospheric air. These processes are illustrated schematically in Figure J7 (Shapiro et al., 1980). Stratospheric air, characterized by high ozone concentrations and large potential vorticity values (the product of thermal stability and absolute vorticity) subsides within the stable layer beneath the jet maximum, the so-called jet-stream front. Deep and sustained intrusions of stratospheric air to the middle troposphere and below are associated with explosive cyclogenesis.

Conversely, tropospheric air intrudes into the stratosphere in a large wedge between the stability tropopause and the potential vorticity tropopause. In contrast to the stratospheric intrusion, the tropospheric air is recognizable from low ozone concentrations and smaller potential vorticity values. Low-pressure troughs are thus characterized by high total ozone content, due to the sinking motion in the upper troposphere and lower stratosphere. Low-latitude tropospheric air is transferred poleward in high-pressure ridges, reducing the ozone values there.

Jet stream winds also have an important effect on airline operations and the planning of their economy. Flight times may be improved in transcontinental and transoceanic flights by riding the jet stream, while headwind flights are diverted around the jet stream path when possible, as required by Air Traffic Control regulations. Strong shears in the jet stream region may cause clear air turbulence that may, under serious conditions, lead to material fatigue and even aircraft failure.

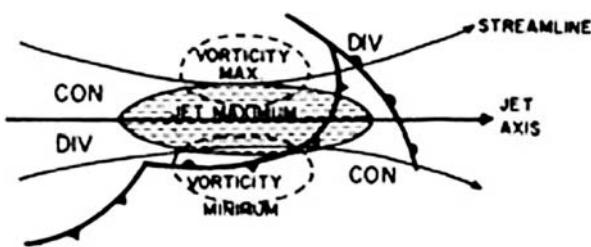

Figure J6 Schematic position of convergence and divergence at jet stream level and fronts at the Earth's surface.

KATABATIC (GRAVITY) WINDS

Katabatic winds occur when air is cooled from below over sloping terrain. Such cooling causes a shallow blanket of air adjacent to the surface to become colder and therefore heavier than the atmosphere above, thus forming a thermally distinct layer that exchanges little energy with the overlying air. The slope of the ground imparts a component of gravitational acceleration to the surface layer, thus allowing the air to drain downslope.

Radiative cooling of the air plays a dominant role in most katabatic wind systems, particularly those that occur in mountain valleys where katabatic flow forms one component of a local wind system referred to as the mountain and valley breeze (Defant, 1951). In such locations the katabatic wind, or mountain wind, is a nighttime event, spurred on by cooling in the higher elevations. The situation is reversed during the day when radiative heating at the same elevation causes air next to the ground to move upslope in a flow known as the anabatic wind. Either case is accompanied by a return flow in the air above the surface layer.

Katabatic winds are more persistent where the ground is covered by ice, provided the air remains warmer than the ground. Such conditions are found in warm air advected over melting valley glaciers in summer where a katabatic flow, sometimes referred to as the glacier wind, occurs over the ice throughout the day. However, far more favorable conditions are found over major ice caps, where the air may be warmed through large-scale subsidence. Radiative cooling in the lowest layers of such air gives rise to the major katabatic systems that dominate the wind regime of Antarctica (Ball, 1957).

Various forces govern the katabatic wind, the importance of each depending upon local conditions and the scale of the flow (Mahrt, 1982). The most important is the force generated by gravity acting on cold air at the ground, a force that drives the wind with increasing strength as the slope of the surface

increases. It may be substantially modified by forces arising from other accelerations that occur over time and space (Kottmeier, 1986). Local pressure gradient forces arising from differential surface heating or cooling may also be at work, either reinforcing or weakening the katabatic wind. As time and space scales become large, the Coriolis force assumes growing importance, deflecting the wind so that it flows at an angle to the slope azimuth.

Scale determines the thickness of the katabatic wind layer, and the speed at which the air moves. The relatively small scale of valley wind systems, where cooling might occur over distances of 5 km or less, tends to restrict katabatic layers to thicknesses that rarely exceed 10 m, and wind speeds on the order of 1 to 5 m s⁻¹. Antarctic katabatic winds, which can be generated over distances of hundreds of kilometers, may extend through the first 0.5 km of the atmosphere and achieve speeds in excess of 25 m s⁻¹. They are especially well developed near coastal Antarctic locations such as Cape Dension where, at mean monthly speeds approaching 90 km h⁻¹, they rank among the world's strongest winds.

KEPLER'S LAWS

Johann Kepler (1571–1630) was one of the founders of “classical” astronomy. By painstaking calculations from the observations of Tycho Brahe he was able to obtain empirically the three fundamental laws of celestial mechanics, two in 1609 and a third in 1619. At first it was assumed with Copernicus that planets were in circular motion about the Sun, in short the Heliocentric Theory, which rejected the Ptolemaic geocentric concept of the solar system. Kepler tried to compute circular orbits from Tycho Brahe’s data, but eventually recognized that planetary orbits were elliptical, and this opened the way to his famous laws.

The first law

The orbit of each planet is an ellipse with the Sun as one of its foci. The longest axis of an ellipse is called its major axis (AB) and half this length, defining the center point (C), is the semi-major axis. The ratio of the distance from C to the sun (S) over the distance SA is called the eccentricity. The ellipse may then be specified by these two distances. Geometrically the orbit may be plotted mechanically by taking a piece of string twice the length of SA and fixing the ends at point S and S' the second focus, an equal distance from B as S is from A ; a pencil placed in the loop of string, maintaining it taut, will then move in the ellipse as defined. The distance from the planet to the sun, or radius vector, thus varies constantly. The complete planetary circuit in such an ellipse, or orbit, is its revolution, the time occupied being the revolutionary or sidereal period. The planet when nearest to the Sun is said to be in perihelion; when farthest away aphelion. If the eccentricity were zero we would have a circle, but according to probability reasoning the chance of evolving such an orbit is zero.

The second law – law of areas

For a given period of time as the planet moves in its orbit, the radius vector sweeps out an equal geometric area. Plots of equal area along such an ellipse evidently intersect the orbit in arcs of varying length, longest near perihelion and shortest near aphelion. It follows that the orbital (and angular) velocity of the planet is highest when closest to the sun and lowest when farthest away. The mean angular velocity or mean motion through 360° is then easily determined by dividing the revolution period by 360, and is usually expressed in degrees, minutes, and seconds of arc per day. Since the angular momentum of a planet (J) relative to the sun is given by its mass (m) times its velocity (v) times the distance (y) at any moment, i.e. $J = mv y$, it can be shown that the angular momentum remains constant or conserved.

The third law – the harmonic law

The cube of a planet’s semimajor axis (its mean distance from the sun) divided by the square of the sidereal period is the same for every planet. The Earth’s mean distance from the sun is known as the astronomical unit (AU). In Kepler’s day the actual distance was not well established, so by taking the AU as unity

and the unit of time as 1 year, the quotient of the third law formula for the Earth was likewise 1; thus for any other planet the square of its sidereal period (expressed in years) provides the cube of its mean distance from the sun. In this way the periods, easy to determine, gave the clue to the mean orbital characteristics of the planets even though the precise scale was not known.

KÖPPEN, VLADIMIR PETER

As noted by C. W. Thornthwaite, the most important name in the history of climatology, and to many the father of modern climatology, is Vladimír Peter Köppen (Thornthwaite, 1943). Köppen published his first significant paper in 1868 and was researching, writing and publishing at the time of his death. He was born on 25 September 1846, in St Petersburg, the capital of the Imperial Russian Empire, and died in Graz, Austria, on 22 June 1940. Raised in an intellectual academic environment of German, French, and Russian scholars, Köppen developed a deep sense of environmental perception, a wonder for the varied vegetal zones of Imperial Russia, and an appreciation of the effects that climate has upon life on Earth. His grandfather was a German medical doctor invited to Imperial Russia by Empress Catherine the Great. He became a personal physician to the royal family. His father, Peter von Köppen, was a geographer who served on the faculty at the Imperial Academy of Science. Appointed to the highest academic rank in Imperial Russia by Tsar Alexander II, Peter was granted a seaside estate on the southern coast of the Crimea. As a child, Köppen explored the vegetal zones on the low mountain ranges along the Black Sea coast. Variations in vegetation, soil, and land use stimulated his interest in the geography of plants and the relationship of plants to climate.

Köppen began his formal academic studies when he was accepted as a student at the University of St Petersburg in 1864. His undergraduate major was in botany. Between academic terms he traveled from St Petersburg to the family estate in the Crimea. The vegetal changes he noted on the trip south and then living in the beautiful subtropical littoral of the Crimea broadened his biogeographic perspectives. Köppen transferred to the University of Heidelberg in 1867. He received a PhD from Heidelberg in 1870. His doctoral dissertation was focused upon the relationship between plant growth and temperature. Köppen returned to St Petersburg in 1871 to a position at the Central Physical Laboratory. In 1874 he returned to Hamburg, Germany, as head of a newly established division of weather telegraphy, storm warning systems, and marine meteorology at the German Naval Observatory. Köppen became the meteorologist of the

observatory in 1879, and in 1884 published a world map of temperature belts according to the number of months above or below a certain mean temperature. At the time this was considered a very significant publication. He delimited six principal temperature belts – tropical, subtropical, summer-hot-temperate, winter-cold-temperate, cold, and polar (*Briefnachlass*, 1932).

Köppen's map stimulated other physical science researchers. Oscar Drude adopted the six principal belts and created a world map of floral kingdoms. A.F.W. Schimper expanded Drude's seminal work on plant geography and published his work in 1898. Schimper's classification of vegetal zones was similar to Drude's in that the vegetal zones or regions graded from humid to arid. Two years after Schimper published his study, Köppen published his first of many studies on climatic classification; it was a mathematical system of climatic regional differentiation (Köppen, 1900). He contended that plants serve as natural meteorological instruments integrating various climatic elements. Köppen did not see Schimper's publication, and envisioned De Candolle's plant regions of the world to be climatic regions. He focused his research upon determining numerical values for the boundaries of plant regions while retaining De Candolle's use of the letters A, B, C, D, E to represent climatic regions. Realizing the problems associated with his 1900 map, Köppen published a revised climatic map of the world in 1918. He had difficulties in finding numerical means to denote effective precipitation, particularly in delimiting desert and steppe boundaries (Leighly, 1926). Recognizing the lack of worldwide temperature and precipitation data, and realizing the use of mean values restricted precision, Köppen presented at minimum four separate formulas or means to define climatic regions in 1918, 1923, and 1928. In a series of publications on climatic classification, he created the classification scheme shown in Table K1.

Köppen retired from his position at the German Naval Observatory in 1924. He moved to Graz, Austria, a beautiful university town 87 miles southwest of Vienna. Working with Rudolph Geiger he began research on a five-volume *Handbook of Climatology*. It was nearly completed when he died (vol. 1, Part C, was published in 1936). The basic Köppen classification system divided the world into five main zones. These zones were subdivided according to temperature and precipitation, seasonal variations in precipitation, and the effect of temperature and precipitation on vegetation. He ignored other climatic controls that also affect climate such as planetary winds and pressure cells, frontal systems, and ocean currents (Van Royen, 1927). Still Köppen's basic map of world climates and his later revisions have been recognized as a great scientific contribution by most physical scientists, and its simplicity has contributed to its acceptance and longevity. Many problems in defining the climatic regions, and in the formulas or indexes, existed in Köppen's works. Yet his system has been modified, its many problems rectified, and it does give a reasonably acceptable representation of the world's climates.

Wladimir Peter Köppen published more than 500 items between 1868 and 1939. Fluent in Russian and German, he read

much, kept well informed on scientific topics, and was receptive to new ideas and new concepts. Reflecting the background from which he came in Imperial Russia, and from his family, Köppen devoted much time and energy to improving the nutrition of the underprivileged, chronic alcoholism, school education reform, and conservation. He was a founder of the Eimsbuttel Boys Home in Hamburg, worked to secure a peaceful Europe, and provided help to refugees. A modest, small, dignified scholar, he made a very significant contribution to climatology (AWI, 2002).

KRAKATOA WINDS

When the giant volcanic eruption of Krakatoa (also Krakatau) occurred in the Sunda Strait, between Java and Sumatra, Indonesia, on 27 August 1883, its ash was carried up to the lower stratosphere (18–34 km). The volcano is located at 6°9'S, 105°22'E, and at the time of the eruption there was an easterly equatorial air flow, so that the ash initially at the 9 mb (32 km) level, after some weeks settled down at about 25 km and was carried around the globe. This particulate loading affected the cloudscapes in the troposphere, particularly at sunrise and sunset, at times creating dramatic coloration which persisted in some places, e.g. London and Paris, for up to 3 years.

Information about the eruption and its effects was gathered over several years by the Royal Society of London, and published. The local geology and environmental effects were published in Dutch by Verbeek. In the century that followed, smaller eruptions have occurred from time to time, and a new island, Anak Krakatau ("Child of Krakatoa") has begun to form. A semi-popular book-length review of the entire history was published in the year 2003 by a geologically trained journalist and in 2004 it was presented on television by the BBC in its science series.

The name "Krakatoa Winds" was first used by Van Bemmelen (this and other references in Fairbridge, 1967). From the meteorological point of view the Krakatoa Winds are most interesting, because the year after the eruption, 1884, the ash clouds were seen to reverse, to create a westerly stratospheric air flow, sometimes called the "Von Berson Westerlies" (Palmer, 1958). These westerlies are actually a lower-level air flow, which rises and falls in a cyclical manner (Bjerknes, 1969; Reed et al., 1961; Wexler, 1951). Furthermore, this biennial reversal is not quite

Table K1 Climatic regions classification

Af	As/Aw		
Cf	Cs/Cw	BS	BW
Df	Ds/Dw		

regular and has sometimes become triennial (Schove, 1983). It has subsequently been correlated with the QBO or Quasibiennial Oscillation. This QBO periodicity has been found to have a long-term average of 2.172 yr, which appears in the spectra of sunspots (Currie, 1973) as well as in many terrestrial time series (Schove, 1983). Evidently these stratospheric winds are externally forced, but their physics still leave much to be explained. Sir Gilbert Walker (1924) proposed they belonged to equatorial upper-level cells of what is now called the "Walker Circulation" (Pielke and Oort, 1995, p. 419).

The velocity of these winds is up to 25–50 m/s (i.e. 50–100 knots). The mean velocity of the initial dust cloud was 60 knots (Wexler, 1951). Subsequent to the 1883 eruption, several equatorial or low-latitude volcanic eruptions, e.g. Agung and Pinatubo, together with the nuclear bomb tests in the Marshall Islands, have added information, developed further by instrumental testing and satellite studies. An analogous and even greater eruption was that of AD 535, which has been described in a book by Keys (2001). It is believed to have also been located in the Sunda Strait, but has not yet been thoroughly investigated.

KYOTO PROTOCOL

In 1992, at a meeting in Rio de Janeiro, the United Nations Framework Convention on Climate Change (UNFCCC) was adopted. Its purpose was an attempt to combat global warming by stabilizing the emissions of greenhouse gases. The Kyoto Protocol or, more properly, the Kyoto Protocol to the United Nations Framework Convention on Climate Change, is a proposed amendment that was adopted in 1997 at a Conference of Parties (COP) in Kyoto, Japan.

The Kyoto Protocol commits developed countries to reduce emissions of carbon dioxide, methane and nitrous oxides and to phase out hydrofluorocarbons, sulfur hexafluoride, and perfluorocarbons over a 30-year period. It reaffirms the idea that developed countries must supply technology to other countries in climate-related studies and related projects.

The Protocol was endorsed by 160 countries and will become binding provided that 55 countries, including developed nations responsible for most global emissions, ratify the accord. By 2002 some 104 countries had signed the agreement. Signing the agreement is essentially symbolic, and for the Protocol to become fully effective the UNFCCC requires that parties complete their "instruments of ratification, acceptance, approval or accession".

Since the Kyoto meeting other COP have attempted to resolve problems and issues, not always with success. Over time, and with appropriate political activity, full ratification may occur.

L

LAKES, EFFECTS ON CLIMATE

Bodies of water modify the atmospheric environment in their vicinity. Small bodies of water of a few hectares or less cause small, local modifications that are generally not significant. Larger bodies of water, such as lakes, cause more significant effects on climate at scales ranging from the microscale to the synoptic scale. The effects of lakes on the atmosphere vary with areal extent, depth, and configuration of the lake, the velocity and direction of the winds, whether winter ice forms on the lake, and the regional climate of the lake. Large, deep lakes cause more pronounced modifications than small, shallow lakes. Most of this discussion will focus on the effects of large lakes on climate.

The effects of the Great Lakes of North America on climate have been studied extensively, as have the climatic effects of other large lakes of the world. Studies have also been conducted on artificial lakes, such as reservoirs. Some studies of the effects of lakes on climate have been observational with collection of field data for a few months or several years. Other studies have been computer models of the expected effects.

Lakes affect the climate through alterations of the atmospheric boundary layer due to: (1) the thermal lag of lake surface temperatures compared to the adjacent land areas, (2) the availability of open water over lakes for evaporation, and (3) alterations of winds by lakes as a result of contrasts in surface roughness between the lake and the land surfaces.

Large lakes, such as the Great Lakes of North America, contribute large amounts of latent and sensible heat to winter storm systems. Large lakes cause passing synoptic scale cyclones to accelerate toward the lakes and rates of intensification increase over the lakes during the ice-free, unstable season of September–November. Passing cyclones during the ice-covered, unstable season of December–April and during the stable season of May–July accelerate less than during the ice-free September–November season and rates of intensification do not change over the lakes. Computer simulations in general circulation models show that the Great Lakes cause an intensified temperature gradient north of the lakes in fall and winter. This

intensifies the mean jet stream core and displaces it northward. Such synoptic scale forcing is unlikely from lakes smaller than the Great Lakes.

Air temperature

Effects of lakes on the air temperature climate are due primarily to the thermal lag of lakes. This is most pronounced for lakes in climates with a large seasonality in temperature. Water has a heat capacity that is about three times greater than the heat capacity of soil and, with mixing in water, lakes warm up slowly in spring and summer and cool down slowly in fall compared to land surfaces. The effects on climate are greatest for the largest lakes, such as the Great Lakes ($>25\,000\text{ km}^2$) but are significant also for lakes and artificial reservoirs of less than 200 km^2 .

Lakes create a modified marine climate along their shores, especially on the prevailing downwind shore. Summer temperatures are cooler over and near large lakes and winter temperatures are warmer. Extremes of heat and cold temperatures are reduced by lakes. The moderating effects of lakes on winter air temperatures are reduced, but not eliminated, if the lake surface freezes.

The start of the growing season in spring is delayed by the chilling effects of large lakes, but the first freeze in fall is also delayed near lakes. The freeze-free season is generally lengthened by several weeks near large lakes, although growing season heat availability for plants is reduced near the lake due to cooler summer temperatures. This effect on climate extends 10–30 km inland for the largest lakes. The moderated air temperatures and longer freeze-free seasons near lakes have led to the cultivation of fruit crops along the shores in climates where they may not otherwise be suited.

Moisture and precipitation

Moisture fluxes over a lake are dependent upon the vapor pressure difference between the lake water surface and the overlying air. Evaporation is at a maximum in late fall and early winter when the vapor pressure difference is greatest. Evaporation is diminished when the vapor pressure difference reaches a minimum in spring and early summer. Water vapor will

condense onto a lake, the reverse of evaporation, if the water temperature is cooler than the dewpoint of the air.

Lakes are commonly colder than prevailing air temperatures in spring and summer due to the thermal lag discussed previously. A stable marine layer develops in the lower atmosphere under these conditions. This causes a suppression of convective cloud development and suppression of afternoon rain shower and thunderstorm activity over the lake and adjacent land downwind. On the other hand, during fall and winter when the lake temperature is commonly warmer than the air temperature, lakes release large amounts of sensible heat and latent heat to the atmosphere. This causes an unstable lower atmosphere and stimulates convection, condensation, clouds, and precipitation over the lakes and downwind – a process called lake-effect clouds and precipitation. The number of cloudy days in winter is 36% greater downwind of Lake Michigan, USA, than upwind of the lake, while the number of cloudy days in summer is 15% less downwind. Fogs may occur over and adjacent to lakes in spring and summer when the lake is cold with respect to the air, and in winter when steam fogs form in cold air over warmer lake waters.

In regions where winter temperatures are below freezing, lake-effect snowfall is common over and downwind of lakes, causing two to three times as much snowfall as occurs upwind of the lake. Lake-effect snowfall is diminished if the lake surface freezes. Lake-effect rainfall occurs from early autumn until temperatures fall below freezing. The enhanced snowfall downwind of large lakes causes additional expenses for snow removal along transportation routes and requires additional strength in buildings to support the roof snow loads. The enhanced snowfall also provides opportunities for skiing and other winter recreation.

Wind patterns

Wind speeds over lakes are higher than over land due to less friction over water surfaces. Data from the Great Lakes show wind speeds over the lakes are 30% higher than inland stations in summer and 100% higher in winter. On land adjacent to lakes, wind speeds are greatest near the shore and diminish farther inland where friction slows the wind.

A lake breeze may develop on spring and summer days with weak synoptic scale flow and a lake that is much cooler than the land and prevailing air temperatures. A cool, moist onshore air flow from the lake across the shore toward land develops several hours after sunrise and persists through the afternoon. The lake breeze may extend several kilometers inland and cause air temperatures to be 5–10°C cooler along the shore than inland. The zone of convergence at the lake breeze front can initiate convection and clouds.

LAMB, HUBERT H. (1914–1997)

The British scientist Hubert Horace Lamb was one of the twentieth-century pioneers of modern climate research. With a handful of peers, scattered across the inhabited continents, he transformed the subject of climatology from the rather dry record-keeping exercise it had become during the first half of the twentieth century into the dynamic study of climate variability that it is today. Hubert Lamb's particular contribution stemmed from his broad interdisciplinary interests and expertise. He established an international reputation as a scientist able to cross subject boundaries freely, making use of often fragmentary data to weave a rich story of climate change and its impact on human affairs.

Lamb studied history and languages before entering Cambridge University, then transferred from the natural sciences to geography whilst an undergraduate. Thus, he was well prepared to handle the wide range of evidence of climate change in the recent and more remote past. His two-volume work, *Climate: Present, Past and Future*, published in the 1970s, provides a fitting testament to his ability to analyze, evaluate and synthesize data ranging from observations from the modern meteorological network, through anecdotal evidence from the most recent millennium, to biological and other proxy indicators over geological timescales. That he earned the respect of practitioners in a wide array of disciplines contributed in no small way to the widespread acceptance of climate change as a subject warranting serious academic study during the 1950s and 1960s.

Lamb's interdisciplinarity was coupled with a deep understanding of the workings of the climate system, stemming from his years as a bench forecaster. Joining the Meteorological Office in 1936, he was transferred to the Irish Meteorological Office during the 1940s, having refused to accept an instruction

to work on the meteorology of gas spraying. In Ireland, his main responsibility was forecasting for the new trans-Atlantic passenger flights. In 1945, Lamb resigned from this post after disagreeing with the Director of the Irish Meteorological Service over the effect of increasing workloads on aircraft safety, and rejoined the British Meteorological Office the following year. Shortly afterwards he headed south to the Antarctic as expedition meteorologist on the whaler *Balaena*. It was during this time that Lamb, on the basis of his own observations in southern waters, began to doubt that climate was quite as constant as generally believed. An empirical scientist at heart, he pursued this realization by developing new indicators of the state of climate and the atmospheric circulation and extending these records back in time. It was a short step to studying the potential causes of climate change.

July 1970 saw the publication by the Royal Society of one of Hubert Lamb's most significant contributions to climate research, the monograph "Volcanic dust in the atmosphere; with a chronology and assessment of its meteorological significance". The landmark report contained not only the well-known chronology of volcanic eruptions and dust veil index but also an exhaustive review of the scientific basis of the volcanic forcing mechanism and a preliminary analysis of the observational evidence linking climate change and volcanic events. It had long been recognized that the pollution ejected by a major, explosive volcanic eruption could affect weather and climate. Lamb's achievement was to draw together existing material from a number of disparate fields, initiating currents in climatological research that remain evident today.

In 1971 he left the Meteorological Office and established the Climatic Research Unit at the University of East Anglia as a base for interdisciplinary work on climate change. Director of the Unit for 6 years before retirement, he again broke new ground, creating a research group that remains recognized as a world authority on natural climate variability and anthropogenic change. After retirement, Lamb published two editions of his highly regarded account of climate and human affairs, *Climate, History and the Modern World*, returning to his historical roots.

During his later years Lamb was sceptical of the more strident claims regarding the dangers posed by global warming. As he observed in 1994, "there has been too much theory and not enough fact in predicting the future". He died on 28 June 1997, aged 83, having lived to see the United Nations Framework Convention on Climate Change come into force. Climate change was now not only a subject of academic concern but was firmly on the political agenda, a development that Hubert Lamb played no small part in making possible.

LAND AND SEA BREEZES

Land and sea breezes develop because of differential heating and cooling of adjacent land and water surfaces. Water has a greater heat capacity than land, i.e. land absorbs and emits radiation more efficiently and faster. The diurnal temperature differentials between land and water create a distinctive wind pattern – an example of thermal circulation.

During the day the air over land is heated and expands more rapidly than that over water, resulting in pressure changes and a thermally driven circulation with rising air over land and sinking air over water (Figure L1a). At the shoreline the cool sea air blows inland and is known as a sea breeze.

A sea breeze usually begins several hours after dawn and intensifies in the afternoon. The inland-moving sea breeze causes a decrease in temperature and a rise in humidity. The cooling effect on land is crucial for human comfort, particularly in the tropics (the Europeans called the sea breeze "the doctor", as it helped overcome the tropical heat in Africa); its influence can penetrate to about 30–40 km inland. This air is quite shallow, and ranges to several kilometers deep at its maximum development. A sea breeze front may develop between the warm inland air and the cool sea air. This front is responsible for the abundant precipitation in Florida. Sea breezes here develop on both sides of the Florida peninsula and converge over central Florida, producing strong thunderstorms.

At night the land cools more rapidly than water, resulting in a higher pressure relative to that over water. The circulation reverses and wind blows offshore; this is known as a land breeze (Figure L1b). A land breeze has a smaller magnitude than a sea breeze because the water surface does not gain heat but retains the heat absorbed during daytime, thus producing a smaller temperature difference between land and water at night. A land breeze can penetrate seaward to about 10 km.

Similar thermal circulation may develop over lakes. The inland-moving wind is called a lake breeze. Lake breezes form in regions around the Great Lakes and are common in later spring and summer.

LANDSBERG, HELMUT E. (1906–1985)

Helmut E. Landsberg died on 6 December 1985, in Geneva, Switzerland, while attending the ninth session of the World Meteorological Organization (WMO) Commission for Climatology. He was at that time a professor emeritus of meteorology at the University of Maryland, College Park.

As a renowned climatologist of the twentieth century, Landsberg advanced our knowledge of climatology through his own research, that of his students, and that of his many co-workers. He was in the forefront of teaching at universities, guiding international organizations, and directing national agencies. He developed regional and national applied climatological networks. He integrated atmospheric science into human affairs through political input and public documents. He stimulated professional organizations to interact and clarify scientific thought, and he interwove government, university, and private practitioners into a creative medium for scientific progress.

Landsberg was born in Frankfurt am Main, Germany, on 9 February 1906. He spent his student years at the University of Frankfurt, taking a basic curriculum of physics, mathematics, and geophysics, and completed his thesis dissertation in seismology in 1930 at the Geophysics Institute. Landsberg developed an intense interest in the atmosphere, principally from an observational viewpoint. He turned to practical forecasting by joining the Taunus Observatory, where he stayed until 1934, ultimately becoming its chief. The observatory provided extensive experience and broadened Landsberg's perspective. Indeed, it was at Taunus that his love for libraries blossomed.

Landsberg was recruited to teach geophysics at Penn State in 1934. As the first meteorologist at that institution he set up an observatory with the help of some students and began a teaching program that evolved into the present meteorology department.

In 1941 he joined the faculty at the University of Chicago, where he developed a field course for cadets who were in attendance during that period.

Shortly before the end of the Second World War, Landsberg moved out of academia to the federal government and into the world of science administration. He first was a consultant to the US Air Force and then became executive director of the Commission on Geophysics and Geography of the Research and Development Board, a position he held from 1948 to 1951. From 1951 to 1954 he was director of the Geophysics Directorate of the Air Force Cambridge Research Center. There he had occasion not only to develop in-house research with young protégés but also to fund high-quality university research. He then returned to Washington to direct the Office of Climatology of the United States Weather Bureau (USWB), at which position he remained until reorganization of the Weather Bureau into the Environmental Science Services Administration (ESSA) in 1965. At that time he became head of the Environmental Data Services of ESSA.

Landsberg returned to the academic world in 1967 and spent his remaining years there. He joined the University of Maryland as a research professor and concurrently held several administrative posts. He was acting director of the Institute for Fluid Dynamics and Applied Mathematics and subsequently became director of the newly founded Meteorology Program. In 1976 he retired from the university as a professor emeritus but continued to work with no loss of intensity.

Landsberg was elected to membership in the National Academy of Engineering in 1966, and was an honorary life member of the New York Academy of Sciences. He was a fellow of the Royal Meteorological Society, the American Academy of Arts and Sciences, the American Association for the Advancement of Science, the American Geophysical Union (AGU), the Meteoritical Society, the American Meteorological Society (AMS), and the Washington Academy of Sciences. In addition, he was a member of the German Meteorological Society, the American Institute for Medical Climatology, the

International Society of Biometeorology, the Mount Washington Observatory, the Sneedenberg Society of Natural History, the Society of Sigma Xi, the Society of Sigma Pi Sigma, the Society of Sigma Gamma Epsilon, and he was an honorary member of Phi Beta Kappa.

He served as president of the WMO Commission for Special Applications of Meteorology and Climatology from 1969 to 1978; he was a member of a WMO Advisory Working Group from 1978 to 1981; and he was a member of its Commission for Climatology from 1981 until his death. He served the National Academy of Engineering as a member of its Awards Committee in 1974 and 1975. At the National Research Council (NRC) he served on the Geophysics Research Board as chairman of the Geophysical Predictions Panel in 1977 and 1978, and as a member of its Panel on Energy and Climate from 1975 to 1978. For the NRC Division of Physical Sciences, he was a member of its Climatic Impact Committee from 1972 to 1975. He served the government as a member of the National Advisory Committee on Oceans and Atmospheres from 1975 to 1977. He served the universities as trustee to University Corporation for Atmospheric Research (UCAR) from 1968 to 1972 and assisted the private sector as a certified consulting meteorologist of the AMS. He served the AMS as councilor from 1952 to 1960, as vice-president in 1963–1964, and as chairman of the Awards Committee in 1974–1975. In support of the American Association for the Advancement of Science (AAAS) he was vice-president of Section E in 1972. He served the AGU as vice-president, Section on Meteorology (1953–1956), as president of that section (1956–1959), as vice-president of the Union (1966–1968), and finally as its president (1968–1970).

Landsberg loved books and acquired a unique and unequalled collection of rare historical books on meteorology, which he subsequently donated to various libraries. He was an associate editor of the *Journal of Meteorology* (1950–1961), the editor of *Advances in Geophysics* (1952–1977), the editor-in-chief of the *World Survey of Climatology* (1964–1985), and the chairman of the Publications Committee of the International Society of Biometeorology (1960–1985).

For his extensive professional contributions he was rewarded by numerous acknowledgments. He received the Exceptional Meritorious Service Award from the Department of Commerce in 1960. The AMS bestowed on Landsberg their Award for Outstanding Achievement in Bioclimatology in 1964, the Charles Franklin Brooks Award for Outstanding Services to the Society in 1972, and the Cleveland Abbe Award for Distinguished Service to Atmospheric Sciences by an Individual in 1983. The Deutsche Meteorologische Gesellschaft EV, the German Meteorological Society, awarded him the Alfred Wegener Medaille in 1980. He was the recipient of the William Bowie Medal in 1978 from the AGU. In 1979 he received the International Meteorological Organization Prize from the WMO. The W.F. Peterson Foundation Gold Medal was awarded to him in 1983, and in 1985 he was honored with the Solco W. Tromp Memorial Award by the Enviroscience Foundation. Ultimately he was bestowed the National Medal of Science by President Reagan in 1985.

Landsberg's scientific productivity was astounding and his breadth of interest and involvement remarkable. He left almost four hundred written published documents, including several books, and his written contributions to collective documents from his many committee assignments would substantially augment that total. His research explorations commanded numerous topics, including seismology, geography, geology,

climatology, weather forecasting, bioclimatology, urban climate, climate history, and climate services among many others. He had the perception and serenity that unfailingly led to meaningful solutions for the most complex of problems.

LAPSE RATE

The lapse rate is generally understood to be the decrease of temperature with height (or depth in oceanography), defined symbolically as

$$\gamma = \frac{\partial T}{\partial z}$$

where γ is the lapse rate, T is temperature and z height. In meteorology and oceanography two distinct types of lapse rate are used.

1. *Environmental or lapse rate in situ* is the temperature decrease with ascent through the atmosphere; it reflects the actual temperature change with altitude. The temperature instrument samples successively different parts of the air to determine the temperature conditions in the environment, commonly by a radiosonde instrument sent up by balloon.
2. *Process lapse rate* is the temperature of the same sample of air recorded as it changes with vertical motion. In this case the rate is determined by the character of the sample. Two contrasting air types may be considered:

Unsaturated air, called dry air, cools adiabatically due to expansion as it is lifted. This is called the *dry adiabatic lapse rate*, which has a numerical value of nearly $1^{\circ}\text{C}/100\text{ m}$ or $5.5^{\circ}\text{F}/1000\text{ ft}$, derived from the first law of thermodynamics and the equation of state for adiabatic conditions. Thus, one can determine the dry adiabatic lapse rate for any planetary

atmosphere in general and substitute particular values of the constants. Following Byers (1959), to obtain the adiabatic rate of temperature change with height, one may substitute dp from the hydrostatic equation into the differential form of the adiabatic equation with the result

$$C_r \frac{dT}{T} + \frac{R\rho gdz}{mp} = 0.$$

and since, from the equation of state $p = pm/RT$,

$$C_r \frac{dT}{T} = -\frac{mp}{RT} \frac{Rg dz}{mp}$$

and

$$\frac{dT}{dz} = -\frac{g}{C_r}.$$

This gives an expression for the rate of change of temperature with height in an adiabatic process, the negative sign indicating that the temperature would decrease with altitude. The term g/C_p has the value of approximately 10^{-4}C/cm , or $1^\circ\text{C}/100\text{ m}$, as mentioned above.

Moist air is cooled by lifting to the dewpoint, after which further cooling causes condensation of the water vapor to liquid or ice (sublimation), which releases the *latent heat*. Thus the *moist adiabatic lapse rate* (or *pseudo-adiabatic* since it is not truly adiabatic) is less than the dry rate due to the added heat. Following Byers (1959):

$$dT = \frac{-L}{C_r} dw.$$

Evaporating an amount of liquid water $-dw$ produces an amount of vapor $+dw$. Since this is a mixture, it is more convenient to use the specific humidity change dq in place of the change in mixing ratio dw . The new temperature, then, is

$$T'' = T_m + dT = T_m - \frac{L}{C_r} dq$$

$$= T_m - \frac{L}{C_r} (q'' - q_m).$$

where T'' and q'' are the actual temperature and specific humidity, respectively, resulting in the cloud. The numerical value varies from $0.3\text{--}1^\circ\text{C}/100\text{ m}$ or $2\text{--}5^\circ\text{F}/1000\text{ ft}$, depending on other conditions (pressure, temperature), but it is usually taken as near $6^\circ\text{C}/100\text{ m}$ or $3^\circ\text{F}/1000\text{ ft}$.

The *average lapse rate* is the mean *in situ* lapse rate for many observations, usually given as $0.5^\circ\text{C}/100\text{ m}$ or $3^\circ\text{F}/1000\text{ ft}$.

The lapse rate normally increases slightly with altitude. Near the tropopause the observed lapse rate approaches the dry adiabatic lapse rate, which is $9.8^\circ\text{C}/\text{km}$. The stratosphere has a lapse rate nearly zero (i.e. it is *isothermal*) until ozone begins to affect it. Reversals or negative lapse rates result from the overlap of contrasting air masses or, near ground, from nighttime high net radiation, and are then called *inversions* (see Figure L2).

When an environmental lapse rate exceeds the dry adiabatic rate, and the *potential temperature* decreases with height, it is said to be a *superadiabatic lapse rate*. Such a situation would develop on a microclimatic scale over a warmed land surface such as a desert or a paved road as the airmass warmed. Lapse rates over $1^\circ\text{C}/100\text{ m}$ are superadiabatic.

There usually is also a *diurnal variation in lapse rate*, owing to daytime warming and nighttime radiative cooling. Daytime heating may steepen the lapse rate, which may exceed the adiabatic rate, causing instability and convection. Cooling at night

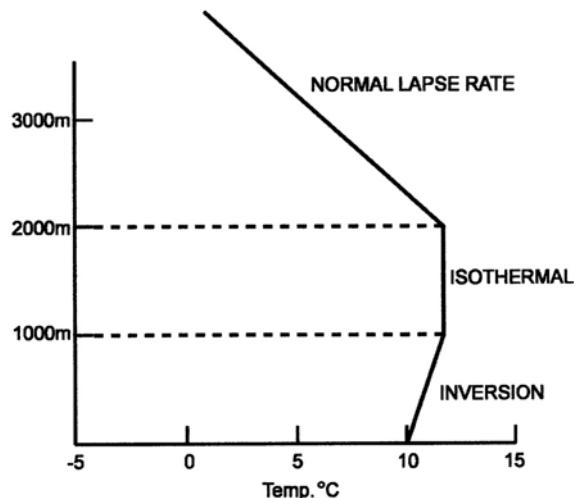

Figure L2 Normal lapse rate, isothermal condition, and inversion.

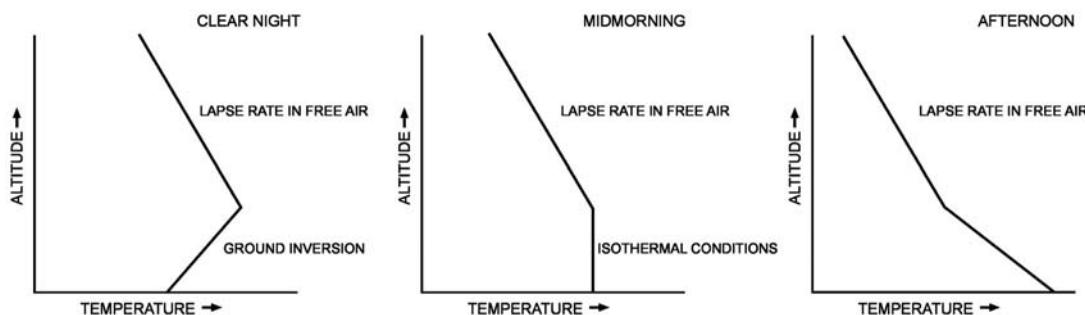

Figure L3 Diurnal variation of lapse rates over land in clear weather.

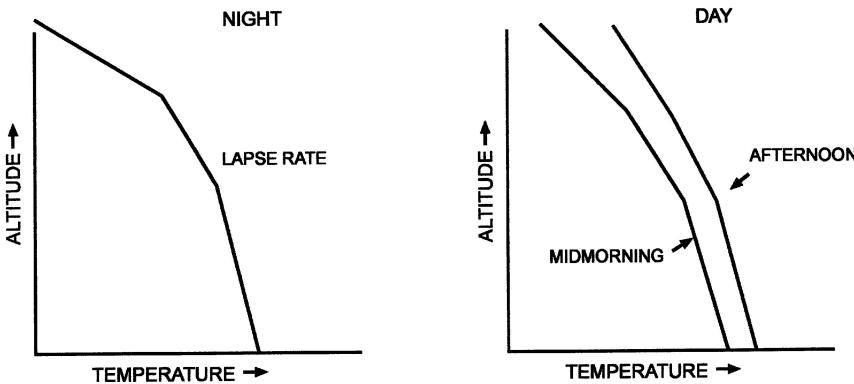

Figure L4 Lapse rates over the oceans. The temperature of the ocean remains nearly constant both day and night. Since there is little surface heating or cooling, air temperature in lower levels remains virtually constant.

reduces the lapse rate, increases *stability*, and in the early morning may cause inversion (see Figure L3, left-hand curve). Over a warm sea, which neither absorbs nor radiates heat very readily, there rarely is an inversion, but nocturnal instability may occur (see Figure L4).

LATENT HEAT

Latent heat is a form of internal or potential energy stored by evaporated or melted water. As ice melts or liquid water evaporates, the molecules change state – from a solid to a liquid, from a liquid to a gas, or from a solid directly to a gas. The energy required to melt ice or to evaporate water does not result in a change in its temperature; rather, it is stored through the phase change of the water molecules and can be subsequently released through condensation of the water vapor (through either dew or frost formation or precipitation) or refreezing of liquid water. This energy is termed *latent heat* since it does not

result in a change in the temperature of the water molecules – thermometers cannot measure this energy.

A total of 334 J of energy are required to melt 1 g of ice at 0°C, which is called the *latent heat of melting*. At 0°C, liquid water has 334 J g^{-1} more energy than ice at the same temperature. This energy is released when the liquid water subsequently freezes, and it is called the *latent heat of fusion*. Similarly, 2501 J of energy are required to evaporate 1 g of liquid water at 0°C, and this energy is called the *latent heat of vaporization*. This energy is released when the water vapor subsequently condenses, where it is called the *latent heat of condensation*. As before, water vapor at 0°C has 2501 J g^{-1} more energy than liquid water at 0°C. Thus, latent heat changes are symmetric with respect to the direction of a phase change, as is required through the Law of Conservation of Energy.

By contrast, to raise the temperature of 1 g of water by 1°C requires only 4.19 J of energy. Note that it takes almost six times as much energy to evaporate 1 g of water at 0°C than to raise its temperature to 100°C!

Water vapor can change directly to ice without ever becoming a liquid, as during the formation of frost, for example. Similarly, ice can change directly to water vapor without becoming a liquid, as occurs with dry ice (frozen carbon dioxide) or with ice cubes in a freezer. Since a fundamental law of physics is that energy must be conserved, this *latent heat of sublimation* must equal 2835 J g^{-1} at 0°C – the sum of the latent heats of melting/fusion and vaporization/sublimation at that temperature. Thus, water vapor at 0°C has 2835 J g^{-1} more energy than ice at 0°C.

Latent heat can be thought of as the energy required to break the bonds between the molecules at each change of phase. In ice, water molecules are strongly bound together in crystalline form. When 334 J of energy are added to 1 g of ice at 0°C, these bonds are loosened, producing liquid water at 0°C. If a further 2501 J of energy are added to this gram of liquid water at 0°C, the bonds are broken entirely, producing water vapor at 0°C. As a result, water vapor can be thought of as having “stored” energy as latent heat because condensing water vapor will release far more heat into sensible heat than can be stored by temperature changes in the water vapor alone.

In the above discussion the latent heats have been specified for a temperature of 0°C. At warmer temperatures the water molecules contain more kinetic energy (i.e. their *sensible heat* is

greater) and thus less energy is required for evaporation to occur. Thus, the latent heat of vaporization decreases with increasing temperature. For example, the latent heat of vaporization equals 2442 J g^{-1} at 25°C and only 2264 J g^{-1} at 100°C . Similarly, molecules of water contain less internal energy at colder temperatures so that less energy is released when they freeze. For example, the latent heat of fusion equals only 289 J g^{-1} at -20°C . Latent heats, therefore, are inversely proportional to temperature. Bolton (1980) gives an equation to describe the relationship between the latent heat of vaporization/condensation, L_v , in Joules per gram of water, and temperature, T , in $^\circ\text{C}$ as

$$L_v = (2501 - 2.37T) \text{ for } -35^\circ\text{C} \leq T \leq 35^\circ\text{C}.$$

Storms in both the tropics and midlatitudes, including tropical storms (hurricanes) and thunderstorms, are really latent-heat engines, fueled by energy released by the condensing moisture. As it takes a comparatively large amount of energy to evaporate water, a considerable amount of energy is released when that moisture condenses. Consequently, the advection of a large quantity of water vapor enhances the severity of the storm and the loss of this water vapor advection often contributes to the storm's demise. This is one of the reasons why hurricanes often dissipate shortly after landfall.

LIGHTNING

At any one time some 2000 thunderstorms are at work (Uman, 1987) illuminating the skies and striking the Earth with lightning between 25 and 300 times per second – more than 8.6 million times a day. This contributes significantly to the electrical energy balance of the Earth and its atmosphere.

Lightning is the discharge of static electricity within thunderstorm clouds, between clouds and the ground or into the surrounding air. Dust storms, fires and volcanic eruptions can also provide the necessary turbulent atmospheric environment for lightning to occur.

The necessary condition preceding any lightning flash is a separation of charge within the associated cloud or clouds. That is, electrons and positive ions must somehow be transported to different regions of the cloud to form an electrical dipole. The generally accepted model for a typical cumulonimbus lightning cloud has a region of negative charge just above its base, with the positive region just below its top. The voltage difference between charged centers may reach several million volts. Once

the voltage difference exceeds the insulating capacity (dielectric strength) of the air, a lightning stroke occurs. While a satisfactory, quantitative description of charge separation in the turbulent environment of a thunderstorm is still lacking, most atmospheric physicists are in agreement that the process involves the interaction, by collision, between supercooled water droplets and ice particles at and above the freezing level in the cloud. This explanation unfortunately leaves out occurrences of lightning in “warm clouds” as in the tropics, although warm cloud (entirely above 0°C) lightning has never been completely substantiated.

The lightning flash

What we see as a single cloud-to-ground lightning flash is actually several separate discharges in rapid succession, moving both from cloud to ground and from ground to cloud, as many as 30–40 strokes, each lasting only 0.00005 s (50 microseconds) to 0.01 s. A moving camera, as early as 1903, was used to show those properties and later the speed of each lightning stroke.

The cloud-to-ground discharge begins with a virtually invisible stepped leader stroke that moves downward at about $1.5 \times 10^5 \text{ m/s}$ in regular distinct steps, typically of 50 m length, seeking the most conductive path to the ground. As the stepped leader approaches the ground, an upward discharge occurs from the ground to meet the leader. When a conductive channel is thus established, a highly luminous return stroke travels upward from the ground at about $3 \times 10^7 \text{ m/s}$. This may be followed by other leaders, called dart strokes or dart leaders, using the same channel, each followed by return strokes, with speeds intermediate to the stepped leader and original return stroke.

Cloud-to-ground discharges typically lower negative charge to Earth (the negative CG or $-CG$). CG discharges are sometimes initiated by positively charged leaders, with the subsequent return strokes lowering positive charge to the ground (the $+CG$). Once thought to be quite rare, the $+CG$ is now thought to make up about 10% of all CG (Lyons, 1999).

Only one-fifth of all lightning bolts are cloud-to-ground; intracloud (IC) lightning is the most common. Air discharges, where conducting channels from the cloud do not reach the ground, and cloud-to-cloud strokes are less frequent. Figures L5 and L6 illustrate the CG and IC forms.

Figure L5 Cloud-to-ground lightning flash under the base of a cumulonimbus cloud over Mesquite, Arizona (photo courtesy of William T. Reid).

Figure L6 Intracloud lightning, also known as crawler lightning, explodes across the Great Plains skies (photo courtesy of William T. Reid).

Types of lightning flashes

Lightning flashes are also typed by their appearance. Highly branched cloud-to-ground discharges are called fork lightning, whereas streak lightning has very few branches. Sheet lightning is an intracloud discharge where the channel and branches are not visible; the discharge appears as a white sheet against the cloud. If the lightning is so distant that only some light near the horizon is seen, it is called heat lightning.

Air discharges come out from the bottom of the cloud branching into the air but do not reach the ground. These discharges are more common in dry areas where the cloud base is normally much higher. Air discharges have been seen shooting up vertically from tops of thunderstorm clouds even into the stratosphere. The discharges may extend as far as 20 km from the thunderstorm before finally reaching the ground. What may appear to be coming from clear sky and not from a distant cloud is a "bolt from the blue".

On rare occasions, if a strong wind is blowing, the separate strokes of a nearby flash can be seen as ribbon lightning, the appearance produced as the channel is blown sideways. Bead, or chain, lightning appears when the return stroke breaks into luminous beads, as the light intensity of the channel decays, some portions cooling faster than others.

Ball lightning, or *kugelblitz*, is a rare and unusual form that is not well understood. It appears near a lightning discharge as a ball of luminosity with a diameter of about 20 cm, usually red, orange, or yellow in color, making a hissing sound and leaving a foul-smelling odor. As most frequently reported, it usually lasts only a few seconds, floating down to the ground, where it strikes something and either explodes or simply dissipates quietly. A related phenomenon, corona or "St Elmo's Fire", discharged at the ground under electrified clouds, can form a luminous glow of light from the mast of ships, airplane wings, or church steeples when they become extremely positively charged.

There are also forms of lightning moving skyward from tops of thunderstorms. Sprites, which are enormous red-colored aurora-like features, lasting 100 ms or less, can span the stratosphere and even parts of the mesosphere. They appear to be a response to large peaked positive CG (Boccippio et al., 1995). Another high-altitude response to energetic +CG are elves,

which are brief (500 μ s) disks of light found above thunderstorms at about 90 km. Blue jets are rare powerful beams of blue light traveling upward out of thunderstorm tops at speeds of 100 km/s up to 50 km elevations (Wescott et al., 1995). Upward-moving "superbolts", over 100 times brighter than typical lightning, have also been recorded traveling into the stratosphere from thunderstorm cloud tops (Thurman, 1977).

Lightning climatology

Lightning climatic data have been traditionally linked with thunderstorms, so that lightning days and thunderstorm days should correspond, although one relies on sight, the other on hearing. In the US, as well as in most other countries, thunder must be heard by a trained observer in order for an official thunderstorm to occur. As most airport weather stations are quite noisy, and many weather offices are located in closed buildings, comparisons between lightning networks and official thunder reports show thunderstorms may be underreported at many sites.

Most lightning networks only record CG lightning, only a fraction of the total flashes that may result in thunderstorm records. Various correlations between thunderstorm days and actual flash density, expressed as flashes/km² per year, have resulted in estimates of 1–2 flashes/km² per year per 10 thunderstorm days (Lyons, 1999). However, regional variability in this relationship shows that this estimate can be far off the mark. Two major differences are shown to exist between the average thunderstorm patterns and those of lightning in the US (Changnon, 1993). In the intermountain west the number of thunderstorm days and events is relatively high, while CG lightning flash frequency is low. Here the flash counts per thunderstorm event are also much lower than in regions east of the Rockies. The second disparity occurs along the East Coast from the Carolinas to New York, where high flash frequencies accompany not so high thunderstorms. Average CG flashes in the west run between 10 and 25 per thunderstorm event. Florida, the Midwest–High Plains and the northeast average more than 125 CG flashes per event, while the mid-Atlantic region is highest with averages of 200 CG flashes per thunderstorm event. Over North America, central Florida is known as the "Lightning Capital" of the United States. Recent data from the US National Lightning Detection Network (NLDN) indicate that central Florida most likely has the highest long-term CG flash density with over 11 flashes/km² per year (Orville and Huffines, 2001). However, year-to-year variations have placed the maxima over the Midwest or southern Louisiana in some years. Comparisons between NLDN and satellite data indicate IC to CG ratios over the Great Plains to be nearly 6:1, while coastal Gulf stations are nearly 2.5:1 (Christian et al., 2002).

Globally, about 78% of all lightning flashes (IC and CG) occur between 30°N and 30°S latitudes, with those over land or their immediate vicinity ten times more frequent than those over oceans, depending on season (Christian et al., 2002). Recent satellite measurements put the global lightning flash rate at 44 (± 5) flashes each second, with nearly 1.4 billion flashes/year over the Earth. Concentrations of activity over interior South America and equatorial Africa are well documented, as well as the overall maximum activity around the Indonesian Islands. The Congo Basin is the planet's hot spot, with mean annual flash density of 80 flashes/km² per year, including an area over 3 million km² with flash densities above 30, that of central Florida. The annual cycle is dominated by the Northern Hemisphere's summer peak. Seasonal differences follow heating patterns and

the shift in the Intertropical Convergence Zone. Over the oceans, higher rates are shown year-round in the western Atlantic and western Pacific basins where cold air passing over warm water provides instability. Lightning minima are found in polar regions, subtropical deserts and oceans, and along western, cold-water coasts of continents, in general.

Lightning measurements

The total energy produced by a lightning flash depends on its magnitude and duration. An average return stroke carries a current of 30 000 amperes, which at 125 million volts may develop a peak power in its brief lifetime to raise a large ship 6 feet. One survey of 60 million lightning flashes found 23% had peak currents >75 kA, with the largest positive cloud-to-ground (CG) reaching 580 kA and the largest negative 960 kA (Lyons et al., 1998). "Cold" lightning of very short duration but high current usually causes explosions when it strikes, while "hot" lightning of longer duration but lower current is known to burn things and cause forest fires. Most of the lightning flash's energy is expended as heat. Spectroscopic measurements have shown that the temperature of a lightning channel peaks near 30 000 K in a few microseconds. The air around the channel is heated so rapidly it expands at a supersonic rate, producing the shock waves heard as thunder. The global frequencies of lightning strikes were previously derived from thunderstorm or thunderstorm days information. More recently, local, regional and national lightning frequencies are estimated using lightning detectors, based on spherics (atmospheric electric or magnetic fields) research and satellite observations. Lightning detection networks are based on two distinct methods used to detect and locate CG lightning. One is based on magnetic direction finding (MDF), while the second uses time-of-arrival (TOA) techniques. The current US National Lightning Detection Network (NLDN) is made up of a hybrid system using the best of both methods (Cummins et al., 1995). The NLDN provides data on the time, location, polarity and peak current of the first stroke in a flash, also stroke multiplicity and estimate of location accuracy. Operating continuously since 1989, flash detection efficiency ranges between 80% and 90% (Cummins et al., 1995). Other national and regional networks have developed in many other areas, including Canada, Brazil, Japan, Europe, Asia, and Australia. Global measurements became possible with the use of optical sensors carried by satellites. An interesting dataset was acquired by a military satellite that observed local midnight lightning, on a global scale, for 1 year (Orville and Henderson, 1986). In April 1995 NASA's Optical Transient Detector (OTD) was launched. The polar-orbiting satellite passes overhead twice a day. Although not continuous, the observation intervals vary throughout the day for each location, making a more uniform sampling of lightning over much of the Earth. The LIS (Lightning Imaging Sensor), which has been updated on the Tropical Rainfall Measuring Mission (TRMM) spacecraft in 1997, has provided global data for both IC and CG lightning for several years. A need for a geostationary sensor for continuous coverage seems obvious for warnings of potentially dangerous lightning storms. Lightning deaths in the United States continue to fall; however, annual fluctuations seem to be linked to climatic features, such as thunderstorm days and average surface temperature values (Lopez and Holle, 1998).

LITERATURE AND CLIMATE

Below, the cracked, brown earth,
Like ancient earthen-ware,
Spreads out its dusty, worn
Old surface, baked and bare.

Above, the polished blue
Of a burnished August sky
Is an inverted bowl
Of every drop drained dry (Converse, 1927).

In these few lines and sparse verse are contained a vivid description of the Great Plains landscape and the experience of drought. Literature has had a long relationship with climate as the human species attempts to capture its home environment and convey a sense of it to others, develop an understanding of why landscapes vary from one place to another, and communicate as well as preserve our environmental knowledge. Literature can be any writings of universal interest, carefully

crafted in form and expression. Literature can be in the form of fiction, writing from the imagination, as in novels, short stories, drama, or poetry. Or it can be non-fiction, writing from “real-life” situations, such as essays, histories, or scholarly works. The term literature can refer also to writings dealing with a certain subject, period, language, or location. Climate is the prevailing atmospheric conditions of a location or region, its annual patterns of warmth and cold, moisture and dryness, cloudiness and clear, determined after an extended period of observation, usually over many decades. The term can also be used to describe a region characterized by a given climate. Today contemporary scholars associate climatology with the sciences and literature with the humanities, but these categorizations are fairly recent. Learned individuals historically practiced both arts and sciences, such as Leonardo da Vinci. Despite the seeming dichotomy, there remains today a strong reciprocal relationship between literature and climate: climatologists utilize literature and literary writers utilize climate. In exploring this relationship, examples from the American Great Plains will prove illuminating.

The Great Plains are a region, while readily brought to mind's eye with its flat landscape and enormous sky, most often defined by the climate. The Plains stretch from south of the Rio Grande to the edge of the Boreal Forest in the north, including vast stretches of the United States and Canada. The western boundary of the Plains generally is viewed as the foothills of the Rocky Mountains. The eastern boundary is more of a challenge: there is no sharp physical feature to delineate it. Climatic features are most often invoked as a result, such as the 20-inch isohyet or the tall-grass/short-grass prairie boundary, both pointing to the margin between humid and subhumid climatic regions.

On the Plains, climate not only serves to define the region, it is also central to life. As environmental historian Donald Worster points out:

The Great Plains of North America offer a revealing place to study the challenges of rural communities trying to cope with climate and that chaotically changing envelope of gases we call the atmosphere. Despite the seeming monotony of flat, immutable land meeting big, unchanging sky, the plains are in fact the most volatile place on the North American continent. Their complexity lies not in land forms but in climate. Nowhere else do Americans confront such extremes of cold and hot or such rapid oscillations around the crucial point that divides wet from dry (Worster, 1999).

The distinctive environment of the Plains results in a distinctive sense of place communicated in its literature. Some of the earliest uses of Plains climate in literature can be found in the traditional stories of Plains Native American tribes, such as the drought that led to the creation of the Great Medicine Dance (called the Sun Dance by other Plains tribes), according to the Cheyenne:

Long ago, when the earth and the people dwelling upon it were young, our tribe was starving. The earth itself was starving, for no rain was falling. Plants and trees wilted. Many rivers dried up. The animals were dying of hunger and thirst (Erdoes and Ortiz, 1984).

By accepting and performing the ritual, Maheo, the Creator, promised that “the rains will fall again”. In this case, both the humans and the Earth are at the mercy of climate, foreshadowing the European-American experience on the Plains.

Climatologists and literature

Literature has served climatology for centuries. The roots of climatology in Ancient Greece, as well as Ancient China, took the form of written descriptions of climate based on observation but also at times imagination. While instrumentation and standardization of climate measures are the contemporary norm, scholars investigating the Earth's climatic past rely on “weather diaries” and other available weather descriptions (Lamb, 1995). By combining descriptive reports with known climatic events and proxy data it is possible to produce sound studies that advance our understanding of past and present climate. Chu K'o-Chen, considered the father of Chinese meteorology, utilized a wide range of writings to construct the climatic history of China. Carvings on oracle bones, descriptions in regional gazetteers, poetry and literary descriptions of birds, flowers, and trees were used to supplement the available records and assess climatic change (Chiao-Min Hsieh, 1976). Tyrell (1987) utilized historic travel accounts of Kenya to reconstruct nineteenth-century vegetation patterns, creating a snapshot of the Kenyan physical environment prior to colonization. Climatologists have also utilized literature to humanize climate, to communicate the human experience of climatic conditions. Roots, in introducing work on glacial mass balance measurements, reminds his readers that evocative language can be an effective communicator of science:

On a more poetic and less scientific plane, the nineteenth-century naturalist-poet Clarence King, describing a valley glacier as a great white dragon, alluded to the concept of mass balance when he told how the dragon crawled down the valleys to flee the sun, but slept and grew fat during the cold dark days of winter. It would be hard to describe glacier behaviour much better today (Roots, 1984).

Besides employing literature as source material or to richly convey climatological information to readers, climatologists have also used climate data to support literary works as well as to speculate on the employment of climate data in constructing imaginary landscapes. In “Anne Frank's diary – a meteorologist's view” (1995), Persson draws on weather data to confirm Frank's text, correlating Frank's depiction of weather with the recorded weather. Pike's “An Appreciation of the Weather in *The Lord of the Rings*” (2002) examines the principal weather scenes of the novel and ties them to typical British climate patterns.

Correspondingly, in Great Plains research, historical writings have been employed in a variety of ways to advance our understanding of its climate. Rannie and Blair (1995) examined an “unusual” 1993 weather pattern on the upper Plains, involving a trough and strong negative pressure, producing record precipitation and severe flooding. Noting a similar pattern occurred in 1958, they wondered if a similar event had occurred prior to instrumental records. Using an account of a military expedition and settlement accounts, Rannie and Blair established an analogous pattern had likely occurred in 1849, suggesting that the pattern may be more common than originally thought.

“Desert myth and climatic reality” explores the concept of the Plains as “Great American Desert” from a climatological perspective (Lawson and Stockton, 1981). Authors Lawson and Stockton reconstructed Plains drought history with tree-ring indices and available records, mapped the reconstructed moisture conditions according to the early expedition routes, and then compared them to diaries, journals and excursion records.

Major Stephen Long's expedition of 1819–1820, responsible for the introduction of "Great American Desert" on American maps, was found to have passed through a region experiencing extreme drought, thought to rival that of the 1930s. Long and his expedition's perception of a desert may not have been an "illusion" but rather an experienced "reality".

Finally, *The Dreaming Is Finished: human perception of the Great Plains through poetry, 1890–1950*, examined poetry written about the Plains, by individuals on the Plains, to assess whether the extreme drought conditions of the 1930s impacted how the Plains were perceived and described (Dando, 1992). While elements of Plains climate including drought did appear in the poetry, overwhelmingly the imagery of the Plains was as a verdant garden with ample precipitation and favorable conditions for agriculture. The poets tended to focus their writings on the rich potential of the Plains yet did convey a sense of frustration in an environment they could neither control nor predict. Drought did not appear to impact human perception of the region: what was more significant was the passage of time. Early Plains settlers wrote of transforming the landscape as well as the climate of the Plains. By the end of the study there was recognition of human transformation of the landscape, positive as well as negative, as well as acknowledgment of humans adapting their methods to the Plains climate.

Whether we are considering the Great Plains or any other part of the world, climatologists have applied literature to their subject: to convey the "feeling" of climate, to capture data not otherwise documented, or even to express their own experiences. A document on the National Oceanic and Atmospheric Administration's (NOAA) website is entitled "Weather Man Poems" and comprises poems written by George Mindling, "Official in Charge" of the Atlanta Weather Bureau Office in 1939. The 12 poems are written from the "weather man's" perspective and can only be truly understood and appreciated by someone in similar situations. Climatologists are, after all, human and "the aim of artist and scientist alike is to communicate a new and valuable way of regarding the natural world around us" (Stephens, 2003).

Literature and climate

To write about places and environments is to call them into being, whether they are real or imaginary. Yi-fu Tuan writes: "Naming is power – the creative power to call something into being, to render the invisible visible, to impart a certain character to things" (Tuan, 1991). Writing about climate makes concrete human experiences and observations, rendering them in a form that can be compared and contrasted with other descriptions. It can be the beginning of climatology or an entryway to another world existing solely in our imaginations. While words are the basis of climatic descriptions, climate can shape literature. Mitchell contends "It is my conviction that literature, like all art, is ultimately a reflection and illustration of the landscape that produced it" (in Mallory and Simpson-Housley, 1987). Geography, being composed of the topography, the climate, and the human landscape, has an immense influence in shaping society and can be "read" in the literature of the region.

Literary scholars and human geographers have examined writers' use of climate and its impact on their literary constructions, such as Pérez and Aycock's *Climate and Literature: reflections of environment* (1995), Mallory and Simpson-Housley's *Geography and Literature* (1987), and Pocock's *Humanistic Geography and Literature* (1981). Great Plains literature, rich in description conveying a sense of the region's

climate, has a well-established body of literary scholarship (Keahy, 1998; Quantic, 1995, 1997; Thacker, 1989). All writers utilize climate, together with place, in a variety of ways: as in establishing the setting, indicating the passage of time, serving as a symbol or metaphor, or character development (Lutwack, 1984; Pérez and Aycock, 1995).

The most straightforward use of climate in literature is as spatial location. If an actual place name is used, a realistic depiction of the place and climate is typically expected from its readers who may have first-hand experience of the location. In the case of the Plains, the landscape is known more for its absences: lack of water, physical features, and trees. With such absences, writers focus on capturing the sense of space of land and sky, the constant wind rippling the grasses, the sharp contrasts in weather (Quantic, 1995). Quantic (1997) points out "in a place with no familiar geographical features, men and women had to learn to see the Great Plains". Many enjoyed what they saw: "Even against our will, the bigness and peace of the open spaces were bound to soak in.... We could not but respond to air that was like old wine.... Never were moon and stars so bright" (Kohl, 1938). The "bigness" and "peace" of the Plains is often likened to an ocean: ocean imagery is found throughout Plains literature, capturing the expanse but also the "sameness", the "waves" and the silence.

Specific environments, at times, become stereotyped with certain types of writing: such as rainforests (jungles) or arid lands (deserts) with adventures or the arid American West with the Cowboy Western. The Great Plains environment is largely associated with pioneer dramas, pitting humans against their environment, such as Ole Rølvaag's *Giants in the Earth* (1927) or Willa Cather's *O Pioneers!* (1913). The environmental conflict is ultimately against the Plains climate, as the settlers struggle to survive in the face of erratic moisture patterns, drought, hail, blizzards, and tornadoes. Many of the classic Plains characters, such as Rølvaag's Per Hansa or Cather's Alexandra Bergson, must come to terms with the Plains landscape and conquer it or be defeated by it (Quantic, 1995). The environment at times is virtually a literary character, providing the conflict that drives the action. Louise Erdrich paints a vivid portrait of a tornado in her novel *Tracks* (1988):

The odd cloud became a fat snout that nosed along the earth and sniffled, jabbed, picked at things, sucked them up, blew them apart, rooted around us as if it was following a certain scent, then stopped behind us at the butcher shop and bored down like a drill.

In Erdrich's description, the tornado becomes a malevolent beast, rooting and snorting around until it attacks. In Rølvaag's *Giants in the Earth* the Plains environment provides the tension but is personified:

Monsterlike the Plain lay there – sucked in her breath one week, and the next week blew it out again. Man she scorned; his works she would not brook.... She would know, when the time came, how to guard herself and her own against him! (Rølvaag, 1927).

Climate, abstract, remote but with very real human consequences, is personified or bestialized, allowing climate to occupy space, perhaps even to have conscious thoughts. But the personification of Plains climate has not all been negative. The Plains landscape has often been symbolized as a woman, with the representation depending on the historical period. In writings from early European settlement (or representing this time),

the Plains are a fertile young bride, waiting for her husband, the settler, to consummate the marriage and bring forth new life. Imagery from the settled Plains suggests a nurturing mother, providing home and sustenance. In Plains as woman imagery, the settlers must come to terms with the Plains, establish a "relationship" with it, if the "marriage" is to work.

Climate can be used to indicate the passage of time. Time passing can be expressed through the cycle of seasons:

Gestating in the mid-year
Seldom did it show.
Youthful green in springtime.
White, and gaunt with snow (McRae, 1986).

McRae uses Plains as woman imagery, likening the changing seasons to women's fertility over their lifespan. Evoking past landscapes can also suggest the passage of time:

The place is as dry as a crater cup,
Yet you hear, as the stars shine free,
From the barren gulches sounding up,
The lap of a spawning sea... (Clark, 1915).

The evocation of dinosaurs and oceans (referring to the Plains once being ocean floor) captures the timelessness of the Plains, while pointing to past climates that were markedly different.

Climatic shifts also can indicate spatial movement, as in Canadian poet Robert Kroetsch's *Advice to my Friends*,

Early yesterday, driving west alone
Across the prairies, I thought of swinging
south off Number One to visit shortgrass
country. Down there, everything is real,
even the emptiness. The buttes are bare.
Trees are only a memory... (R. Kroetsch, 1985).

Space and distance are common themes and imagery in Plains literature. Particularly in land not "domesticated", expanses of grasslands are depicted to stretch on forever, unless broken into management segments by roads, fields, and farmsteads, constrained by human actions. The literary journeys of settlers are depicted as crossing climatic regimes while also symbolizing spiritual journeys.

Climate may be symbolic, serving both geographical and literary ends. The repeated association of certain conditions with specific values has resulted in what Lutwack (1984) terms "archetypal place symbolism". Dark clouds on the horizon are seen as "ominous", foreshadowing dark events to come. The sun coming out is a hopeful sign. Lush vegetation is indicative of life, evoking the Garden of Eden. Deserts, lacking vegetation, are akin to death. Most relevant to the Plains is the desert/garden imagery that is pervasive in its literature (Quantic, 1995). Garden imagery presents the Plains as a cornucopia of richness, everything lush and productive, vibrant with life:

Across bronze farmlands binders click their way,
While livery horses nibble at a spray
Of tender grasses near the raveled edge
Of broken loam. Elusive quail in sedge
And covey call their wandering broods.... (Hoover, 1940).

With the Edenic imagery comes the implied position of humans in charge of the garden, of humans conquering the Plains. The climate is obviously ideal for human habitation, even conducive to great success. With the desert imagery, the Plains are stripped of vegetation, the sun appears overpowering, and there is no refuge for any species:

Beneath me the fissured earth powders barren in my hands;
my taut, dry body knows the earth's pain.

There in the vertical glare of the sun
the bald hill lifts a blanching alkali spot;
my soul is like that in its desertness (Crafton, 1927).

The desert is both in climatic region and in spirit: everything is stripped bare, exposed. The desert/garden split is reflective of the wet/dry climatic pattern of the Plains. While a firm temporal pattern has not been established, there is evidence that the Plains alternate between wet and dry periods (Worster, 1999).

In the dry periods hope comes only in the form of rain, which at times supported the belief of positive climatic change. The notion of "rain follows the plow", can be found, not only in essays and historical accounts, but also in its imaginative literature, such as "Quivera – Kansas". The poem describes Coronado's search for Quivera, the departure of the Spanish, and the arrival of American settlers. While acknowledging the Spanish, it has the Plains unresponsive until the arrival of the "blue-eyed Saxon race", weaving an impression of European exploration but also of American Manifest Destiny:

And it bade the climate vary;
And awaiting no reply
From the elements on high,
It with plows besieged the sky –
Vexed the heavens with the prairie.

Then the vitreous sky relented,
And the unacquainted rain
Fell upon the thirsty plain,
Whence had gone the knights of Spain,
Disappointed, discontented (Ironquill, 1899).

"Quivera – Kansas" not only captures the notion of plowing transforming climate but also the environmental determinism that tied landscape conquest with race, here suggesting that the "Latin race" could not work the Plains-desert but the "blue-eyed Saxons" altered the climate and made it productive.

Today, the appreciation of the Plains' sparse landscape has been termed "Prairie Zen" and continues to inspire writers, such as Kathleen Norris' *Dakota: a spiritual geography* (1993). While some are repelled by the Plains' climatic extremes and sparse landscape, others are drawn to it, appreciating the subtle textural changes in its topography and vegetation, enjoying the ever-changing panorama offered by its expansive sky. The nature of the plains as garden and desert can be seen as embodying the cycle of life, death and rejuvenation. To appreciate the Plains is to accept them as they are; their landscape, their climate, their sense of place:

The prairie is never really a thing or even a group of things. This absence leaves us with nothing to stand against, nothing to be a subject toward. We cannot play the role of detached evaluator. We can only accept the gentle onslaught of prairie, the sterilizing light and the desiccation of hubris.... The prairie is an experience, not an object – a sensation, not a view. The prairie is a way of being and not a thing at all (Evernden, 1983).

Reflecting on climate and literature

Plains literature has been shaped by its climate while also reflecting it. We could select almost any world region and illustrate the

relationship between its climate and its literature. Climate figures prominently in the work of Colombian novelist and Nobel Prize laureate Gabriel García Márquez, whose work is set in his home region, the Caribbean coast of Colombia (Elbow, 1995). Russian author Ivan Turgenev's writings reflect his roots on the Russian Plain (Paul, 1987). All humans experience climate. It is an essential element of our life on this Earth. Humans also desire to share and connect with others, whether they are climatologists or writers. At the heart of climate and literature is the simple human desire to communicate.

Cross-reference

Cultural Climatology

LITTLE ICE AGE

Subject to varying definitions, the “Little Ice Age” (LIA) is here taken to be the dramatic climatic deterioration that followed the “Medieval Warm Period” (of the high Middle Ages, *q.v.*). A recent book on the subject by Brian Fagan (2000) bears the subtitle *How Climate Made History (AD) 1300–1850*. Lamb (1977) described the catastrophic cooling in Britain after about AD 1310, many villages being completely wiped out. On the European continent conditions were even worse and in Bohemia (modern Czech Republic) at one stage up to half the population died of starvation. Alexandre (1987) has catalogued a year-by-year documentation, and Barbara Tuchman (1978) has presented a socioeconomic picture of the “calamitous” fourteenth century. “The Great European Famine” lasted no less than three consecutive years (1315, 1316, 1317). The first overall treatments were by LeRoy Ladurie (1971) and by Jean Grove (1988), though now both are a little dated. The coldest episodes were around 1315, 1530, 1600–1616 (Fernau neoglacial) and 1800–1825 (Napoleonic era).

Glaciers are not always the best indicators of climate, because they tend to vary with elevation and show sluggish response behavior. The famines of the fourteenth century were mainly the result of heavy year-round precipitation, but as temperatures began to fall, increasing snows led to glacial advances. It was not until the seventeenth century that the maximum glacier

advances in the Alps were documented. However, in Greenland the first advances began in the thirteenth century, and the Norse settlers began their progressive withdrawal; the last survivor was finally frozen to death in the mid-fifteenth century (McGovern, 1981).

In North America the best-known human reactions were among the Anasazi people of the southwest, where progressive desiccation led to failures of their staple crop, maize, and their retreat to upland canyons, where cliff-dwellers survived for a while, before their final extermination. In the Pacific, which had been extensively colonized by the Polynesians before the first millennium AD, the atoll settlements were partially threatened by droughts, resulting in migrations to the “high islands” that were mostly well watered. Isolated settlements such as Easter Island became overpopulated, and by about 1350 moai carving was abandoned as deforestation and droughts led to internecine warfare.

South America, with its topographic variety providing a constant buffer against climatic fluctuations, did not fare badly in the LIA, although the periodic incidence of “super-El Niños” led to catastrophic floods along the major river valleys of Peru, the coastal belt of which is normally semiarid. The glaciers in Patagonia, as also in New Zealand, appear to have fluctuated more or less in phase with those of the northern hemisphere, although some areas alternate (Carter and Gammon, 2004). Eustatically, the LIA was marked by the “Paria Emergence” (Fairbridge, 1961).

In Africa, apart from the Nile Valley and other major waterways, the subsistence farming of most of the people favored migratory solutions to periodic droughts. This was highly effective in the days before colonial boundary lines. In the well watered “inland delta” of the upper Niger a powerful empire developed.

In the Nile Valley and the northern rim of Africa, after AD 622, the Islamic hegemony introduced a new culture that was largely based on the use of sub-Saharan slaves who could be sold off during droughts. The price of slaves in the markets of Morocco and the other North African centers correlates quite closely with the LIA rainfall indicators (from tree rings). In the Nile Valley the general fertility (and economy) depended largely on the regularity of the summer flood that was fed by the monsoonal rains in Ethiopia. The flood records were generally maintained with great care, and closely monitored because they provided the taxation basis. Power spectrum analyses have provided evidence of both the 11/22-year solar and 18.6-year lunar cycles (Currie, 1987, 1995).

In Asia, particularly the west-central parts (now Kazakhstan, Uzbekistan, etc.), the first inkling of a former general desiccation came from Ellsworth Huntington (see Huntington and Visher, 1922), an American geographer and explorer, who discovered that there had been a general aridification during the LIA. The great river, the Oxus or Amu Darya, during classical times, had flowed from the northern borders of Afghanistan and Damir Mountains westward to the Caspian Sea (near Krasnovodsk), but decreasing volume and encroaching Kara Kum dunefields (in AD 1559) deflected its flow into the Uzboi Channel and the Aral Sea. Here a vast inland sea, the “Oxian Lake” existed, as noted by Alexander the Great, Strabo and Marco Polo.

Glaciers in the Tieni-Shan, Kuan Lun, Karakoram and other mountains in western China and northern Himalaya, fed oases that traditionally serviced the Old Silk Road and other trade routes in the time of Greece and Rome. General desiccation forced the abandonment of many sectors and rerouting to more favorable localities. People have pointed to the parallelism of

the desiccations with the low eustatic levels in the sea-level curve of Fairbridge (1961).

The level of the Caspian Sea is largely dependent upon the latitude of the jet stream and rainfall in the Volga Basin. It is therefore out of phase with the level of the Black Sea, which is eustatically linked to that of the world ocean. During much of the twentieth century its level was falling, in contrast to the general rise of the world trend, but in the last decade or so, precipitation in the Volga basin has been rising, and likewise in the Caspian. Environmentalists had claimed erroneously that the fall in the earlier part of the century was due to dam construction. On the other hand, the Aral Sea fluctuations prior to the modern irrigation diversions were in phase with the world ocean.

In China there are two distinctive climatic indicators: the southern sector with the Asian monsoon and the northern one with the yellow dust (loess) transport from the region of the Gobi Desert, together with the yellow mud of the Hwang-Ho and Gulf of Pohai. As shown by an abundant literature touching on climate matters in China, the weaker monsoons led to summer rainfall deficiencies, a feature of the LIA, together with increasing north-easterly winds bringing dust storms in the winter season. Short-term modulations reflect both the sunspot cycle and the 18.6-year lunar period (Currie and Fairbridge, 1985).

In Southeast Asia the monsoon is the dominant factor, but flooding in the great river valleys during the LIA reflects the heavier snowfalls in the upper waters, all of which are located on the north face of the Himalayas or in eastern Tibet, but debouch over a wide span – from west to east – the Indus, Ganges, Brahmaputra, Irrawaddy, Salween, Mekong and Yangtzi. The LIA flooding left a particularly impressive result in the region of Angkor (Cambodia) where the annual flood causes the lake of Tonle Sap to back up. However, this LIA back-up was repeated on a vast scale and the entire temple complex was eventually buried under more than 10 m of mud.

A very generalized picture of the LIA is thus presented, but with enough contrast to make it clear than global averaging, almost universally espoused by modeling climatologists, is not a reasonable procedure. Regional compartmentalism, recognizing airmass systems and circulations, seems more actualistic and logical than the indiscriminate stirring of a giant stewpot with its inevitable inhomogeneous data sources. Historical studies (e.g. Lamb, 1977) show occasional overlaps of one compartment to another occur, creating for example the freezing of the Thames in England, snowfall in Ethiopia, heavy rains in central Australia, and so on. They call for explanation, but do not excuse homogenization.

Luni-solar forcing

In as much as most of the span of the LIA lies outside the range of modern instrumental records, a variety of proxy evidence is employed, based on:

1. Documentary material such as diaries, historical events, e.g. the El Niño cycles, the Scandinavian auroras, and the Schöve sunspot cycle reconstruction.
2. Ice cores, Greenland, Canadian Arctic, central Andes, western China and Antarctica.
3. Tree rings, particularly where analyzed for ^{14}C flux and ^{18}O evidence.
4. Lake varves and fluvial flood levels, the lake varves being treated primarily in Sweden, the marine varves in the Santa Barbara Basin (California), the flood levels (in annual records) on the Nile.

5. Beach-ridge series in sites where chronologic calibration is feasible, as in the Hudson Bay and northern Scandinavian and Russian littorals.

Power-spectrum analyses, covering worldwide sources and an extensive variety of geophysical indicators, disclose that both the 11–22-year sunspot cycle and the 18.6-year lunar cycle are universally present (Currie, 1987, 1995). From lacustrine proxies in western Canada, Campbell et al. (1998) conclude that “postglacial climatic anomalies such as the LIA and the Younger Dryas were at least in part periodic phenomena rather than the result of unique, aperiodic events”.

It should not be forgotten that there are two distinct avenues that link solar activity with Earth systems, i.e.:

1. Electromagnetic radiation (optical, UV etc.), focused on the intertropical belt.
2. Particulate magnetic radiation (in the solar wind), focused on the magnetic poles.

The principal lunar cycles also have two critical areas, i.e.:

1. The Indonesian–New Guinea constriction, where ocean tides modulate heat transfer to the atmosphere and the orographic uplift carries it to the stratosphere.
2. The geostrophic currents, notably the Gulf Stream, are accelerated by lunar declination, bringing sensible heat to the North Atlantic and Arctic Ocean (Murmansk Current). Positive feedback is added by the melting of sea ice and reduced albedo.

Of overwhelming importance are the magnetic cycles that are related to the solar inertial orbits of the systemic barycenter (described in detail in Fairbridge and Sanders, 1987; and expanded by Charvátová, 1997). On Earth the incoming solar particles are funneled into the magnetic poles and displayed above the stratosphere in the auroras. The entire LIA interval was covered by Scandinavian diaries (mainly by the Lutheran pastors, who used the auroras as messages from the deity). A classical analysis of the 800-year record by Ekholm and Arrhenius (1898) discovered not only the sunspot cycle, but also the lunar cycle. The latter, primarily seen as an Earth-oriented tidal phenomenon, also involves the sun, and was recognized by Pettersson (1914), although it is often ignored (Sanders, 1995).

Four intervals of high geomagnetic activity are recognized, coinciding with sunspot minima, of varied length and importance. They are named after solar pioneers, in chronologic order:

1. Wolf Minimum.
2. Spoerer Minimum.
3. Maunder Minimum.
4. Sabine or Dalton Minimum.

Their importance and duration is indicated by the values of ^{14}C flux derived from tree-ring analyses (Stuiver and Braziunas, 1989), but subject to the sampling intervals and instrumental “errors” of the technology (about ± 5 years, on average). The dendrochronology in this interval has been so often repeated and checked that the dates obtained are not subject to any correction.

The pattern of ^{14}C flux suggests bimodal states, fluctuating from length intervals of an “adagio” mood (gentle oscillations: Windelius and Carlberg, 1995) to brief but violent phases (“staccato” mood). Comparable bimodality was independently observed by Charvátová (1997). The key parameter was the radius of the sun’s orbital loops (Fairbridge and Sanders, 1987), and their symmetry, the simplest form being compared with a three-leafed

clover (Charvátová’s “trefoil”). The whole orbital symmetry cycle (OSC) has a length of 178.73 years, being controlled by the beat frequency of the two largest planets Jupiter and Saturn (19.8593 years $\times 9$), each clover-leaf loop being one-third of this.

Superimposed on this is the sunspot cycle (SSC mean: 11.121 years) and its magnetic reversal (SMR: 22.24 years), but that is not quite in phase with the 178.73-year orbital symmetry cycle. A second cycle of 177.94 years is set up by alignments of Jupiter, the heliocenter and the barycenter (the “King–Hele Cycle”), which is $16 \times$ SSC, and $8 \times$ SMR.

During the late twentieth century worldwide concern regarding atmospheric pollution by CO_2 , CH_4 and other “greenhouse gases” has led to an interest in “natural”, i.e. preindustrial, climatic patterns. On several different time scales there is a systematic tendency for a sawtooth pattern to develop. The scale may be 100 000, 10 000, or 1000 years, or even shorter. Time marches on, unidirectionally. Graphs should be drawn with the x (ordinate) parameter, i.e. time, always advancing from left to right, so that the viewer perceives the future, or unknown area, to the right. Thus a sawtoothed curve of the last 10 000 years will show the Medieval Warm Period (*q.v.*) terminating at about AD 1300, and the LIA beginning at about that point. Temperatures will fluctuate, but the coldest extremes will appear gradually lower and lower, with the maximum cold indicators of the Maunder Minimum about AD 1680. A steep rise is then initiated to reach a preliminary peak around AD 1760. A ratio of 380:80 (or 4.75) defines the “cut” of the sawblade. Since 1760 the anthropogenic rise destroys the natural pattern.

All climatic factors and different regional aspects should not be expected to conform to such a simplistic model, due to multiple delaying or feedback mechanisms (latent heat in large water bodies, albedo, ice-melting rates, forest growth, etc.). Mann (2002) points out the value of multiple proxies. Other writers have suggested developing climatic patterns over the LIA and its aftermath (Free and Robock, 1999; Jones et al., 2001; Rind, 2002). A consensus, however, is beginning to emerge: the sun must play the essential role (Shindell et al., 2001).

climate has appeared in many monographs and textbooks (Fukui, 1938; Landsberg, 1941; Sapozhnikova, 1950; Yoshino, 1961, 1975; Berényi, 1967; Barry, 1981). However, R. Geiger, a founder of microclimatology, did not use the term local climate; instead, he used *orographisches Mikroklima* (orographical microclimate) and *Kleinklima* (small climate) in his early works (Geiger, 1927, 1929). He continued to use these terms in the revised editions of his book (Geiger, 1961, 1965). These terms are now used as synonyms for microclimate, topoclimate and mesoclimate.

Although any region of the Earth's surface can be either small or large depending on the point of view for the classification, the expanse of a region can be determined based on the climatological phenomenon under consideration. Local climate is the climate in an area where local conditions of the Earth's surface are clearly different from those in the nearby surrounding areas; for instance, it is the climate in and around mountains, hills, rivers, lakes, coasts, forests, and cities. Different definitions of local climate and different sizes of an area of local climate have been used by different research workers; for example, Landsberg (1941) used local climate for a climate scale between the spot climate and the regional climate; Mörikofer (1947) first defined the horizontal scale of local climate as an order of 100–1000 m; Flohn (1959) and Barry (1970) defined it as an order of 100 m to 10 km and the vertical scale an order of 10 cm to 1 km (Yoshino, 1975). A schematic illustration of local climate is given in Figure L7.

Elements, factors, and conditions of local climate

Elements of local climate are similar to those of global climate, i.e. air temperature, precipitation, wind, humidity, sunshine, insolation, and so on; but air pressure, which is one of the most important elements for global climate, does not play an important role in local climate. Factors affecting local climate are topography, land and sea distribution, ground cover, and so on; but latitude, which is the most important factor affecting global climate, has no bearing on local climate.

To understand the physical processes that influence the formation of local climate, location, exposure, and different conditions of the ground surface – such as color, apparent density, heat capacity, moisture content, and permeability of the soil, characteristics of vegetation cover, albedo, and roughness of the ground surface – should be taken into consideration. These are all factors that influence the heat, moisture, and momentum exchange on the ground surface (Thorntwaite, 1953). Accordingly, the investigation of local differences in these factors is necessary on the open, flat ground. In a hilly area it is also necessary to investigate thoroughly the influence of terrains on the air current and to discuss the distribution of the climatic elements caused by this influence. Here, the word terrains means the inclination and the direction of main valleys and ridges, the extent of mountain masses, and so forth.

Most local climates are distinguishable primarily under the condition of weak winds and usually clear skies. Therefore, in Germany, a nickname *Schön-Wetter Klimatologie* (fair-weather climatology) was once given to local climatology, because local climatological observations were performed only under fair-weather conditions. This means that the wind, one of the elements of local climate, plays an important role in determining the local climate distribution. It also implies that a study in the synoptic-climatologic framework is desirable. For instance, in the investigation of local climatological features such as frost

LOCAL CLIMATOLOGY

The first use of the term "local climate" is unknown; however, German climatologists began to use it frequently as a synonym for *Kleinklima* (small climate) in the early 1930s. Since then local

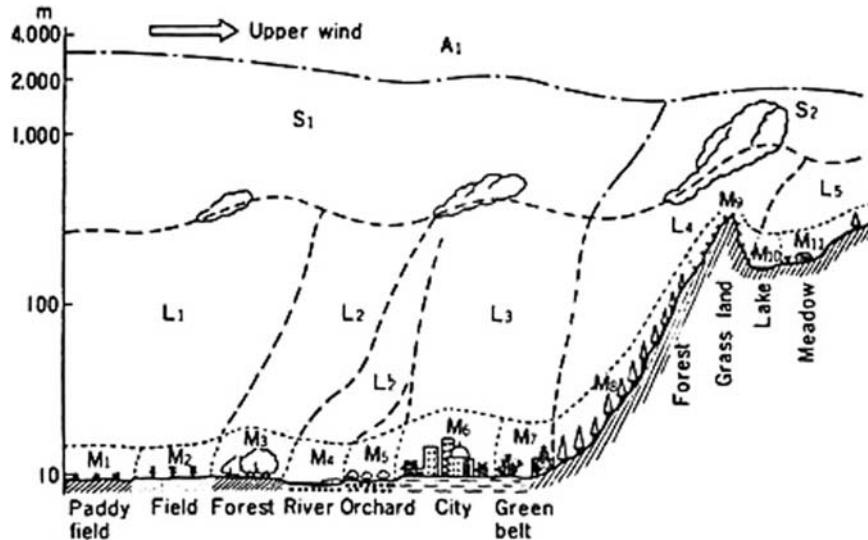

Figure L7 Schematic illustration of micro- (M₁–M₁₁), local (L₁–L₅), meso (S₁–S₂) and macro (A₁) climatic phenomena (Yoshino, 1975).

distribution, occurrence of strong local winds, existence of heat islands in cities, and precipitation maximums on mountain slopes, the synoptic climatologic conditions are important for the consideration of local climatic phenomena.

A detailed classification of meteorological and geographical factors producing local climates was presented (1958), as shown in Table L1.

History of local climatic description

Many local climatic events have been recognized since ancient times, even though the term local climate was not used. Marcus Vitruvius (75–26 BC), a famous Roman engineer and architect, made remarks concerning local climatic conditions for planning cities. He dealt with the direction of slopes and stressed that the distance to swamps, lakes, and beaches must be considered from the standpoint of local climatic conditions. In ancient India it was pointed out in the *Mānasāra Silpásāstra* that the direction of major roads should be decided by referring to the prevailing wind directions. Also in India, the *Arthaśāstra*, a book on politics written in the fourth century BC by Chanakya, has a chapter that deals with local differences of rainfall, probably measured by a rain gauge.

In Japan, *Harima-Fudoki* (Regional geography for Harima), written in the early eighth century, recorded the grades of soil that may represent the overall environment suitable for the agricultural production in an area 40 × 60 km. Although the judgement of productivity seems to have been based on subjective criteria, this record is noteworthy because it presents not only a map showing the conditions 1200 years ago, but also a map based on observed results on the local climatic conditions with grades in a small area.

Sir John Evelyn (1620–1706), a famous British diarist, wrote in his book, *Fumifugium, or the Inconvenience of the Aer and Smoke of London dissipated*, published in 1661, that “the weary Traveller at many Miles distance, sooner smells, than sees the City to which he repairs” (Landsberg, 1981). This is a keen observation on the dissipation of polluted air from London from the standpoint of local climatology. He also reported an

observation on the result, due to local differences, of the severe frost damage in the century that occurred in the winter of 1683–1684.

Table L1 Geographical factors producing local climates

Factor	Items to Be Mapped
Type of surface	
Rock	Type, color, thermal conductivity.
Soil	Type, texture, color, air and moisture content, thermal conductivity.
Water	Surface area, depth, movements.
Vegetation	Type, height, density, color, seasonal change.
Agricultural	Fallow land; type, height, and color of crops; seasonal change.
Urban and industrial	Material (concrete, tarmac, wood, metal, etc.) color, thermal conductivity; sources of heat, moisture, pollution, etc.
Properties of surface	
Geometrical shape	Flat, convex, concave, etc.
Energy supply	Latitude and altitude, degree of screening of natural horizon, aspect, slope, exposure.
Exposure	Shelter provided by macro- and micro-ographic features; shelter provided by buildings, trees, etc.
Topographic roughness	Rural areas: extent of woodland, grassland, arable; location of windbreaks and hedges; degree of agglomeration or dispersal of individual buildings. Urban areas: distribution and average height of different types of built-up zones; orientation and exposure of streets, blocks and individual buildings; density of parks, gardens and other open spaces; vertical profiles across area.
Albedo	Type of surface.
Radiating capacity	Type and maximum temperature of surface; observed earth radiation.

Source: From Stringer (1958), p. 384.

Mountain climates were observed in connection with the development of modern alpinism. Horace Bénédicte de Saussure (1740–1799) was one of those who were dedicated to mountain climbing and the science of mountains. He contributed to the understanding of local differences of mountain climates.

The forest influences on local climate were also observed in many places of the world in the seventeenth and eighteenth centuries in connection with the construction of windbreaks and shelter belts.

People in the seventeenth century were already well aware that urban areas have unique climates as compared to rural districts. Howard first compiled in 1818 various records on the climatic elements for London and released them in 1833 after arranging the observed records for the years between 1797 and 1831 (Howard, 1833). Heat island, fog, wind, insolation, sunshine hours, and air pollution were the main subjects of local climatological recognition in the nineteenth century.

Agricultural microclimatology has been developing since the beginning of the last century. For example, in Russia it started at the Main Geophysical Observatory in Leningrad since 1932 (Gol'sberg, 1970). Many researchers studied local climatic conditions for agriculture from subtropics, arid areas to boreal forest regions. A local climate subdivision of the climatology division was established at the Observatory in 1949–1950. A book entitled *Microclimate and Local Climate* was written by Sapozhnikova (1950), a leader of the subdivision. An English translation of this book was widely read in the USA.

From the standpoint of air pollution, it has been pointed out that air as a storage medium, mainly in a local scale, could no longer sufficiently purify itself on a global scale since the 1950s (Wanner, 1997).

After modern climatology and meteorology became established disciplines, year-long records by instrumental observation, air temperature lapse rate on mountain slopes, change of precipitation amount with increasing altitude on slopes, air temperature at seashores and lakeshores, land and sea breezes, mountain and valley breezes, ground temperature distribution on small hills, and other such measurements became the main topics of local climatology.

Development of research methods, summarizing the previous studies (Geiger, 1961; Geiger et al., 1995; Oke, 1978; Yoshino, 1975) could be chronologically classified into the following three periods:

1. The period when analyses were made on the effect of local conditions at a certain climatological station. This was accomplished by comparing mean values of adjacent stations. The climax period of this research method was from the nineteenth century to the beginning of the twentieth century.
2. The period when analyses were made in as much detail as possible on the horizontal distribution of the climatic elements in small areas. In Vienna, air temperature distribution was observed by driving a car to various locations in the city on 12 May 1927. After this study, cars became indispensable for so-called mobile observation in small areas.
3. The present period when climatic phenomena in small areas are examined by experiments such as wind tunnels and mathematical models using supercomputers. Remote sensing techniques are introduced also in this period after the 1970s.

The above chronological classification is not necessarily included in individual research of local climatology. The research

methods of the first and second stages are still significant today. All three methods should be used together in small areas. One example of research that used all three methods was a project on the local wind Bora along the Adriatic Coast of Croatia, and in the Ajdovscina Basin of Slovenia (Yoshino, 1976).

Local climatic phenomena

Insolation and sunshine

Insolation is affected by the elevation and slope inclination of a mountain. The higher a mountain, the shorter is the distance for solar rays to travel through the atmosphere. They also become stronger at higher altitudes, because the amount of water vapor and dust in the atmosphere decreases. The sun rises earlier and sets later on high mountains, so the annual variation of insolation becomes smaller than on lowlands.

As a rule, it is expected that sunshine hours become greater with increasing elevation but they decrease distinctively where fog occurs frequently. Figure L8a shows the relationship between the annual total sunshine hours and the height above sea level and a maximum at 400–500 m. On the other hand, the relationship between the annual and August total number of fog days and the height above sea level is given in Figure L8b. These curves show marked maximums at 1500 m above sea level, which correspond to the minimum of sunshine hours at the same elevation.

These phenomena are related to other local climates in the mountains. For instance, the vertical change of the annual range of minimum sunshine hours and the maximum at 1100–1200 m on the mountains in central Japan. However, the heights of

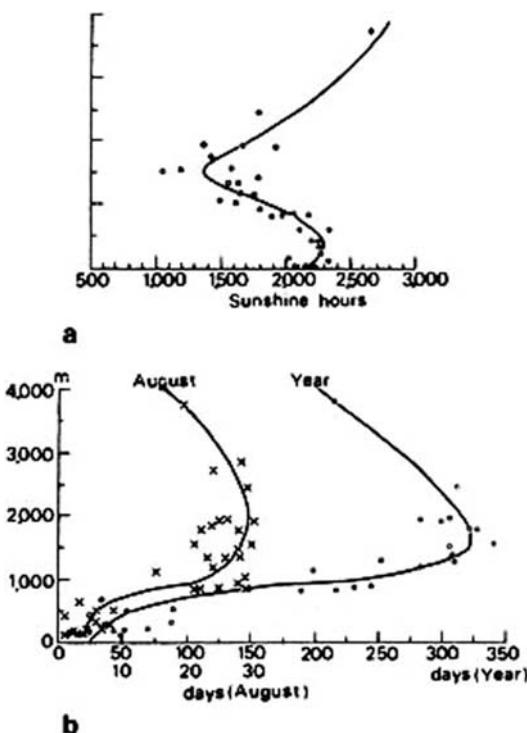

Figure L8 (a) Vertical distribution of annual sunshine hours in Japanese mountains; (b) vertical distribution of number of days with fog in the Japanese mountains (from Yoshino, 1975).

minimum sunshine hours and the maximum fog (cloud) occurrence change from region to region in accordance with macroclimatic conditions. In particular, the height of condensation level changes from lower latitude to higher latitude except for the subtropical high-pressure zone, which experiences a different height for maximum fog (cloud) occurrences on mountains.

On the valley slopes in the higher mountain areas, contrast of climates between sunny side and shadow side is quite obvious, in particular, in the middle and high-latitude regions. Not only air temperature, sunshine hours, and other climatic elements, but also landscape such as remaining snow in spring, vegetation, land use and human settlements show clear contrast as caused by these local climate differences. Since human life is affected by these conditions, place names are reflected sometimes by these conditions (Yoshino, 2001): Sonnenseite (Sunny-side) or Sonnenheim (Sunny-village) in Austria, Adrey (in the Roman language), Adritto (in the Italian language) or Poele chaud (in the French language) in Switzerland, Sol, Solana, and Soula (sun in the Catalonian language) in Spain, and Hinata, Himuki or Hyuga (Facing sun) in the Japanese language are the examples of sunny side slopes. Contrarily, Schattenseite (Shadow-side) or Winterhadle (Winter-slope) in Austria, Ubac, Opaco, and Pierre gelee in Switzerland, Baga, Ubach, and Ubago in Catalonia, and Hikage, or Kage in Japan are the examples of place names of shadow side slopes.

Precipitation on mountains

The amount of precipitation increases with height and reaches a maximum at a certain height on the slope of a mountain because of the lifting of moist air caused by the orographic effect. The mechanism of this rainfall is air ascending along a slope, water vapor condensing into water droplets through the adiabatic change and falling as raindrops at a certain height. Precipitation decreases at higher slopes, above the height of the rainfall maximum. Therefore, precipitation on high mountains is scarce. The distribution of annual precipitation on both sides of Mount Everest (8848 m) shows a maximum at Zhangmu on the southern foot, caused by prevailing southerly, moist winds, and decreases toward the summit as shown in Figure L9. On the northern side, precipitation is only 200–300 m because of the so-called rainshadow effect and the high elevation of the Tibetan Plateau. For example, annual precipitation at Tingri (28°40'N, 87°00'E) is 236.2 mm.

Lauscher (1976) distinguished five types of vertical distribution of precipitation on mountains of the world: (1) in the tropics there is a marked maximum at 1.0–1.5 km; (2) in the equatorial climates there is a general decrease in precipitation with increasing height; (3) the subtropics show a transitional type with a slight increase at increased height; (4) in the middle latitudes there is a sharp increase with height; and (5) in the polar regions there is a very weak decrease with height. A more detailed examination, however, would show that there are many local and regional deviations. For instance, Lauer (1976) found the maximum belts of annual total precipitation on the Cameroon Mountains, Mexico, depending on height above sea level, as shown in Figure L10. In general, the drier a mountain base, the higher the maximum belt of annual precipitation totals, as shown in Figure L10. Lauer came to the conclusions that: (1) in the monsoon circulation regions within the tropical westerly winds, the maximum belt descends to sea level as shown for the examples in the Cameroon Mountains; (2) on the Caribbean slopes of the Mexican Meseta, the maximum belt appears between 600 and 1400 m with weak secondary

maximums around 3000 m; (3) in the desert of marginal tropics, such as those in the Sahara, convection by intense heating is set off within disturbances in the tropical easterlies giving a maximum precipitation at 2500 m in the Hoggar Mountains.

Thermal belt on mountain slopes

It is said that Thomas Jefferson described the thermal belt, calling it a *verdant zone*, in 1781. The stratification of air temperature in the valleys and the enclosing slopes was brought to the attention of Silas McDowell of Franklin, North Carolina, a learned farmer, in connection with fruit growing. He mentioned the concept of thermal belts in 1858 (Dunbar, 1966).

Below the thermal belt, air temperature inversion is intense near the ground on clear calm nights; hence, the air temperature is lowest at the lowest level. On the contrary, above the thermal belt, air temperature decreases with height at a normal lapse rate.

A detailed study of the distribution of air temperature around Mount Tsukuba (876 m, 70 km NNE of Tokyo) showed the thermal belt at heights about 200–300 m above sea level, as shown in Figure L11.

According to the comparative study with previous results, the following can be summarized on the thermal belt (Yoshino, 1975):

1. The height of the center of the thermal belt appears at a height of 100–400 m above a valley floor situated below a mountain. In most cases it is 200–300 m.
2. The position of the thermal belt depends on the cross-section shape of the valley and mountain slopes.
3. The thermal belt is higher and more distinctive on a clear, calm night.
4. The thermal belt is higher in winter than in summer.
5. Climatologically, the appearance frequency of the thermal belt depends on the occurrence of synoptic conditions which bring clear, calm nights.

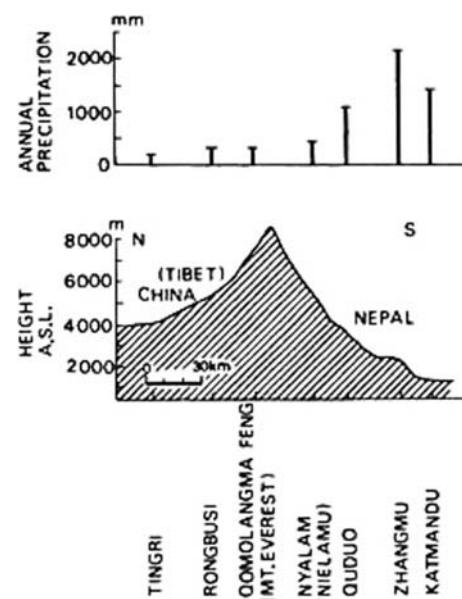

Figure L9 Annual precipitation along the north-south cross-section of Mount Everest, Himalaya.

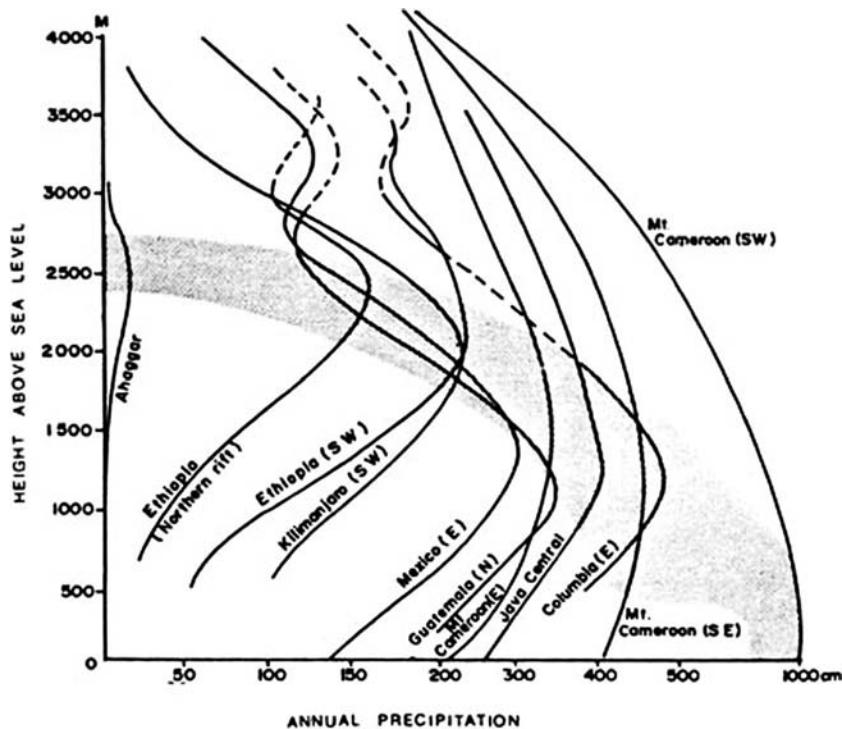

Figure L10 Vertical distribution of annual precipitation in the tropics, showing the maximum belt (shaded areas) dependent upon annual totals (from Lauer, 1976).

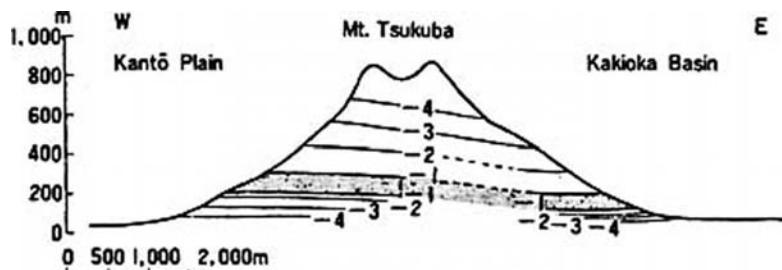

Figure L11 Vertical zonation of monthly mean minimum temperature along the west–east cross-section of Mount Tsukuba, Japan, January 1955 (from Yoshino, 1975).

There are many examples of fruit orchards, such as orange, peach and pear, and of human settlement and plants that originally were grown in lower-latitude regions and are found at the thermal belt of mountain slopes in the middle latitudes, because of the favorable thermal conditions. Thermal belts provide very good examples for the use of local climatic conditions to benefit human life.

Cold-air lake, valley inversion, and inversions on plains

The accumulation of cold air in a basin or in a valley on a clear, calm night is called a *cold-air lake*. The diameter of cold-air lakes varies from a few meters to several kilometers in most cases. Large cold-air lakes, several tens of kilometers in

diameter, are sometimes found. Although not commonly used at present, a large cold-air lake has been called a *cold-air sea*, and a small cold-air lake a *cold-air pond*.

The layer of cold-air accumulation is an inversion stratification: that is, temperature is the lowest at the ground surface. This inversion layer is formed not only by strong cooling by the nocturnal outgoing long-wave radiation at the basin or the valley floor, but also is intensified by the inflow of cold air from the surrounding slopes.

Summarizing the results and schematic illustrations obtained from many parts of the world, the following conclusions can be drawn:

1. The thickness of the cold-air lake or valley inversion is 0.2–0.3% of the relative height between the bottom of the basin or valley and the surrounding mountain ridges.

2. Over the cold-air lake, a downslope wind or cold-air drainage flows down from surrounding slopes, whereas its compensating current, an upwind, occurs in the upper layers. These winds form a circulation system.
3. The level of compensating currents coincides with the thermal belt on the above-mentioned slopes. Therefore, the cold-air lake is generally deeper in the colder season than in the warmer season.
4. Some cold air from the slope flows into the cold-air lake as an important source of cold air to the lake.
5. Above this circulation system, general upper winds flow. A model of these wind systems is shown in Figure L12 (Yoshino, 1984).

At the open ground surface on a plain, the air layer near the ground begins to cool rapidly about 1 hour before sunset under a calm, clear sky condition. This is due to the greater radiation loss of heat at and near the ground surface. As a result of this process, an increase in temperature with height begins at ground level. This is called ground inversion, surface inversion, low-level inversion, or radiation inversion.

The inversion layer plays an important role in the local distribution of weather and climate. In particular the wind direction, velocity, and pollutant diffusion are much different under the influence of the nocturnal inversion layer than under the daytime, unstable conditions. In fall and winter a dense but local fog layer is formed near the ground, frequently due to the cooling of air near the ground.

In the cold-air lake, therefore, the fog is dense; it is called cold basin fog or valley fog. Fog disappears with the dissipation of the inversion layer in the morning hours. This means, in turn, that the appearance of this local fog is a sign of dominant anticyclonic conditions synoptically, and one can anticipate fair weather in the daytime.

Local climate in coastal regions

Climate in coastal regions is characterized by a smaller diurnal and annual air temperature range and the noticeable periodic change of wind direction, i.e. a land breeze at night and a sea breeze during the day.

There are both direct and indirect causes for the smaller diurnal and annual range in temperature. The direct cause is the difference between the physical characteristics of land and water. Since the warming caused by insolation in the daytime is smaller above the water surface than above the land surface, because of the higher specific heat of water, water turbulence, transparency, and increased evaporation from water, the maximum air temperature above water is lower and the cooling by long-wave radiation above the water at night is smaller. Therefore, the diurnal variation is smaller on the coast than inland.

The indirect effect of smaller temperature changes is caused by wind. Generally speaking, winds are stronger on the coast than inland because of the smaller roughness on the coast. Strong winds cause lowering of the temperature in the air layer nearest the ground during the daytime hours and an increase in temperature near the ground at night. Thus, the diurnal range of air temperature is small on the coast. The onshore sea breezes on the coast further counteract a rise in air temperature in the afternoon in the warm season. Conversely, synoptic scale winds on the coast lessen the extreme lowering of air temperature at night during the cold season, because they do not allow development of an intense inversion layer under the stronger wind condition. This may be one reason for the smaller annual range in air temperature in the coastal region.

An extreme example of marine climate is seen on small islands and capes; they have low frequency of frost occurrence but higher humidity and less air pollution. For instance, the monthly mean minimum air temperature in January at Cape Ashizuri ($32^{\circ}43'N$, $133^{\circ}01'E$), Shikoku, Japan is $7.3^{\circ}C$, but $1.6^{\circ}C$ at Tosashimizu ($31^{\circ}47'N$, $132^{\circ}58'E$). The horizontal distance between these two stations is only about 10 km and the horizontal temperature gradient is $0.6^{\circ}C/km$. Although wind is considered an element of local climate, it also acts as a climatic factor for influencing the distribution pattern of other elements of local climates. This phenomenon is clearly seen in the coastal region.

Local front, local cyclone, and local anticyclone

In local climates, fronts, cyclones and anticyclones are important from the dynamic standpoint because they cause

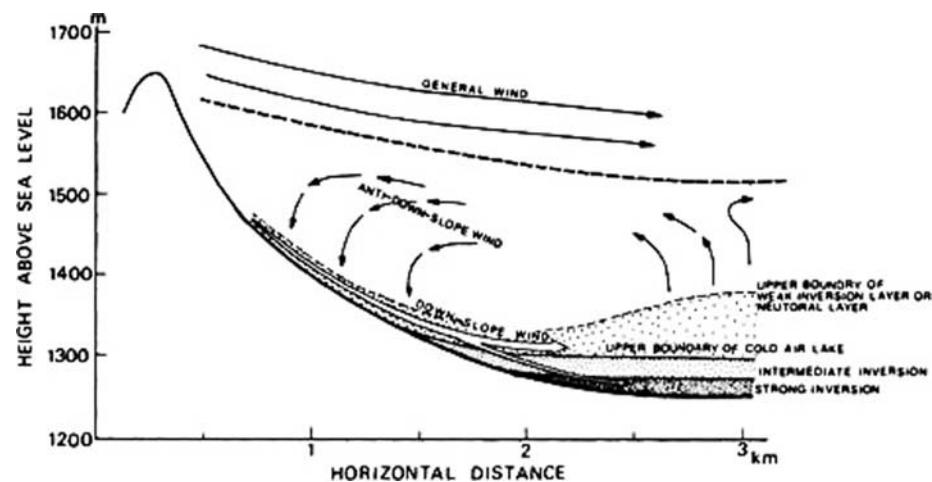

Figure L12 Schematic illustration of cold-air lake and cold-air drainage in a basin on a clear, calm night.

differences in local weather. In general meteorology, a front or frontal zone means the boundary between two airmasses of different densities. On the other hand, the local front can be distinguished not only by the difference in air temperature, but also by the discontinuities of wind direction, moisture, clouds, precipitation, visibility and pollutants. In most cases air pressure differences are small along the local front.

A sea breeze front sometimes becomes a smog front because pollutants stagnate on the ocean side of the sea breeze front. This situation occurs frequently in California (Kauper, 1960). Along the local front two converging air streams sometimes create a severe local storm, causing intense precipitation during a short period. On the local front between a cold mountain wind or land breeze and the warmer synoptic-scale wind such as a monsoon, precipitation occurs at night or in the early morning. Such precipitation is generally not heavy but occurs very frequently in some places. In this sense it is important climatically. A typical example may be the morning maximum precipitation found at the mouths of Himalayan valleys.

Local cyclones are formed thermally over the broad flat land areas under the influence of intense insolation during the warmer season and in the relatively warmer inland seas, lakes, and bays during the colder season. Mechanically, local cyclones are formed on the lee side of mountain ranges (Atkinson, 1981). A local cyclone itself seldom causes heavy precipitation, but it develops very quickly in some cases, bringing strong precipitation.

Local anticyclones often develop in winter over broad basins and land areas surrounded by relatively warmer water, whereas in summer they are formed over the broad water surfaces surrounded by relatively warmer land areas. The former is typically created over central Japan under the weak winter monsoon situation (Nomoto, 1975) and the latter over the Great Lakes in the summer (Strong, 1972).

Land-use/cover change, human activities and local climate

The IGBP (International Geosphere, Biosphere Program) contains many core projects, most of which are concerned with (a) conditions on Earth's ground surface, and (b) analyses of the impacts of land cover change on the planet's biogeochemistry, climate and ecology and their complex relationships. On the other hand, the IHDP (International Human Dimensions Program) deals with interaction among land-use change and global environmental change under the influence of human activities. Linkage between the human activities and physical dimension of global environmental change is shown in Figure L13. The special dimensions of global, regional, local and micro-scales are noted on the right-hand side of the figure. The driving forces (upper left-hand side) are population, level of affluence, technology, political economy, political structure, attitudes and values. Developments of local climatology related to agricultural land-use are: (a) division of area according to local climates, (b) establishment of practical application of local climatological knowledge, (c) statistical analysis of small local differences caused by land-use/cover and microtopographical conditions, (d) simulation by modeling at a local scale, (e) analyses by remote sensing methods, and (f) presentation of local-scale phenomena on maps or through other visual methods (Yoshino, 1997).

LOCAL WINDS

In many areas of the world, regional conditions give rise to winds that have been identified by the inhabitants as having a special effect or as occurring at a definite season. The recurrence of these winds caused them to be seen by the people living in an area as having a uniqueness particular to that region. Accordingly, these local winds were identified by names applicable to a given location.

The effects of these local winds depend on their thermal and humidity characteristics and the velocities they attain. Warm winds, such as the Santa Ana of California and the Sukhovey of the USSR, are extremely dry and cause widespread desiccation of plants. As indicated by the frequency of forest fires in California, the prevalence of such winds and resulting tinder-dry vegetation is a hazard. Such warm winds, however, can also be highly beneficial. The Chinook of Canada, for example, often hastens the melting of snow in spring to permit early planting activities.

In analyzing the causes of local winds, it is evident that most of them are either the Föhn-type wind, resulting from adiabatic heating of descending air, or of a wind that is associated with a regional pressure system that causes a channeling of air by topography. Figure L14 provides an example of the Föhn-type wind and Figure L15, the Mistral, a wind that results from the relative positions of pressure systems.

A comprehensive listing of local winds has been compiled by Forrester (1982) and the following descriptions are drawn largely from his account.

Abroholos

A squally wind on the southeast coast of Brazil, more frequent from May through August.

Austru

A west wind blowing over the lower Danube lands in the winter, usually bringing dry, clear, and cold weather.

Bad-i-sad-o-bistroz

A violent downslope wind affecting Afghanistan and adjacent areas, blowing from the northwest from May to September. Sometimes called *the wind of 120 days*.

Bali

A strong east wind that blows over the eastern end of Java across the Java Sea.

Barat

A squally, occasionally violent, and damaging wind blowing across the Celebes Sea to the northeast coast of the island of Celebes. The barat occurs most frequently from December to February.

Barber

A term used in some sections of the United States and Canada to describe a strong wind carrying precipitation that freezes on contact with objects, especially the beard and hair.

Barine

Unusual winds from the west that blow over eastern Venezuela.

Bayomo

A violent gusty wind usually associated with thunderstorms forming on the windward side of the Sierra Maestra mountain range in southern Cuba. The winds travel with the storms southward from the land over the south coast of Cuba.

Belot or Belat

A strong land wind from the north and northwest that blows along the southeast areas of Saudi Arabia during the period from December to March. Sand picked up from the interior by this wind often imparts a hazy appearance to the atmosphere.

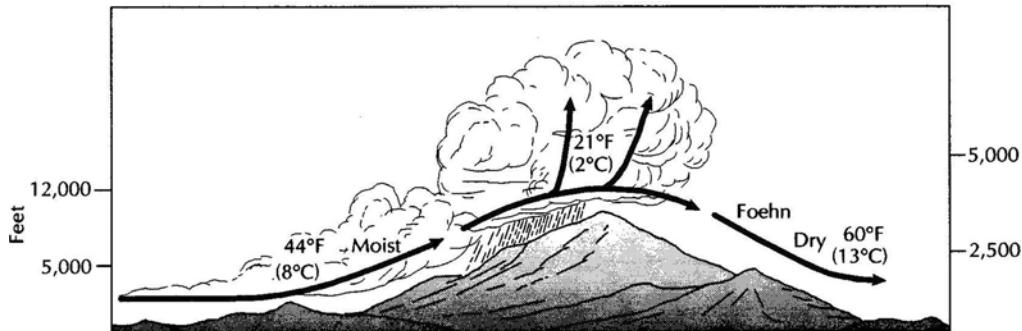

Figure L14 An example of the formation and characteristics of the Föhn wind. Elevations in feet (left axis) and meters (right axis).

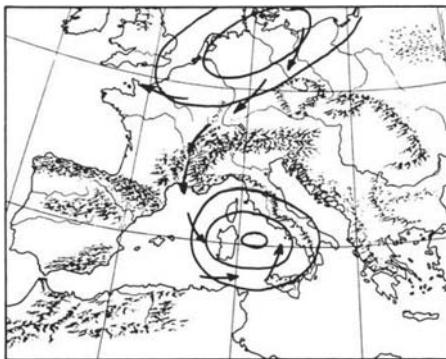

Figure L15 Synoptic conditions that give rise to the Mistral.

Bentu

An east wind blowing in the Mediterranean along the coast of Sardinia.

Berg

Hot, dry, and occasionally dust-laden winds blowing from interior portions of a large part of the southern African continent. Most frequent in the winter season, the berg generally flows in a southerly direction and can bring high temperatures for a period of several days all the way to the southern coast areas of Africa.

Bhoot

In India, a term describing a relatively small-scale counter-clockwise whirling of air filled with loose dust, somewhat similar to a dust-devil.

Bise

A strong outbreak of cold dry air from the north that sweeps over the mountainous regions of southern France and Switzerland.

Blizzard

A term used in Canada and the northern United States to describe a howling, cold, piercing wind, usually of gale force, out of the north or northwest. These winds are intensely cold and punishing.

They sweep southward in strong surges, moving from areas between Hudson Bay and Alaska. They are laden with blinding, powdery snow, mostly picked up from the ground.

Bohorok

A dry, warm, downslope type of wind that blows frequently from May to September from the leeward side of the Barison Mountains in the southwest to the northwest coast of Sumatra. The wind comes from the Indian Ocean, but loses much of its moisture on the windward side of the backbone mountains in Sumatra.

Bora

Excessively cold wind that moves rapidly southward from the valleys of the Karst and Dinaric Alps across the Adriatic Sea, affecting the Dalmatian Coast from Trieste to Albania. The bora's icy wind sometimes exceeds 100 mph. Also in the gulf of Finland (USSR and South Finland) for a cold northeast wind from Siberia.

Borasco

Winds associated with violent thunderstorms, especially in the Mediterranean.

Bornan

One of the many valley winds in the Swiss Alps, blowing over the central part of Lake Geneva from the valley of the Drance.

Brave West

The strong, often stormy winds from the west and northwest – the prevailing belt of westerly winds of the Temperate Zone of the Southern Hemisphere.

Breva

A valley wind blowing over Lake Como in northern Italy.

Brickfielder or Brickfelder

A hot, dry, and dust-laden wind blowing across the south of Australia from the deserts of the interior during the summer. The name originated in Sydney because of the dust the hot winds raised from the brickfields south of the city.

Brisa

Trade winds that blow from the northeast over the coast of South America or from the east over Puerto Rico.

Brisote

A northeast wind, part of the trades, blowing at a stronger than normal rate over Cuba.

Broboe

A dry wind prevailing from the east from June to October blowing over the southwest part of the island of Celebes.

Brubu

A squally wind in Indonesia.

Bruscha

A cold northwest wind in the Besgell Valley, Switzerland.

Bull's-eye Squall

A sudden squall forming in apparently fair weather. This type of squall is characteristic over the ocean off the Cape of Good Hope, South Africa. Its name is derived from the appearance of a small and isolated cloud seen at the beginning of the squall marking the top of an otherwise invisible vortex of the storm.

Buran

A dreaded, wildly violent, intensely cold wind that breaks out throughout Siberia and into south Russia from the northeast. Similar to the blizzard of the United States and Canada, the buran is dangerous because of its snow-filled character.

Burga

A strong windstorm in Alaska, usually attended by snow or sleet.

Cacimbo

A cooling sea breeze blowing from the southwest to the port of Lobito on the coast of Angola in western Africa. The refreshing breeze, occurring almost daily in July and August, starts about 10 a.m. and lasts through most of the day. It is cooled by its passage over the Buenguela water current lying to the west of Lobito in the South Atlantic.

Cat's paw

A light puff of wind in America just barely noticeable – enough to cause a patch of ripples on water. It is a very light breeze that affects a small area.

Challihu

A strong southerly wind experienced in parts of India during the spring months. It is the forerunner of the southwest monsoon wind that prevails during the summer months. The latter wind, moving from the Indian Ocean, is moisture-laden, and as

it moves northward into the mountainous areas, yields enormous amounts of rain on an almost daily basis.

Chergui

An intrusion of hot air into Morocco in northwest Africa from the Sahara Desert areas to the east.

Chili

A hot wind from the deserts of North Africa and Saudi Arabia flowing into central and southern portions of the Mediterranean. Chili is the name applied when this wind passes off Tunisia. It is a dry wind, carrying considerable amounts of dust and sand, occurring more frequently in the spring months.

Chinook

A dry, warm wind blowing from a westerly direction down the east slopes of the Rockies in North America. This föhn-type wind loses its moisture on the windward sides of the Rockies and heats up as it slides down the lee sides. The chinook sometimes raises the air temperature as much as 25°C in less than a half-hour, causing a rapid melting of snow; thus, the chinook is sometimes called the *snow eater*.

Chubasco

A violent squall-type wind associated with severe thunderstorms, frequently occurring on the western coastal sections of Central America and Mexico between Costa Rica and Point Eugenio (Lower California), most frequent during the rainy season from May to November.

Churada

A fierce rain squall in the Mariana Islands, occurring mostly during January, February, or March.

Cockeyed bob

A squall wind associated with thunderstorms on the northwest coast of Australia, most frequent from December to March.

Collada

Strong northerly winds blowing over the Gulf of California.

Contrastes

Winds that blow from opposite directions even though a short distance apart. The western Mediterranean area frequently is subjected to these contrasting winds in the spring and fall seasons when airmasses may move toward each other from the European continent and the desert regions of Africa.

Coromell

A nighttime offshore breeze occurring with great regularity in the La Paz area at the southern part of Lower California from

November to May. At these times the land area cools rapidly at night and the overlying air flows toward the relatively much warmer water areas around La Paz.

Coronazo

Strong south winds blowing from the west coast of Mexico. These winds are usually the eastern peripheries of tropical storms located well offshore to the west.

Criador

A west wind in northern Spain, usually associated with traveling atmospheric disturbances that bring rain.

Crivetz

A cold wind blowing from the northeast over the lower Danube lands from the Russian interior.

Datoo

A westerly sea breeze that blows over Gibraltar from the adjacent water of the Atlantic Ocean.

Doctor

A term originating in England to describe the cooling sea breezes occurring in the tropics. The term *Cape doctor* refers to a strong southeast wind blowing on the South African coast.

Dust devil

A rapidly rotating column of air about 100 ft to 300 ft or higher that picks up dust, straw, leaves, or other light material. It usually develops on calm hot afternoons with clear skies, mostly in desert regions and has no relationship to a large-scale dust storm. In the southwestern part of the United States it is called a *dancing devil*; in India a *devil*; and in South Africa a *desert devil*. In Death Valley, California, it is sometimes called a *sand auger*. It also is called a *dust whirl*.

Elephanta

A strong wind blowing from the south or southwest along the Malabar coast at the extreme southwest end of India during September and October. It heralds the beginning of the dry season and marks the ending of the rainy southwest monsoon.

Etesian

Outbreaks of pleasantly cool air blowing over the eastern Mediterranean, particularly over the Aegean Sea. These outbreaks are most frequent in July and August, generally are moderate to strong, occasionally attaining gale force, although the stronger velocities are limited to the northerly portions.

Feh

A gentle breeze of the Shanghai region.

Föhn

A wind characteristic of many mountainous regions of the world and called by different names in different countries

(chinook, Santa Ana, etc.). The term Föhn is more specifically applied in many Alpine valleys, notably in the upper Rhine, the Reuss and upper Aar in central Europe. It is a warm dry wind blowing down the lee side of a hill, mountain, or mountain range after it has risen over the windward side where it has lost its moisture. Such winds may have a marked effect on the climate of a region, sometimes creating an oasis of warm pleasant weather in what would normally be a cold region. In the Reuss Valley of Switzerland, such winds blow on an average of 48 days a year, mostly in March, April, and May.

Gallego

In Spain, a cold wind from the north.

Gharbi

Occasionally, winds from the Sahara Desert blow northward over the northern and eastern Mediterranean. As these hot winds move northward, they occasionally pick up moisture en route and arrive on the north coasts of the Mediterranean as strong winds, warm and damp. These winds are called *gharbi* in the Adriatic and Aegean sea regions. They bring heavy rains, especially on mountainous coasts. Some of the dust of the Sahara is often mixed with these rains, causing "red rain".

Ghibli

A dry hot wind in Tripoli, flowing from the hot deserts of North Africa.

Gregales

A strong polar outbreak of air from the northeast sweeping over the northeastern coasts of the Mediterranean, usually in spring and autumn, and associated with extremely variable weather conditions.

Habob

Extremely severe dust storms that occur mostly in the summer in large regional areas of northwest Africa, including Egypt. When such squall winds blow in these areas, walls of loose dust advance with the wind, rising to heights of several thousand feet, about 15 miles along a front and moving at speeds of about 35 mph. It is mostly a dry squall caused by the interplay of southwest monsoon winds at the surface and dry hot winds from the northeast aloft.

Harmattan

This wind is a continental part of the globe-encircling trade winds. It dominates the Sahara Desert and impresses its extremely dry and warm characteristics on a huge area of north and northwest Africa. In the summer the parching winds blow moderate to strong from the Mediterranean Sea southward and eastward to about latitude 17°N. In the winter, the wind blows from latitude 30°N to coastal areas of West Africa, sometimes penetrating to the African equator.

Helm

A strong wind in the Pennine Chain in north-central England. One portion of the mountain chain, east of Westmorland County,

runs northwest-southeast for about 10 miles, with an average steep-descending southwest slope of about 2000 ft. Extremely strong winds blow from the northeast over the Pennines to the Westmorland-Cumberland regions on the central west coast of England. These helm winds are sometimes associated with a roll or series of rolls of clouds that overhang the crest of a wind wave to leeward of the hills. The mountaintop clouds that form in the windstorm are called *helm clouds*.

Howling fifties

A term probably originating with whalers and others of the nineteenth century who sailed the oceans of the southern hemisphere. These sailors found the winds to be punishing over their routes southward, unhampered by land or mountains. The different latitudes of the general area over which these strong prevailing westerly winds blow (40–50°S of the equator) were given names that reflected their impression of these battering winds; thus, the howling fifties and the roaring forties.

Imbat

A refreshing sea breeze that tempers the heat of the North African coastal areas.

Kai

A balmy south wind in China.

Kapalilua

A prevailing type of sea breeze in Hawaii.

Karaburan

From early spring to late summer, these gale-force winds form daily in the Gobi Desert and surrounding regions in the heart of Asia. Blowing from the east-northeast, they carry clouds of dust from the desert. The blowing sand often darkens the air and is the reason for the karaburan sometimes being called the *black storm*. Lighter dust from the stirred sands carries far beyond the desert areas and provides a characteristic summer haze. These winds rage by day only; at night the desert air calms and skies clear rapidly. In this respect the karaburan of the Gobi and the harmattan of the Sahara are somewhat similar.

Kaus

A wind blowing from the southeast over the Persian Gulf during the winter. It is usually temporary in character and associated with low-pressure areas moving over the gulf region from across the Mediterranean. The wind usually brings cloudy skies, some rain, and above-normal temperatures.

Khamsin

In the winter season, Egypt is invaded alternately by outbreaks of cool and hot winds. Khamsin is the name given to a hot wind sometimes pulled into Egypt from Arabia, the Gulf of Aden and possibly the Arabian Sea far to the south and east. The khamsin, besides being quite hot, is extremely dry and so hazy with fine dust that lights are sometimes required at midday. It

usually continues for a few days and then is swept away by an invasion of cold air moving from the northwest behind a cold front. As the cold air arrives, dust and sand is raised, the sky becomes cloudy and sometimes showers fall. Khamsin winds are usually moderate in force but may reach gale force. The mean frequency is about three a month in February, March, and April.

Kharif

A strong, often gale-force wind blowing from the southwest in the Gulf of Aden. It is called the kharif on the Somaliland coast on the south shore of the gulf where the wind descends sand-laden and uncomfortably hot from the African interior.

Knik

A strong southeast wind in the vicinity of Palmer, Alaska.

Kohilo

A light, pleasant breeze of Hawaii.

Kona

A somewhat oppressive and sultry wind of Hawaii, from the southwest.

Koshava

A stormy northeast wind in Yugoslavia, carrying snow from Russia.

Leste

A hot, dry wind blowing from the east and south sections of the north-central African desert regions to Madeira and the Canary islands.

Leung

A cold wind from the north blowing over the China coast.

Levanter

A strong east wind frequently blowing through the Strait of Gibraltar from the Mediterranean. When the wind is excessively strong and stormy, it is sometimes called *levantades*.

Levanto

A hot wind from the southeast that blows over the Canary Islands; similar to the leste wind.

Leveche

One of the many hot and dry winds that originate in the hot deserts of North Africa and Saudi Arabia, affecting areas of the middle and south Mediterranean. All of them may be grouped under the general term *sirocco*, but they are so important in different areas that many of these sirocco-type winds have been given different names. Leveche is such a wind, blowing from the south and southeast over Spain.

Maloja

A warm, föhn-type wind flowing down from the high Maloja Pass in Switzerland.

Marin

A sirocco-type wind, blowing with strong intensity from the southeast in the Gulf of Lions and the neighboring shorelines of southeast France. It is quite warm and oppressive, usually attended by cloudy skies and heavy rains.

Matsukazee

A soft, pleasant breeze in some agricultural areas of Japan.

Mistral

This well-known wind, the “masterful” north wind of the Gulf of Lions, surges southward in outbreaks from polar regions over north and central Europe to affect a wide area over the northwest coast of the Mediterranean. It is a cold and dry wind that can cause damage, and is particularly noted in the winter in the lower Rhone Valley. Although it blows throughout the year, it is most prominent in the winter and spring. Marseilles is exposed to the mistral for about 100 days a year. Occasionally, the mistral is wide enough in extent to affect the coast between Barcelona and Genoa, the Gulf of Lions (with squalls reaching over hurricane force), and the Balearic Sea. It has, on some occasions, crossed the Mediterranean to the African coast.

Monsoon

In winter a consistent cool-to-cold dry wind flowing southward across India from the Tibetan plateau. In summer it is a warm, humid flow of air northward over India from the Indian Ocean, and precipitates torrential rainfalls in many mountainous areas of India.

Myatle

A stormy, northeast wind in northern Russia.

Naalehu

A wind that occasionally blows from the arid interior of Hawaii.

Narai

A cold wind in Japan, blowing from the northeast and polar regions of the Asiatic land mass.

El Norte

An outbreak of polar air, originating in north-central United States or the Canadian basin, which sweeps as far south as the Gulf of Mexico and parts of Central America. The term also refers to cold winds from the north that flow over eastern Spain in the winter.

Northeaster

A wind that blows from moderate to strong force from the northeast over the New England coastal regions. This wind,

moving in from the North Atlantic, is generally moist and often chilly or cold. It is frequently accompanied by cloudiness and precipitation. The “nor’easter,” usually a portion of a deep migrating low-pressure area, occasionally can have a severe impact on coastal communities.

Norther

A strong cold wind from the north, originating in the polar regions of Canada, that moves rapidly southward as far as the Gulf of Mexico and eastern coasts of Mexico. Similar to el norte.

Northwester

A moderate to strong wind from the northwest bringing cool to cold temperature over broad regions east of the Rockies. The name also is applied to frequent gale winds that batter the Cape region of South Africa from the northwest, attended by overcast skies and heavy rain in the winter.

Oe

A localized type of whirlwind that occurs off the coast of the Faeroe Islands in the northeastern Atlantic.

Orkan

A high gale of Norway.

Pampero

A violent squall that attends cold fronts as they move from the southwest to the northeast in the pampas of Argentina and Uruguay. It resembles the norther of the United States Plains section in the sense that it is an outbreak of air from polar latitudes. Behind the violent frontal squall the wind eases, blowing moderate and steady. The sky clears and the air is cool to cold. Buenos Aires has about 12 pamperos a year, mostly in spring and summer; Montevideo about 16; the River Plate area has about 20 a year.

Papagayo

A violent wind from the north that invades the Gulf of Papagayo on the northwestern coast of Costa Rica. It is akin to the norther of the United States and el norte of Mexico, resulting from large southward surges of polar air from the North American continent.

Ponente

A westerly wind over the Mediterranean, particularly as a refreshing sea breeze on the western Italian coastline.

Purga

Another name for the dreaded buran of the tundra regions in northern Siberia in the winter. The purga sweeps down from the north with extraordinary violence throughout Siberia and sometimes to south Russia, particularly violent over the open plains sections. The air is filled with snow picked up from the snow-covered tundra areas and this often

cuts visibility to zero. The purga is quite similar to the North American blizzard.

Reshabar

A strong wind blowing from the northwest over the Caucasus Mountain range between the Black and Caspian seas.

Roaring forties

The winds prevailing in areas of the oceans between 40° and 50° south latitude where, day after day, the wind force may exceed 40–50 mph from the west. The winds are the prevailing westerly belt of winds that circle the Earth in the southern hemisphere as part of the Earth's primary atmospheric circulation.

Roc

A cold wind of Iceland.

Santa Ana

A föhn-type wind named after a community southeast of Los Angeles in the coastal area of southern California. During the winter, when north and east winds blow from the deserts and plateaus of lower eastern California, they cross the coast ranges and descend through such passes as the Cajon and Santa Ana to reach the coast as hot and dry winds, often laden with piercing particles of dust.

Seistan

Another name for the “wind of 120 days” or the bad-i-sad-o-bistroz that blows strongly from the north in summer over the Seistan basin in eastern Iran. Known for its consistency over a long period of time.

Shamal

A northwest wind blowing down from the Mesopotamian corridor over Iraq and the Persian Gulf in the summer. It often is strong during the day, carrying clouds of dust and sand, but decreases in intensity at night.

Sharki

A wind from the southeast occasionally blowing over the Persian Gulf.

Siffanto

A warm south wind blowing from the “heel” of Italy.

Simoom or Simoon

A sirocco-type wind, hot, dry, and dust-laden, blowing over the middle and southern portions of the Mediterranean. It is called a simoom when it is abnormally strong over the southeast part of the Mediterranean. The wind blows northward, originating in the hot desert sections of north-central Africa. The Turkish version of this wind is the samuel.

Sirocco

A warm wind of the Mediterranean area usually sweeping northward from the hot and dry Sahara or Arabian deserts. The sirocco usually invades the Mediterranean shores in the spring when many atmospheric low-pressure areas move over the Mediterranean. As the storms move, their forward sectors pull air northward that originated hundreds of miles to the south. Frequently, therefore, the sirocco is dusty. It often picks up moisture as it crosses the Mediterranean and may arrive on the north Mediterranean shores as a warm and damp wind.

Sno

Cold, swift-moving currents of air that fill the Scandinavian valleys in the winter from the highlands, attaining considerably strong velocities in the fiords.

Solano

An oppressively warm and dusty east wind that blows over Gibraltar and southeast Spain.

Sonora

A warm wind crossing Arizona from Mexico and California.

Southeaster

Strong winds from the southeast, sometimes of gale force, that blow near the extreme southwest end of the Cape of Good Hope, South Africa. They usually occur in the winter and often in advance of a cold spell. Clear skies attend the southeaster at the Cape, but the surface layer of air often carries a whitish haze of salt particles and sea spray.

Southerly burster

Cold winds that move in from polar zones northward over Australia. The air moves behind cold fronts that are attended by strong gale-force winds accelerating and intensifying over the highlands of New South Wales on the southeast coast. About 30 bursters a year occur over southern and southwest Australia, most of them in spring and summer.

Steppenwind

A cold northeast wind that occasionally blows over Germany from the steppe regions of Russia.

Stikine

A strong and gusty northerly wind of extreme southern coastal areas of Alaska near Wrangell, named for the Stikine River or Stikine Mountains to the northeast of Wrangell.

Sudestades or Suestado

Strong to gale-force winds from the southeast that affect coastal areas of Uruguay, Argentina, and Brazil. They are part of frequent migrating cyclonic (low-pressure) circulations in these regions and are accompanied by considerable cloudiness and rain.

Suhaili

A strong wind from the southwest blowing over the Persian Gulf, bringing thick clouds and rain.

Sumatra

Strong thunderstorm squalls blowing over the Malacca Straits from the southwest during the southwest monsoon season. These squally winds, attended by severe lightning and thunder, move along fronts that sometimes are about 100 miles long. They usually last for a few hours, and occur mostly at night. They appear to be surges in the southwest monsoon given extra push by the mountain ranges of Sumatra, which lie parallel to the Malacca Straits.

Surazos

Strong cold polar winds of the Andes Plateau in Peru, with intensifying velocities as they sweep through the mountain passes. The surazos usually bring temperatures below freezing with clear skies.

Taku

A strong wind from the east or northeast in the vicinity of Juneau, Alaska. The name is taken from the Taku River, the mouth of which is in Alaska but that flows over the Alaskan line from Canada. At the mouth of the Taku near Juneau, the wind sometimes reaches near hurricane force.

Tehuantepecer

A violent north wind in the region around the Gulf of Tehuantepec on the extreme south coast of Mexico. In the winter, polar winds sometimes pour southward in great surges from the North American continent (norther or el norte). The winds roar southward across the Gulf of Mexico and reach the Gulf of Campeche in the area just southeast of Vera Cruz. The wind then enters a low-level pass on the Isthmus of Tehuantepec in the mountain chain of the Central American Cordillera. It is intensified by this funnel effect and sweeps southward over the Gulf of Tehuantepec at gale strength. The wind is a scourge to boatmen in the gulf because there are few, if any, precursor signs.

Thalwind

A light pleasant valley breeze in Germany.

Tramontana

A pleasantly cool wind blowing from the north or northeast over the Mediterranean. The name is applied more specifically to this wind when it blows off the western coast of Italy.

Vardarac

Cold, dry polar winds blowing in the winter over the north Aegean Sea. They blow down from the Vardar River Valley in southeastern Yugoslavia.

Vento coado

An erratic, gusty wind blowing over hillside communities of Portugal.

Vento de baixo

A sea breeze along the coast of Portugal

Virazon

A consistent and prominent sea breeze blowing from the Pacific Ocean to the coast of Chile. The virazon is particularly strong during summer afternoons at Valparaiso, affecting harbor activities. The opposite-blowing land breeze in the region is called the *terral*.

Viuga

Stormy northeast winds of southern Siberia, associated with passing low-pressure areas.

Waff

In Scotland, a slight puff of air or gentle breeze, quite similar to the cat's paw of the United States.

Warm braw

A warm, dry föhn-type wind of New Guinea in the South Pacific. Crossing the Nassau and Orange Mountains of New Guinea, the air loses its moisture on the southern side of the ranges during the southwest monsoon season and sweeps northward as a warm and dry flow.

Whirly

A small but violent storm in the Antarctic. The whirling winds of the storm may cover an area of up to 100 yards or so in diameter. They occur most frequently near the time of the equinoxes.

Williwaw

(Not to be confused with Australia williwaw or willie-willie.) Strong, gusty wind in southwest Alaska coming down through the valleys and off the glaciers at speeds of 60–100 knots.

Wisper

A well-defined Rhine valley wind.

Yamo Oroshi

Another föhn-type warm, downslope wind blowing in the steep valleys of Japan.

Zephyr

A soft, gentle breeze, mostly from the west, of the Mediterranean regions (note the similarity of the name to zephyrus, the name given to the west wind in Greek mythology).

Zonda

A strong and dry west wind blowing over the western region of Argentina. The wind is hot, dry, and dusty and occurs most frequently in the spring. It acquires its dry character from the föhn action as it descends to Argentina from the Andes Mountains lying to the west.

M

THE MADDEN–JULIAN OSCILLATION (MJO)

The MJO is a low-latitude intraseasonal oscillation, meaning that it passes through an identified cycle in a period of 60–90 days, quite unlike the annual, biennial or decadal cycles of other oscillations. It is so named for Roland Madden and Paul Julian of NCAR, who discovered the wave in the early 1970s. Its identification and possible forecasting is of considerable importance in long-range predictability of tropical and subtropical weather as well as short-term climate variability.

The MJO is a feature of the tropical atmosphere–ocean system that plays a significant role in precipitation variability. It is characterized by anomalous rainfall conditions that can be either enhanced or suppressed. The beginning of the cycle, the anomalous rainfall event, usually appears first over the Indian Ocean and Pacific Ocean. It remains identifiable as it moves over the very warm water of the western and central parts of the Pacific Ocean. On meeting the cooler waters of the eastern Pacific Ocean it usually becomes less defined, only to reappear over the tropical Atlantic Ocean and Indian Ocean. As noted this cycle can last 1–2 months.

The higher or lower than normal precipitation of the event are associated with both surface and upper-air conditions as they relate to ascending and descending air. A knowledge of the cycle characteristics would enable a clearer understanding of tropical rainfall variability, the role of the cycle in relation to Pacific Ocean and Atlantic Ocean tropical cyclones and the impact of the oscillation upon middle-latitude precipitation. In their study of the MJO's role in hurricanes in the Caribbean Sea and Gulf of Mexico, Maloney and Hartmann (2000) found a distinct relationship. They noted that hurricanes are four times more likely to occur when, in the ascending phase, the rising air and surface westerly winds are conducive to formation of the storm.

The Climate Prediction Center (CPC) of NOAA (<http://www.cpc.ncep.noaa.gov/>) shows how the tropical oscillation impacts rainfall in the Pacific northwest of North

America. The evolution of this event is often referred to as the “pineapple express”, so named because a significant amount of the deep tropical moisture traverses the Hawaiian Islands on its way toward western North America.

The MJO is thought to play a significant role in the formation and frequency of hurricanes. If an easterly wave, the initial formation feature of Atlantic hurricanes, meets the cloudy sky phase of the MJO the conditions for hurricane formation improve. The MJO is, of course, moving in the opposite direction to the easterly wave. Unfortunately, although hurricane researchers of the National Hurricane Center have been informally using the MJO, the linkage is currently insufficient for accurate modeling and forecasting.

MARITIME CLIMATE

A maritime climate occurs in regions whose climatic characteristics are conditioned by their position close to a sea or an ocean. Such regions, also known as oceanic climates or marine climates, are considered the converse of continental climates.

Land and sea differences

About 72% of the Earth is covered by water. The continents and oceans basins are unevenly distributed over the Earth's surface, with the northern hemisphere containing some 65% of the total continental surface. The vast area covered by water and its relative distribution play a very important role in the climates that occur not only at sea, but also, to varying degrees, on land.

Properties of water and land

The climate at any location can be determined by evaluating the amount of energy the surface receives and the way in which it is budgeted. This energy budget for the oceans differs from that of land and, as a result, produces a different climatic regime. The basic physical parameters that give rise to the differences are given in Table M1.

Water has a much greater capacity for absorbing and storing heat energy than does other Earth materials. The basis of this difference is the high specific heat of water. Specific heat is defined as the amount of heat required to heat a unit mass by a unit of temperature. In the example given in Table M1, the temperature of water would be raised only one-fifth that of the same amount of a given soil upon applying the same unit of temperature.

The reflectivity of a surface, its albedo, varies over both land and water. Generally, the lighter, smoother, less transparent the surface, the higher the albedo (a perfect reflector has an albedo of 100%). Land surface albedos vary because of the great range of surface types; a desert surface may have an albedo of 25% while an asphalt parking lot may be only 5%. The major difference in albedo over water is the angle of inclination of the sun. If the sun is high in the sky very little reflection occurs, but as the angle increases so the albedo increases. At a sun inclination angle of 90°, water albedo is less than 2%; at 10° it becomes 35%.

Thermal conductivity is the amount of heat that can pass through a given thickness of material in a given time (using standardized units). It is roughly proportional to the density of the material, causing the surfaces of dense material to heat slowly. If transparency is considered along with conductivity, then a marked difference is seen between land and water. Transparency is a measure of how much radiant energy (such as sunlight) can penetrate a surface. Since opaque materials,

granite rocks for example, have no transparency, radiant energy is transformed to heat energy at the surface. The transparency of water permits energy to penetrate to various depths with most infrared energy absorbed close to the surface; with increasing depth other portions of the electromagnetic radiation energy are absorbed until, at about 10m, the unabsorbed blue portion of the spectrum is reflected back. This property gives the sea its blue color.

The heat budget

To these physical parameters must be added the dynamic elements that make up the heat budget of a surface. These include:

1. The amount of energy used to evaporate water is much greater over the ocean than the continent. This means that a large part of available energy goes to change water to water vapor. This latent heat is later released when water vapor changes back to water.
2. The large portion of available energy over the ocean that is used for evaporation, means less is available for sensible heat, the heat energy that is distributed through the atmosphere through turbulent transfer. This causes air over the land to be warmer than that over the ocean.
3. As noted, oceans absorb radiation to a substantial depth; over land the penetration of energy is limited to often less than a few feet. The oceans are mobile and the absorbed energy may be advected to other areas through currents and drifts.

The combined result of the physical and dynamic differences cause temperature variations in oceans to be much less than those of a land surface. The ocean is an equable environment that absorbs, transports and eventually releases stored heat to the atmosphere. Oceans thus warm up more slowly than landmasses but, because they conserve the heat, they cool down more slowly. Temperatures in the oceans are conservative, those over landmasses, which warm and cool quickly, are extreme. This maritime effect will be most clearly seen in extratropical regions where seasonal extremes are expected. In tropical latitudes the seasonality is more a function of precipitation than of temperature.

The influence of oceans

Surface ocean currents

Surface ocean currents are wind-driven and, like the wind, are subject to considerable variation. The actual pattern of world ocean currents can be related to the global circulation of winds and the shape of landmasses. Just as the subtropical high-pressure zones are a dominant feature of the atmospheric circulation so are the oceanic gyres (oceanic circulation cells) associated with them. On viewing a generalized map of ocean currents of the world the dominance of the subtropical gyres is seen.

The direction in which currents flow is important. Those flowing poleward, the warm currents, transport heat energy from low to high latitudes, while the cold currents, flowing from high to low latitudes, bring cool water to warmer areas. The relative impact of this movement upon temperature, particularly coastal temperatures, is illustrated by temperature distribution over the North Atlantic Ocean. The 10°F (-12°C) isotherm is located at about 50°N on the east coast of North America but extends to almost 70°N in western Europe. This is largely the result of the influence of the warm waters by the North Atlantic Drift.

Table M1 Selected properties of air, soil and water

Material	Specific heat	Albedo (%)	Thermal transparency	Conductivity
Air	0.17	6	Very low	High
Soil	0.2	5–20	Variable	Low
Water	1.0	5–10	Medium	Medium

Upwelling

The top waters of the ocean, perhaps down to 100 m, are mixed by motion of the wind and waves. Below this mixing layer there is a general decline in temperature until the coldness of the bottom waters is reached. The strong temperature contrast between top and bottom waters inhibits vertical mixing unless cold water is forced up to the surface. This upwelling occurs in a number of locations, often where surface water is swept away from the coast by divergence or offshore winds.

The upwelling process, while locally important in influencing ocean temperatures, is really part of a centuries-long circulation of the oceans that involves both surface and deep currents. Upwelling represents the return of cold waters to the surface circulation while downwelling is the return of surface water to the depths.

The influence of upwelling, together with cold ocean currents, will affect the rainfall regime of some coastal regions. By inhibiting convection, cold offshore waters result in desert climates along some coastlines. Although the dominant air is maritime, precipitation is minimal. The Atacama and the desert of Baja California provide examples.

Maritime airmasses

Air derives its thermal and moisture properties from the surface over which it originates. Air originating over the oceans, maritime tropical (mT) or maritime polar (mP) air, is generally characterized by (a) relatively small changes in the annual range of temperature in the source region and (b) a high moisture content derived from its origin over the oceans. These characteristics are, of course, reflective of the ocean properties already outlined. The relative frequency of maritime air received by a location will play a significant role in determining its climate.

Precipitation

Maritime precipitation in the westerly belts is marked by the cyclonic activity characteristic of the polar fronts. These are most intense in the winter months, but the fall season is likely to be wettest. The amount of evaporation into the maritime airmasses is related to both water and air temperature over the ocean. Accordingly, since the warmest conditions of the winter season occur in the fall, the latter is marked by the heaviest precipitation. In midwinter and spring a cold continental airmass may become more important.

There is marked diurnal variation in maritime precipitation, having its maximum at night or in the early morning, in contrast to the continental type, which tends to occur in the afternoon or early evening (Haurwitz and Austin, 1944), although admittedly many variants are known. There may, for example, be a maritime type in winter and a convectional, continental type in summer (especially in the lower-latitude stations). In the tropics there is greater radiation over the ocean at night, although the sea surface remains warm; thus the nighttime temperature gradient is steeper than that of the daytime, and convectional rain is common at night.

Humidity

Over the oceans humidity will reach a maximum in the afternoon and a minimum in the early morning, reflecting the diurnal

air temperature cycle. The vapor pressure is controlled in part by the air temperature and in part by the turbulent transport that tends to disperse the humid layer upward, but the latter is less important over sea than over land, where a double cycle tends to develop over the 24-hour period. Relative humidity is lowest in the high-pressure belts of each hemisphere. In the completely maritime stations (all-year) relative humidity is likely to be over 80% at all seasons.

Climates near the oceans

The discussion of the factors that influence climates over the oceans can now be related to the climates that occur in regions close to the oceans. It has been emphasized that the oceans are conservative in terms of temperature changes; such is also the characteristic of maritime climates.

The equable maritime climate is found in small, isolated oceanic islands that are most representative of the influence of maritime airmasses and oceanic climate controls. Table M2 shows examples.

There is an appreciable climatic difference between east and west coast climates in middle latitudes. In continental areas the influence of the oceans on climate is experienced in the west coast locations. This is a result of the general circulation of the atmosphere which, outside of the tropics, is dominated by a westerly air flow. Thus the most frequent airmasses that influence the west coast of middle latitudes are from maritime source regions. Those on the east coasts experience air that moves from a continental source.

Ocean currents, which themselves reflect atmospheric circulation, influence both temperature and rainfall in some west coast locations. The cool air of the offshore water lowers annual temperatures while the resulting stable air provides little rainfall.

Continentiality and oceanicity

To measure the effect of a continental landmass on climate (i.e. a minimum impact of oceans), climatologists use the concept of continentality. As early as 1888 it was suggested that, by measuring the average annual range of climate and adjusting for latitude, continentality could be quantified. Later workers used this idea as illustrated by the formula used by Gorzynsky:

$$K = [1.7(A/\sin \varphi)] - 14$$

where K is continentality, A is annual thermal amplitude and φ is latitude.

Many modifications of this formula have been suggested. Using the formula where continentality is given by

$$[1.7A/\sin(\varphi + 10)] - 14$$

Conrad (1946), showed that Thorshaven in the Faeroe Islands would have a continentality index of 0.

Table M2 Climatic data for some maritime stations

Island	Warmest month	Coolest month	Annual range	Precipitation (mm)
Fiji	26.6	22.9	2.7	3026
Midway	25.9	18.4	7.5	1176
Waitangi	14.9	7.8	7.1	851
Dutch Harbor	11.7	-0.3	12.0	1443

While maritime climates may be expressed by low values of continental indices, oceanicity indices have also been proposed. The first, in 1905, is given by

$$O = 100[(T_o - T_a)/A]$$

where O is oceanicity, T_o and T_a are the mean monthly temperatures for October and April, and A is mean annual range of temperature.

Although the scientific validity of the empiric measures has been questioned (Driscoll and Fong, 1992), they do provide a general comparison of the oceanic and continental influences.

MATHER, JOHN R. (1923–2003)

John Russell Mather was born in Boston on 9 October 1923. After serving as a weather forecaster in World War II, he earned his BA (1945) at Williams College and a BS (1947) and MS (1948) in Meteorology from MIT.

The earliest days of his long distinguished career were spent at the C. Warren Thorntwaite Laboratory of Climatology as

one of the first group of graduate students to become intimately involved in the research of the laboratory. The laboratory, which began operation in 1946, was originally located at Seabrook Farms in New Jersey and, in the spring of 1954, was relocated to Centerton, New Jersey. Mather reveled in the research being conducted there, writing that he enjoyed the job because he could go into the woods and not sit at a desk all day. His investigations while at the laboratory included topics such as micrometeorology, evapotranspiration, soil tractionability, soil moisture, climatic classification, and the movement of radioactive strontium in the soil.

Mather is probably best known for his work with the water budget, defined as the daily or monthly accounting of moisture inflows, outflows and storages at a particular place or over a geographical area for any period of time. He felt that the water budget was the basic tool of applied climatology, providing quantitative information on such things as moisture surplus, deficit, retention and runoff.

Mather earned his PhD from Johns Hopkins University in 1951 and remained at the laboratory for 16 years. When Thorntwaite died in 1963, Mather assumed the presidency of the laboratory, and continued his research there for 9 more years.

It has been said that Thorntwaite had the ideas but Mather put them into practice. In many instances this was true; but Mather took those ideas and refined them, making them his own. He expanded Thorntwaite's 1940 version of the water budget, and in 1955 he co-authored with Thorntwaite, *The Water Balance*, which made the ideas more useful for a wide range of soil and vegetative conditions. Thorntwaite had planned to write a book entitled *Physical and Applied Climatology*. The book was never written; it remained for Mather to do it in 1974. His book, *Climate Fundamentals and Applications*, was the fulfillment of Thorntwaite's plan. In it Mather hoped to show how humans could adjust their activities to the atmospheric environment. Chapters focused on hydrology, water resources, agriculture, clothing, human comfort, human health, air pollution, architecture, and industry.

Mather began teaching part-time at the University of Delaware in 1961. When Thorntwaite died that same year, Mather assumed the presidency of the laboratory and remained as president until 1972 when he left to devote his full efforts to the department at the University of Delaware. Thorntwaite's plans for his Laboratory of Climatology were outlined in a 1943 publication. They included, among other things, the training of climatologists on the graduate level. Students, because of the collaborative nature of the research, would need a broad background in all of the sciences. Thorntwaite's ideas became the foundation on which Mather, as chair, and the faculty built the Geography Department at the University of Delaware.

Mather felt that the best career decision he made was to move to the University of Delaware. He saw creating the new department and hiring new faculty as the most challenging job he faced in his life. As Mather wrote in the department history, three decades after Thorntwaite had written about an institution for climatological research, one had been created at the University of Delaware with the rigor in mathematics and the sciences he envisioned.

Permeating Mather's teaching and research was his desire to make climatology come alive, be dynamic and relevant. He hoped his students would be able to apply the principles of climatology to solving problems concerning humans and their environment. The descriptive, encyclopedic approach to climatology, he felt, was wrong; it was "dry as dust."

Mather's list of publications while at the University of Delaware is extensive, touching a wide variety of topics. He studied large- and small-scale applications of the water budget on climate, soils, vegetation, sea level, stream flow, irrigation, agricultural yield, forest products; the effect of land-use changes on crop yield; the effect of urbanization on the water table; the impact of society on the water budget of a particular area; and natural hazards such as coastal storms. His book, *The Genius of C. Warren Thornthwaite, Climatologist–Geographer*, co-authored with Marie Sanderson, is a major contribution to the history of climatology. In it he and Sanderson detail the life of Thornthwaite and his contributions to the discipline.

Mather's own service to the discipline is extensive: American Geographical Society Council member from 1981 to 2000 and secretary of the Council from 1982 to 2000; President of the Association of American Geographers in 1991–1992; Director of the Center for Climatic Research at the University of Delaware from 1972 to 1991; and State Climatologist for Delaware from 1978 to 1991, to name just a few examples.

Mather received many awards: the University of Delaware's Excellence in Teaching Award in 1989; the Commander's Award for Public Service, US Department of the Army, in 1990; the Francis Alison Award for distinguished scholarship at the University of Delaware in 1991; the Association of American Geographers Career Achievement Honors Award in 1998; the Association of American Geographers Climate Specialty Group's Lifetime Achievement Award in 1999; and the American Geographical Society's Charles P. Daly Award in 1999 for "valuable distinguished geographical labors."

Mather retired from the University of Delaware in the fall of 2000 as *professor emeritus*. He died on 3 January 2003, at the age of 79.

Mather was a "people" person who enjoyed interacting with colleagues and students. His legacy is huge; his ideas living on in his students and publications. He called Thornthwaite the "Father of Applied Climatology" and the Laboratory of Climatology the "mecca" for climatologists from around the world. Because of his position as a valued partner of Thornthwaite, Mather spread the gospel of the water budget to succeeding generations. He was eulogized as "an able leader, whose contributions to geography and especially physical geography have rarely been equaled."

MAUNDER, EDWARD WALTER (1851–1928), AND MAUNDER MINIMUM

Maunder was the son of a Wesleyan minister, best remembered for two things: his solar research, and as the founder of the British Astronomical Association. He attended King's College in London, and later secured a post as photographic and spectroscopic assistant at the Royal Greenwich Observatory; he initiated a long series of daily photographic sunspot records there. Eventually he was able to prepare a famous diagram, known as Maunder's "butterfly diagram", linking the latitudes of sunspot groups with the state of the 11-year solar cycle. He also carried out spectroscopic work. He publicized the apparent dearth of sunspots between the years 1645 and 1715, coinciding with a very cold spell in Europe; this is now formally known as the "Maunder minimum". His photographic records of sunspots were meticulous, and are still of great value today.

The sun was by no means his only interest. He observed the planets, and in a famous experiment demonstrated that the "canals" on Mars, claimed by Lowell and other observers, were optical illusions. He also made careful studies of the zodiacal light. He took part in various eclipse expeditions, notably the Royal Greenwich Observatory expedition to Mauritius in 1901, during which he obtained an excellent series of photographs. On other expeditions in 1896 and 1898 the weather was unkind. Between 1877 and 1887 Maunder was coeditor of the *Observatory Magazine*; for many years he served on the Council of the Royal Astronomical Society, and was joint Honorary Secretary from 1892 to 1897. In 1890 he founded the British Astronomical Association, and subsequently served as President. He officially retired from Greenwich in 1913, but was recalled during World War I to carry on the sunspot record.

His first wife died in 1888. He then married Miss Annie Russell, herself a brilliant mathematician and an astronomer on the staff of the Royal Greenwich Observatory, who collaborated with him in much of his later work in connection with the sun. He wrote several books, including a history of the Royal Observatory (1900), *Astronomy Without a Telescope* (1901) and *Astronomy of the Bible* (1908).

Maunder minimum

The Maunder minimum refers to a period from about 1645 to 1715 when sunspot activity virtually disappeared (Eddy, 1976; Schove, 1983). The Maunder minimum is one of a number of protracted periods of low sunspot activity; among others identified are the Oort minimum (1010–1050), the Wolf minimum (1280–1340) and the Spörer minimum (1420–1530). It was following the work of Gustav Spörer that Maunder first called attention to the interruption of the normal course of sunspot activity during the second half of the seventeenth and first part of the eighteenth centuries. Maunder published his findings in

1894 but the research appeared to have created little academic interest. In 1922 Maunder published another paper with the same title as that produced earlier (A prolonged sunspot minimum), but it remained for more recent astronomers and astrophysicists to verify and discuss it. Eddy (1976) noted that the sunspot dearth, 1645–1715, is supported by direct accounts in contemporary literature of the day. That the low sunspot activity was real, and not caused by a limitation in observing capability, is illustrated by drawings made of the sun at the time. Additionally, a tree-ring anomaly spanning the same period shows evidence of a concurrent drought in the US Southwest (Douglass, 1928) and when a ^{14}C lag time is assumed, there is a high degree of agreement in time between major excursions in world temperatures and excursions of solar behavior in the records of ^{14}C . The coincidence of Maunder's prolonged sunspot minimum with the coldest excursion of the Little Ice Age has been noted by many researchers examining possible relations between solar activity and terrestrial climate (e.g. Schneider and Mass, 1975; Fairbridge, 1987; Grove, 1988). Given the time relationship between the Little Ice Age and the Maunder minimum, the role of solar variability and sunspot activity has also been examined in terms of recent and future climatic change (e.g. Kelly and Wigley, 1990) and as it may be related to possible changes in the sun's brightness (Baliunas and Jastrow, 1990).

MAURY, MATTHEW FONTAINE (1806–1873)

Matthew Fontaine Maury was born in Spotsylvania County, Virginia in 1806 and died in Lexington, Virginia in 1873. Maury worked his way from midshipman to Lieutenant in the US Navy. From 1825 to 1834 his voyages took him to Europe, the Pacific coast of South America, and around the world. He showed special interest in navigation, publishing a *Treatise on Navigation* in 1836. Although his sea career was ended by a leg injury in 1839, Maury was appointed as superintendent of the Depot of Charts and Instruments in 1842. His job title changed to director of the US Naval Observatory and Hydrographical Office in 1844, when the Depot was moved and renamed. In this post Maury collected both ocean current and meteorological data, recorded in specially designed logbooks, from sea captains. He began publishing *Wind and Current* pilot charts of the North Atlantic in 1847, helping to reduce sailing times. He also proposed cooperative weather observation stations on land. Maury used two research vessels after 1849 to collect ocean temperature data and sea-floor samples. Data collected led to his publication of a bathymetrical map of the North Atlantic Basin in 1854, which depicted the sea floor between Yucatan and Cape Verde.

Maury wrote *The Physical Geography of the Sea* in 1855, recognized as one of the earliest oceanographic books, if not the earliest. Maury is widely considered to be "the father of oceanography". Several editions of *The Physical Geography of the Sea* were published, with later iterations taking on the title *The Physical Geography of the Sea, and its Meteorology*. With the exception of polar movement, Maury's 1855 depiction of global circulation appears to be remarkably close to current understandings. As important as his contributions were, however, many of his ideas rightly received criticisms on scientific grounds (e.g. tradewind control by magnetic forces).

Maury resigned and became commander of the Confederate Navy during the Civil War, then Imperial Commissioner for Immigration under Emperor Maximilian of Mexico. With the collapse of the Mexican Empire he moved to England, returning to the US in 1868 as professor of meteorology at Virginia Military Institute. His professorship there lasted until his death in 1873.

MEDIEVAL WARM PERIOD OR "LITTLE CLIMATIC OPTIMUM"

Histories in western Europe have long recognized a “post-Carolingian” climatic amelioration, approximately since the death of Charlemagne (AD 814), the first of the “Holy Roman Emperors” of the Middle Ages. Long-term indicators (sea level, glaciers, etc.) suggest it may have begun around AD 550, i.e. the “post-Roman Rise”. The expression “Little Climatic Optimum” (LCO), a term believed to have been coined by Bryson, is essentially synonymous with “Early Medieval Warm Epoch” (Lamb, 1977), our “MWP”, and also with the “Sub-Atlantic” (SA-2) Biozone of some palynologists.

Lamb (1977, p. 35) identifies a broad long-term “summer wetness index” (rising) and compares it with a “winter severity index” (falling), based on 50-year means. Both display a systematic lengthening of the upper westerlies’ wavelength across northern Europe, reaching its peak around AD 1100. A comparable warming swing marked the twentieth century, but is now complicated by anthropogenic pollution. The overall cycle would appear to be about 900 years. The two were separated by the “Little Ice Age” (LIA) from 1300 to 1750. The warmest interval of the MWP in Europe was 1150 to 1300. A study of Canadian borehole temperatures (mentioned by Lamb, 1977, pp. 104–105) suggests that the mean MWP was up to 1.6°C warmer than the average for the last millennium. An interesting humanistic comparison of the MWP and the LIA is made by Fagan (2000).

Sea-surface temperatures in the high latitudes were higher, and sea-ice coverage was appreciably reduced, thus introducing a positive feedback with the decreasing albedo of open water. These factors played an important role in the occupation of Iceland by Viking (Norse) colonists in the ninth century (AD 860). In the North Atlantic there were frequent summers with calm seas and easterly winds that greatly favored their particular type of ships (shallow draft and square sails). Eventually there came the explorations by Eric the Red and Lief Ericsson, the colonization of southern Greenland by the Norsemen (Dansgaard et al., 1975), and their brief settlement (AD 986) at Anse aux Meadows in Newfoundland (“Vinland”), the first European foothold in North America.

In the same MWP Arctic warming came a widespread development of Eskimo cultures, reaching as far north as Ellesmere Land (AD 900). From the Bering Sea they spread out to northern Alaska and in Siberia, as far north as the New Siberian Islands. In the eleventh century a new wave of migrants brought the “Thule Culture” that spread from Alaska to northern Greenland.

In North America native peoples spread northward up the valleys of the Mississippi and Missouri, bringing an agricultural economy into Wisconsin and Minnesota, where pollen studies have shown there were reliable summer rains (Griffin, 1961). Eventually they reached the northern Rockies and even Utah. The Hohokam people were meanwhile developing settled agriculturally oriented communities in New Mexico and Arizona.

In Asia the behavior of the Caspian Sea provides hydrographic evidence of the MWP climate. From the ninth to fourteenth centuries the rise of the Caspian by 18 m flooded vast areas of the

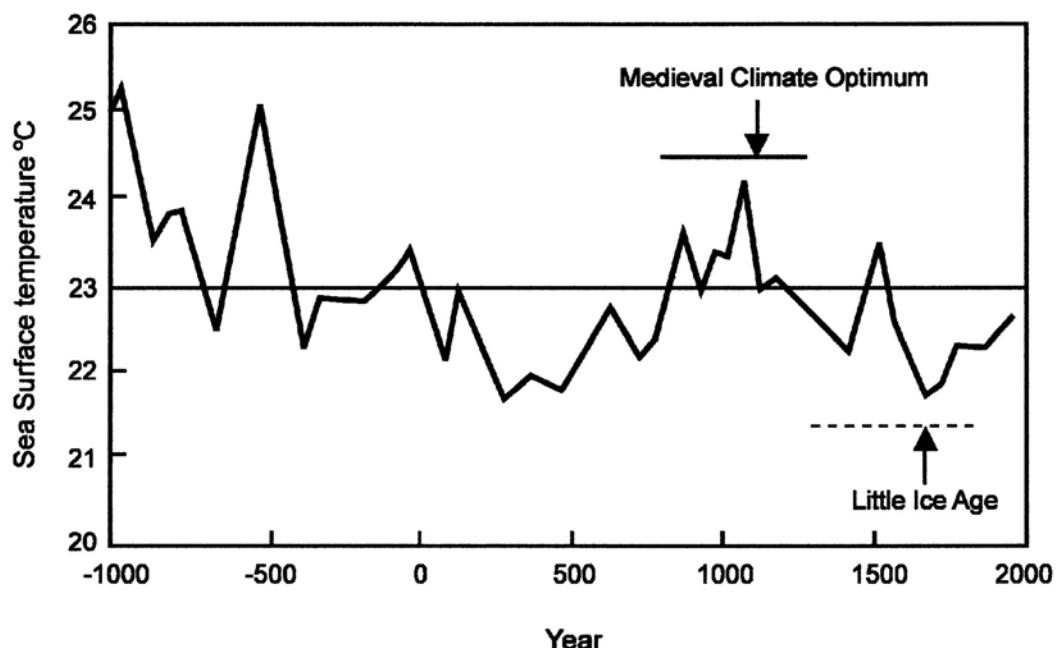

Figure M1 Trace of Sargasso Sea temperature, over 3000 years, based on benthic foraminifera oxygen-18 isotopes (adapted from Keigwin et al., 1994). The positions of the Medieval Warm Period and the Little ice Age have been expanded by the writer (R.W.F.) to conform to the other climatic proxies identified in the text.

Volga delta, reflecting a general increase in precipitation over northern Russia. Clearly this also reflects increased evaporation over the warming Gulf Stream and North Atlantic in general. The populations of central Asia showed a general expansion, but this reached a crescendo in the early thirteenth century, which launched the celebrated conquests of Genghis Khan and his "Mongol Hordes" (AD 1205–1225).

It was the exploration of central Asia in the first decades of the twentieth century that provided the database for Ellsworth Huntington's concept of climatic determinism (Huntington, 1924) that set up a great deal of controversy at a time when climate was assumed (by the "Establishment") to be a changeless aspect of the environment. A long sediment core obtained from Lake Saki (Crimea) illustrates the higher precipitation levels of the LCD also in southern Russia. The thickness of clay varves suggests a heavier rainfall at this time than for 2300 years before (Lamb, 1977, p. 408; Xanthakis et al., 1995).

The MWP warm cycle was registered also in Scandinavia and the Alps by glacier retreats (Röthlisberger, 1986; Karlén et al., 1995). Particularly in Sweden such glacier melts have been dated most precisely by sedimentation measurements in the corresponding glacial lakes. Worldwide response was marked by eustatic sea-level indicators including higher-than-normal beach ridges in many different regions, ranging from the Arctic coast of Alaska, to the coasts of the Gulf of California, and southwestern Florida (Fairbridge, 1992). The first radiocarbon dates of this high sea-level stage were obtained in Western Australia, on Rottnest Island, and became thus the "Rottnest Stage" (Fairbridge, 1961). In Scandinavia it is often referred to as the "Viking Stage" from the abundant relics displayed by the isostatic emergence around Stockholm and Uppsala. In northern Germany, the Netherlands and Belgium (Bennema, 1954), it is partly drowned by tectonic subsidence, but after correction its level was about 0.5 m above present MSL.

Inundation of low-lying coastal areas completely changed the geography in some areas. There was frantic dike building in northern Germany, the Netherlands, Belgium, France and England. The critical moment when man-made dikes were overtapped in particular storms is recorded by historic disasters when tens of thousands of people and livestock were drowned while farms and whole villages were destroyed (Bakker, 1957). In the lower Rhine valley river floods amplified the oceanic factors (Berendsen, 1995). Outstanding events included the flooding of the lower IJssel valley in the Netherlands with the creation of the Zuider Zee (1250/1251, 1287), and in Britain with the creation of the Norfolk Broads (Lamb, 1977, p. 433). Other areas were affected including western France, the Rhone and Po deltas.

The MWP ("Rottnest") rise of sea level had an important demographic effect inasmuch as it drove coastal dwellers inland, creating endless strife with the people (mostly farmers and pastoralists) already occupying the areas. In the southern Baltic (modern Poland and northeast Germany), southern Denmark and the Frisian belt in northwest Germany, postglacial tectonic subsidence amplified the eustatic rise of the MWP. An economic side-effect of the MWP sea-level rise was in the salt industry. During periods of low sea level, as during much of the Roman era, there were coastal salt pans in which sea-water ponds were organized in series to permit progressive evaporation. This was a major industry because common salt (NaCl) is an essential dietary condiment, as well as being in widespread demand for food preservation, leather tanning, etc. With the MWP rise, the

salt pans were repeatedly inundated and in many cases could not be expanded inland because of low bluffs, dunes or cliffs. Industrial disaster was alleviated by a wholesale shift inland to "fossil" salt deposits, mostly of Triassic or Permian age that had been long exploited since the Bronze Age or earlier. These deposits are known in Britain, Spain, France, Germany, Austria, Poland and Russia (Moores and Fairbridge, 1997). Many geographic names in central Europe incorporate the roots Salz, Sal, etc., e.g. Salzburg, Salzkammergut, Salzach, etc.

Metallic ores were extensively mined in mountainous areas of Europe when glaciers receded and exposed dry outcrop areas. With the ensuing Little Ice Age (after 1300), there were neoglacial advances and flooding of mines, leading to closures of the high passes in the Alps (Lamb, 1977, pp. 273–274).

Lamb (1967, 1977, pp. 276f.) was fascinated by the history of grape vines and viticulture in Medieval Britain, a country not particularly celebrated today for its home-grown wines. There were widespread vineyards south of latitude 53°N in Medieval times, some 500 km north of present-day limits in France and Germany. To quote from William of Malmesbury writing in 1150 (translated from Latin) of the vale of Gloucester "here you may behold highways and public roads full of fruit-trees, not planted, but growing naturally.... No county in England has so many or so good vineyards as this, either for fertility or for sweetness of the grape...." The export of British wines to France and Germany was a major factor in international trade, and even led to diplomatic friction. It should be recalled that in 1066 William of Normandy had led an invasion of Saxon Britain, at that time considered a remarkable prize. But then came the Little Ice Age, and soon after 1300, within 10 years the entire wine industry collapsed, the vines surviving only in rare cases under the protection of walled gardens.

The eastern parts of North America and Greenland seem to have shared equally with the European experience of the MWP, as did New Zealand and other parts of the southern hemisphere. However, much of the Pacific region, China, Japan and the western part of North America experienced the exact opposite. In Japan the mean blooming dates of the cherry trees of the imperial gardens in Kyoto have long been monitored as the harbingers of spring and the occasion of joyful festivals. For the MWP, however, the mean blossoming date was a full 10 days later than the millennial average, or 11 days comparing the mean for the twelfth century with that for the fifteenth century. To Lamb (1977, p. 400) "this suggests an eccentric position of the circumpolar vortex over the northern hemisphere in Europe's High Middle Ages, with the climatic zones persistently displaced north over the Atlantic sector and south over the whole Pacific sector and the Far East".

Archeomagnetic studies employing the paleomagnetic orientation of baked bricks or fireplace clays indicate that the North Magnetic Pole at the time lay in the eastern hemisphere (Bucha, 1984, 1988). Naked-eye sunspot observations and auroras (closely correlated to solar activity) were widely reported from China, Korea and Japan, which were then much closer to the North Magnetic Pole (Schove, 1983).

In the Mediterranean latitudes there were commonly heavy summer rains during the MWP. In central America these had an important role in bringing about the downfall of the Mayan civilization in Yucatan and elsewhere, where the maize (sweet corn) economy requires less humid seasons (Brooks, 1949), which needed to be nicely adjusted to their rainy seasons. Suffering repeated droughts, the population in the central valley of Mexico reached a minimum around AD 1000–1100.

The same delicate adjustment of seasons may also help to explain the wonderful surge in culture and religious buildings at Angkor in Cambodia, which reached a crescendo around AD 1000. During the Little Ice Age these structures were seasonally inundated by the rise of the Mekong and backfilling of Tonle-Sap that eventually buried the entire complex in 10 m or more of sediment.

Basing his estimates mainly on botanical proxies (palynology), Lamb (1977, p. 404) presented a comparison between the major climatic intervals for Britain of the last 10 000 years. The MWP discloses the warmest annual mean temperatures since the "Atlantic Biozone" 6000 years ago and 0.8°C above the warmest decades of the twentieth century. It was also wetter, except for the two summer months, July and August, which were characteristically dry, and thus good for grain harvesting, haymaking, thatching and so on (besides viticulture, noted earlier).

A series of northern hemisphere-oriented maps is presented by Lamb (1977, pp. 444/5) for selected centuries depicting troughs of the upper westerlies across Europe and the typical frontal depressions. For summer months during the MWP climax (AD 1000–1099), the mean polar jet swung from southern Greenland across northern Scandinavia to the Arctic shore of Siberia. Meanwhile the major frontal depressions radiated from northern Greenland to east-coast North America, from near Spitsbergen to Sicily, from near Lake Baikal to western China, and from Alaska to about Wake Island. For the same areas and season during the LIA (1550–1599) the polar jet ran across Scotland and southern Sweden, while the principal European frontal depressions ran from western Spain across the British Isles and the west of Norway.

For the winter seasons the MWP polar jet crossed Quebec and swung north of Iceland to the Barents Sea while its southern branch crossed Spain and the Mediterranean to Syria. The latter brought plentiful winter rains and prosperity to the kingdom of Palmyra and the peoples of Palestine and Mesopotamia. Five centuries later in the LIA the winter jet unified and crossed Iceland to head for southern Russia, bringing frequent droughts to the Middle East.

These mean jet trajectories help explain the antiphase relationships between climate proxies in western Europe and the Far East. The inferred position of the polar vortex caused swings to and fro, to eastern or western hemisphere; this appears to be analogous, on a greatly amplified (century) scale, with the "Atlantic Oscillation" (AO) which operates on a decadal basis. Biological proxies are very interesting. In central Europe history reports incidents of locust (*Locusta migratoria*) plagues in the drought summers as follows: ninth century, 8 seasons; tenth to twelfth centuries, none or next to none; fourteenth century, 15 seasons; fifteenth century, none; sixteenth century, 6; seventeenth century, one only; eighteenth century, 6; nineteenth century, 4 (Lamb, 1977). From recent data in North Africa Landscheidt (1987) believed there was a correlation between locust plagues and solar radiation.

Summary

1. The MWP, or LCD (Little Climatic Optimum), is a roughly 450-year climatic cycle, about AD 850–1300. Based on historical documentation this was a warming cycle in Europe.
2. Based on (a) CO₂ and temperature indicators in the Greenland ice cores, and (b) ¹⁴C flux (inverse) levels in the

dendrochronology, this interval is confirmed as a warming cycle, at least 1°C on average above millennial means.

3. Based on the astrochronology (using the 45.4 year resonance interval of the three major planets, Jupiter, Saturn and Uranus), there were three warm peaks: "Post-Carolingian" (AD 852), "Dunkerque-3" (944), "Viking/Rottnest" (1125). Two cool peaks (marked by extended interruptions caused by low sunspots and reduced solar emissions) occurred at the "Normanian" (peak: AD 1034) and the "Ottoman" (AD 1307).
4. In general, precipitation rose in step with the mean temperature oscillations, and glaciers tended to retreat. However, in exceptional areas glaciers showed temporary advances.
5. Mean sea level rose and fell eustatically and in more or less stable crustal areas it caused coastal retreat matching eustatic rise and vice-versa. However, in areas of crustal subsidence or rapid compaction, this relationship was reversed.
6. General atmospheric circulation (prevailing westerlies, trade winds, etc.) slackened, but in the sub-Arctic latitudes the 45-year summer storminess cycle persisted. With weakening trade winds, El Niño cycles became more important (but detailed monitoring is not available). However, the associated warm coastal currents reached farther south in Peru, and farther north in California.
7. The Gulf Stream and Kuro Shio were shifted northwards, with their characteristic ameliorating effects in maritime areas (increased oceanicity).
8. Sea ice coverage in the North Atlantic and Barents Sea decreased. Due to the longer ice-free seasons in areas of abundant sediment supply the beach ridge buildup was in places anomalously high.
9. In sub-Arctic lakes and swamp deposits the level of pine (or conifer) pollen rose in contrast to that of tundra species. Farther south the mixed forest boundaries moved northwards.
10. Equatorial lakes displayed little change in level, as did rainfall, but savanna (monsoon) boundaries tended to shift poleward by some hundreds of kilometers.

MEDITERRANEAN CLIMATES

The Mediterranean climate is distinct for its sunny and dry, mild-to-hot summers, and mild, wetter winters. The archetypal example of this climate is found in the area adjacent to the Mediterranean Sea – hence the name Mediterranean climate. Because its summer season is markedly drier than the other seasons of the year, it is sometimes referred to as the summer-dry climate type. The Mediterranean climate is unique amongst Earth's climates for its pronounced winter maximum of precipitation.

Locations

Besides its occurrence in the Mediterranean Basin, it is found on the west coasts of the continental landmasses, between 25 and 40 degrees latitude. Its proximity to the ocean/sea has a significant influence on its temperature, precipitation, and humidity characteristics – particularly in near-coastal areas. The largest example – in geographic area – of the Mediterranean climate, occurs in the area adjacent to the Mediterranean Sea. Other major areas with this climate type include the west coast of North America, from the Mexico–United States border northward to the Pacific Northwest region of the United States, and southwestern and southern Australia. Smaller examples of Mediterranean climate occur in South Africa (Cape Province) and central Chile. In North America the north–south-trending Cascade and Sierra Nevada Mountains limit the eastern extent of Mediterranean climate. In total, the Mediterranean climate type covers only a very small portion – just 2% – of the continental landmass.

Climate characteristics

The semipermanent subtropical anticyclones in the Atlantic and Pacific oceans are largely responsible for the unique characteristics of the Mediterranean climate type. The strong subsidence and resultant adiabatic warming that occurs on the eastern limb of these anticyclones, produces the pronounced and distinct summer-dry period of the Mediterranean climate. The subtropical highs also act to keep summer cyclones poleward of the region, further reducing the opportunity for precipitation in the summer months.

As an example of just how dry the summer months of the Mediterranean climate can be, Santa Monica, California – located toward the equatorward margin of this climate type in North America – has never recorded more than a trace of precipitation during the months of June, July, and August (Oliver and Hidore, 2002). Winter is the distinctly wetter period for the Mediterranean climate type because the subtropical anticyclones sag equatorward, allowing midlatitude cyclones embedded in the westerlies to bring rain to the area. In Perth, Australia, 85% of the annual precipitation comes during the winter half of the year. In Istanbul, Turkey, the 6 winter months of the year account for 70% of the precipitation that falls annually. San Diego, California, receives 90% of its total precipitation for the year during the 6 months from November through April (Oliver and Hidore, 2002).

Total annual precipitation amounts range between 40 and 80 cm, and characteristically increase poleward because of the diminished influence of the subtropical anticyclones, and thus greater frequency of penetration of midlatitude cyclones. Precipitation totals also increase in the interior highlands as orographic precipitation falls on the windward slopes of mountain ranges. In southern California, Los Angeles and San Diego average 37 and 26 cm of precipitation a year, respectively. However, in the adjacent mountains, annual precipitation totals are four to five times those amounts – with most of the precipitation falling as snow (Lydolph, 1985). Summers in the Mediterranean Basin are not as dry as they are along the west coast of North America because of the greater instability of the atmosphere in the area.

While the winter half of the year is the wetter and stormier half, the amount of precipitation that falls in any given year is quite variable. Moreover, precipitation events are generally shortlived and the period between events is characterized by fair weather. Thus, even during the winter months, pleasant conditions predominate. One caveat to this rule, however, is required along the California coast in El Niño years. During El Niño events the jet stream over the Pacific steers storms into California, bringing wetter than normal conditions to the region.

Along the west coast of North America, as winter progresses the polar front gradually moves southward, bringing precipitation to the more equatorward areas by late in the winter season. Maximum precipitation occurs during December in Seattle and Portland, in January in San Francisco, and in February in Los Angeles and San Diego (Lydolph, 1985). In the highland areas away from the coast, strong thunderstorms can occur and copious amounts of rain may fall in a short period of time – leading to flooding and hazardous mass wasting events.

Sea breezes and coastal upwelling moderate coastal temperatures in the summer. Daily maximum temperatures rarely get much higher than the low 20s (Celsius). In the winter, because of the moderating influence of the ocean, temperatures remain quite mild along coastal areas. Inland however, temperatures

are warmer in the summer and colder in the winter. Sacramento, California, just 120 km to the northeast of San Francisco, has an average temperature for the month of July that is 9°C higher than that of San Francisco (Ahrens, 2002). Inland areas may even experience frost on occasion – which puts economically valuable citrus and other crops at risk.

Coastal areas adjacent to the Mediterranean Sea are warmer than their coastal counterpart in North America because upwelling does not occur in the Mediterranean Sea. Upwelling is quite strong, however, off the California coast during the summer months of the year. Air temperatures all along the length of the California coast, in July, are some 10–11°C below normal for their respective latitudes (Lydolph, 1985). Upwelling tends to be strongest just west of San Francisco Bay, making the area one of the coolest along the entire west coast of North America in the summer months. As moisture-laden air from the Pacific passes over the very cool water close to the coast in the San Francisco Bay area, it is cooled to its dewpoint and fog is produced. This fog is then advected inland. San Francisco, California, is renowned for its numerous days of fog each summer. Fog is common elsewhere along the California coast as well.

Inversions

The subsidence and adiabatic warming that occur on the southeastern edge of the Pacific subtropical high, in the summer, produce strong inversions in southern California's two largest cities, Los Angeles and San Diego. The base of the inversion typically lies only just a few hundred meters above sea level (Lydolph, 1985). Convection from surface heating in the moist marine layer below the inversion mixes emissions from stationary and mobile sources upward, and concentrates them just beneath the base of the inversion, where they collect and form a reddish-brown haze that is a signature of highly polluted urban atmospheres. Mountains to the north and east of the city do not allow for the horizontal dispersion of air, thus letting pollution build to very dangerous levels. Los Angeles, because of its geography and large number of automobiles, is infamous worldwide for its exceptionally high levels of air pollution.

Because inversions are such a common feature of Mediterranean climates, high levels of air pollution are characteristic of many large cities in Mediterranean climates. During the winter months the inversion is not as pronounced because of the equatorward movement of the Pacific High. Moreover, when migrating cyclones pass through the region they dramatically alter the thermal structure of the atmosphere and break down the inversions.

Summary

The abundant warmth, sunshine, high number of rainfree days, and cool sea breezes in coastal areas, make the Mediterranean climate type a favorite vacation destination. Its long, dry summers, however, do not allow for the growth of lush vegetation. Instead, scrubby, low-growing woody plants and trees predominate. In North America this type of vegetation is referred to as chaparral. In the Mediterranean basin such vegetation goes by the name *maquis*. Citrus, grapes (for wine-making), and other fruits and vegetables are grown in Mediterranean climates. Irrigation of these crops is required, however (Lydolph, 1985).

MICROCLIMATOLOGY

Microclimatology, the scientific study of microclimates, is concerned with the atmospheric layer that extends from the surface of the Earth to a height where the effects of the features of the underlying surface can no longer be distinguished from the local climate (American Meteorological Society, 2000). Microclimates vary in response to, and in turn are superimposed upon, larger-scale climates (the mesoclimate and macroclimate). Microclimates span a spatial scale (Figure M2) that includes the envelope of air that surrounds an insect or a spore on a plant leaf to the climatic conditions on a hillslope that permit or preclude the growth of specialty agricultural crops such as grapes for wine production. Hence, the horizontal extent of microclimates is often not rigidly defined, although several millimeters to 1 kilometer is often employed (Oke, 1987). Local climate or topoclimate terminology (Oliver and Hidore, 2002) is often employed between microclimates and mesoclimates to represent spatial scales between several hundred meters and 10 kilometers. Microscale atmospheric phenomena usually have temporal spans of less than a few minutes. Microclimate phenomena and their cumulative interactions, feedbacks and impacts may range from seconds to seasons. The thickness of the air layer of concern in microclimatology is also not rigidly defined (Figure M2). Sometimes it can extend from below the surface (the soil or substrate regime is often considered) to a height where recognizable microclimatic signatures in the atmosphere become essentially indistinguishable. During the night this might extend into the atmosphere for several hundred meters and, during the daytime, for over one kilometer. Usually, a much thinner air layer, in close proximity to the surface, receives particular attention. Another important aspect in the definition of microclimates and their relevance and importance is the perspective that is brought by those observing, studying or utilizing them. Human perspective and its acknowledged subjectivity often play a profound and fundamental role in delimiting the spatial and temporal scales of a microclimate as well as the scope of the controlling mechanisms.

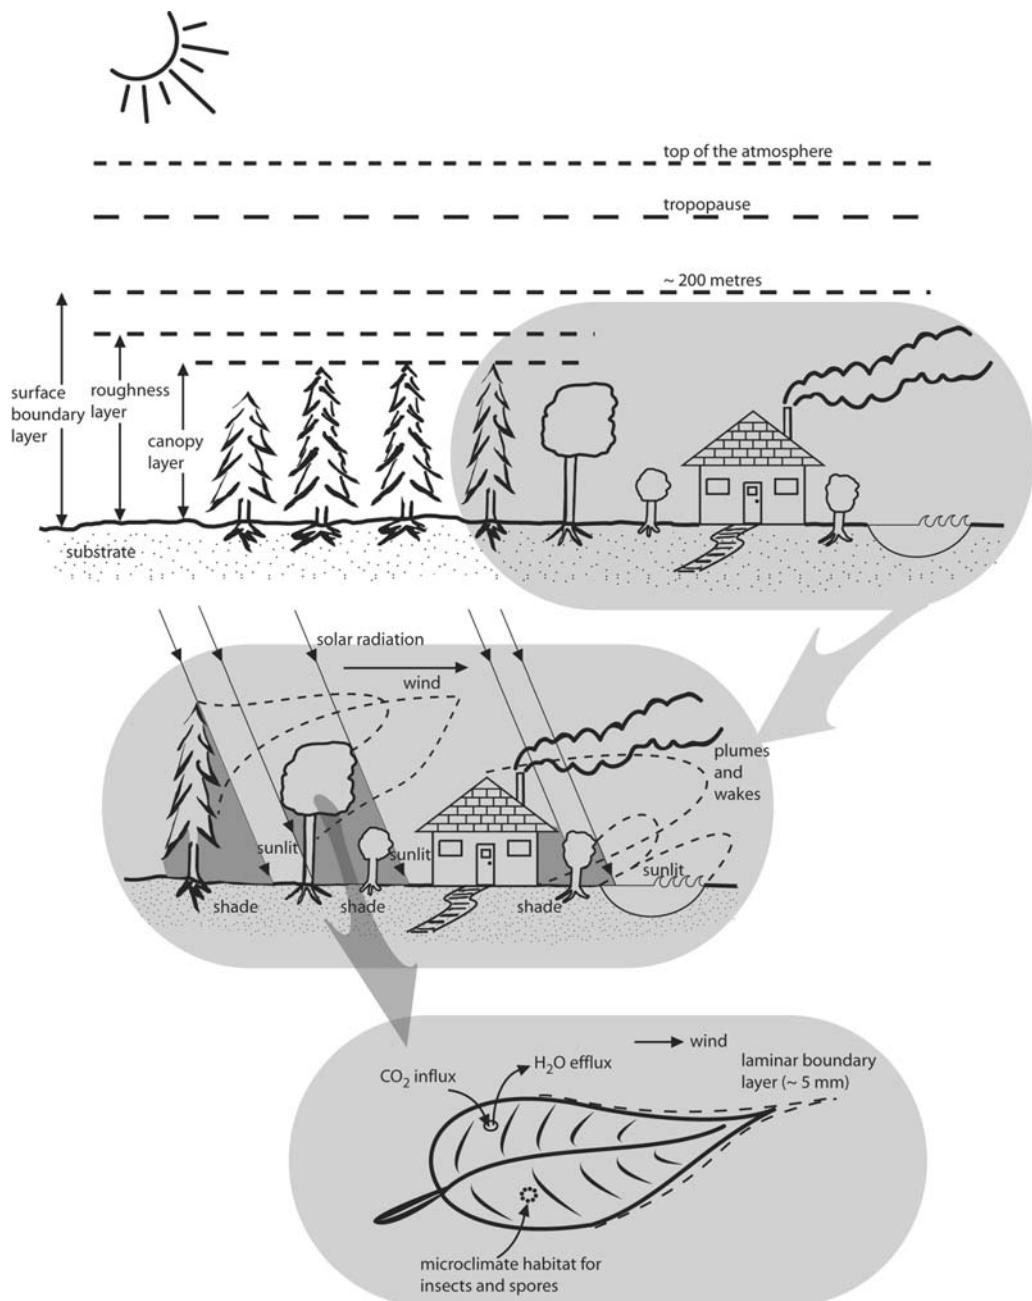

Figure M2 Schematic representation of a vertical cross-section of the Earth's atmosphere. Microclimates extend from the surface, or just below it, to a height where the effects of the surface features cannot be distinguished from the local climate. Numerous microclimates (forest, forest canopy, horticultural plants, building, lake edge, soil surface, insect habitat and others) can be readily identified.

Whereas microclimatology is a subdivision of climatology based primarily on spatial scale attributes, microclimates themselves are often subdivided to consider specific surfaces or habitats. Such subdividing, for example, gives rise to: the microclimatology of plant and animal environments in which the climatic resources for individuals and communities is examined (Bonan, 2002; Jones, 1992; Lowry and Lowry, 2001; Rosenberg et al., 1983; Stoutjesdijk and Barkman, 1992); agri-

cultural microclimatology (Rose, 1966) and forest microclimatology (Lee, 1978) that focus more specialized treatments of particular surface types; forest canopy microclimatology that details biophysical and biochemical processes in foliage environments (Lowman and Nadkarni, 1995; Mynemi and Ross, 1991); urban microclimatology that focuses on human habitation and examines cities, building structures and materials (Brown and DeKay, 2001; Lowry, 1988), air quality (Bell and

Treshow, 2002) and landscape design (Brown and Gillespie, 1995). Additionally, microclimate investigations of many novel environments have been undertaken: cryptomicroclimatology which examines the microclimatology of confined spaces; the microclimatology of cultural heritage which examines the influence of atmospheric variables on cultural objects in both outdoor and museum environments (Camuffo, 1998; Thompson, 1990); animal microclimatology which examines the interrelationship between animals and microclimate variables in both natural and artificial environments (Albright, 1990; Johnson, 1987; Scientific Committee on Animal Health and Animal Welfare, 1999; Unwin and Corbet, 1991). Treatments on microclimatology can be found in general volumes on the atmosphere (for example Oliver and Hidore (2002) and many others) or for specific environments (i.e. mountains (Whiteman, 2000)), in specialized volumes that commence with first principles and cover both theory and application (Campbell and Norman, 1998; Geiger et al., 1995; Lowry and Lowry, 1989; Monteith and Unsworth, 1990; Oke, 1987; Rosenberg et al., 1983; Stoutjesdijk and Barkman, 1992) and in presentations for more focused readerships (i.e. microclimate and spray dispersion (Bache and Johnstone, 1992); extreme heat waves, societal response and human mortality (Klinenberg, 2002); and countless scientific journal publications). Additionally, other treatments have focused on the synthesis of microclimate information for various landscape types within political borders (Bailey et al., 1997).

Human recognition of, and influence by, climate phenomena predate recorded history (Calvin, 1991, 2002). Early human adaptation to the environment, migration and the utilization of resources for both survival and progress attest to an interrelationship with microclimates that parallels the long course of civilization and societal development (Brown, 2001; Butzer, 1971; Jones et al., 2001). Cumulative human impacts across a range of spatial scales have led to marked changes in the Earth's surface, atmosphere and in the concomitant atmosphere-surface interactions. Activities such as deforestation, agriculture, fossil fuel and biomass burning, industrialization and transportation, which occur at the microscale, have led to documented changes that are now being realized at local, regional and global scales (IPCC, 2001a,b,c). In turn, mesoscale and macroscale influences then impact the mosaic of microclimates that blanket the Earth's surface. Although human-climate interaction has been long recognized, the first major synthesis of microclimate research was not published until 1927. *Das Klima der bodennahen Luftsicht* by Rudolf Geiger (1894–1981) was a pioneering contribution, and four German editions appeared before *The Climate Near the Ground* was published in English (Geiger, 1966). It was the most exhaustive work on microclimatology until that time, and a modern edition (Geiger et al., 1995), to celebrate the 100th

anniversary of Geiger's birth, now carries the volume's influence into the twenty-first century. Since the end of World War II, considerable advancements in the study of the Earth's environment, and associated with this microclimatology, have been achieved. A number of interrelated factors have played significant roles: the widespread quest for scientific understanding of the environment and the atmosphere has led to substantial increases in overall knowledge; the theoretical understanding of the air layer in contact with the surface, in terms of energy and mass exchange, has been greatly advanced; the development, refinement and extensive application of instrumentation, data recording and computational technology; the deployment of extensive spatial monitoring networks and the widespread availability of data (i.e. worldwide web and many other sources); the lure of and the opportunity to research unknown, challenging and remote locations on the Earth's surface; and the application of remote sensing technologies across a range of spatial and temporal scales for documenting patterns and trends (Kramer, 2002). Advancements have come from many persons in many countries, and contributions can be viewed as examples of interdisciplinary achievements with much microclimatic research being reported in agronomy, architecture, ecology, engineering, forestry, hydrology, physical geography, zoology and other communications.

The creation and control of microclimates

Microclimates arise in response to the external forcings of energy, precipitation and wind, and the magnitude of these forcings establishes the boundaries and character of the microclimates found. Transformations in microclimates arise from changes in the forcings and changes in the responses that occur at the surface to the forcings. Hence, a mosaic of microclimates is readily created over short distance scales.

The surface of the Earth is warmed by solar energy during daylight hours, swept by winds that are driven by interlocked large-scale circulation (macroclimates) and synoptic systems (mesoclimates), and is moistened by precipitation that arrives in either liquid (rain) or solid (snow) forms. Some of the inputs that create the climate of a surface are cyclical in character, for example the diurnal and seasonal variations in solar energy receipt and the associated thermal regimes. Others are quasi-periodic or perhaps close to random in character, for example the seasonal movement of storm systems, and the spatial and temporal occurrence of precipitation. For any geographical setting a general climatology will be created from the integrated influences of latitude, altitude, continentality and location in relation to mesoscale synoptic flows. Within this, an integrated blend of radiative, aerodynamic, thermal and moisture attributes establishes the microclimate for all surfaces (Table M3).

Table M3 Surface attributes important in the creation of microclimates. Adapted after Oke (1997)

Radiative	-Surface albedo, surface emissivity, surface temperature, geometric positioning of the surface and the surrounding environment that will influence radiant energy receipt and loss
Aerodynamic	-Surface roughness length, zero plane displacement, presence of elements upwind that obstruct or channel wind flow
Thermal	-Thermal conductivity, heat capacity, thermal diffusivity, thermal admittance
Moisture	-The surface character (vegetation, soil, etc.) that impacts plant transpiration and/or surface evaporation; the moisture status of the substrate and its availability for evaporation and/or transpiration

Solar radiation (in the wavelength range 0.15–4 micrometers) that reaches a surface has both direct beam and diffuse components. A portion reaching the surface is reflected, and the reflected solar radiation is dependent on the surface albedo. The

result is net solar radiation (Figure M3), and this provides a direct contribution to surface heating. The albedo is an explicit surface control of the microclimate. Albedos vary from about 5–10% for water (midday), coniferous forest and dark soils, to

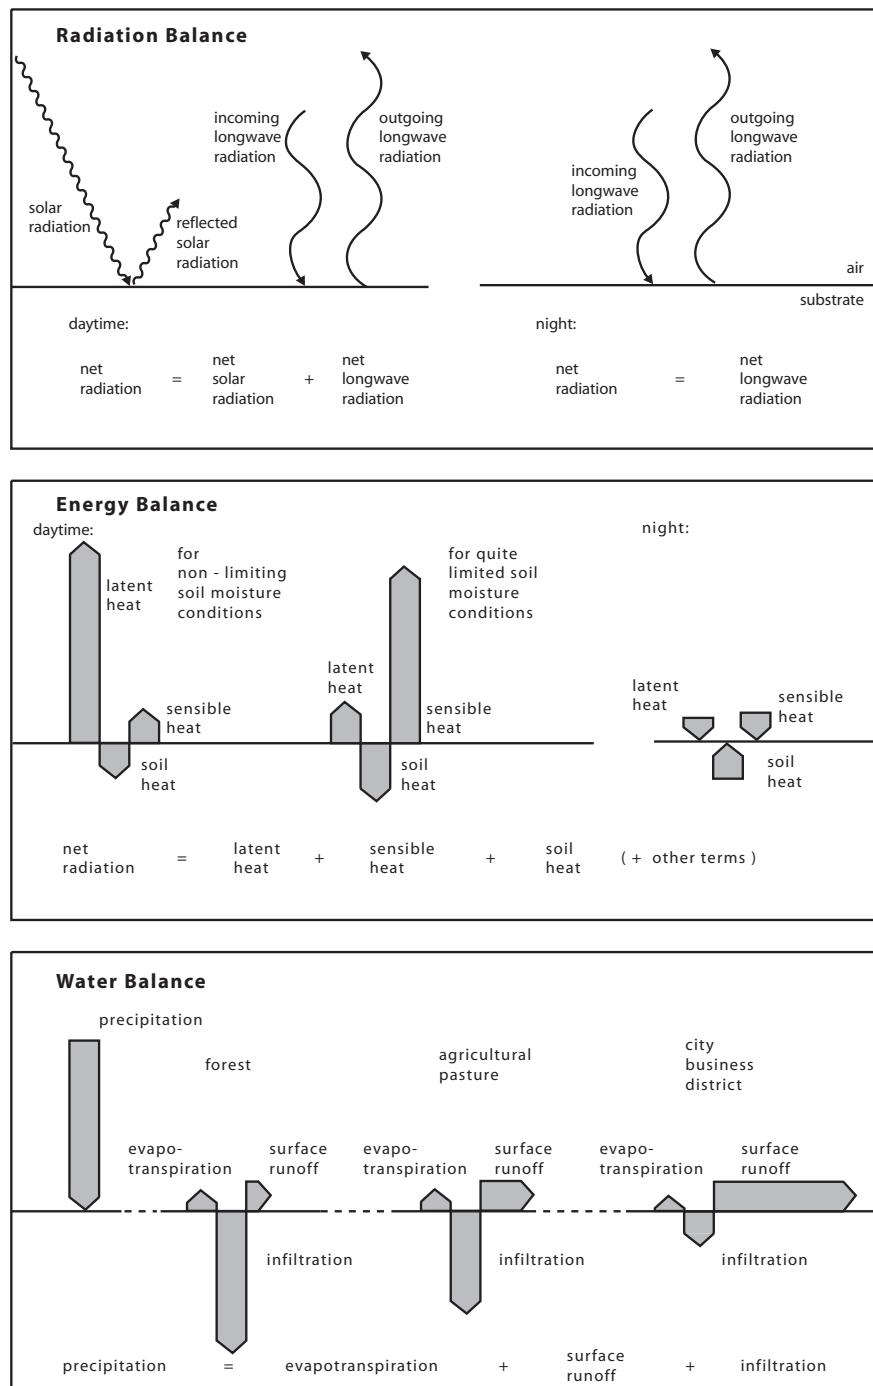

Figure M3 Schematic representation of the radiation, energy and water balances. The radiation balance is presented for both daytime and night periods. The energy balance is presented for both daytime and night periods, with the role of non-limiting and quite limiting surface moisture availability illustrated for daytime periods. For the water balance the response to precipitation input is illustrated for three distinct surfaces (forest, agricultural pasture and a city business district).

20–25% for agricultural crops and other vegetated surfaces, to 80–90% for fresh fallen snow. For three-dimensional surfaces, such as plant canopies, radiation is transmitted from the upper plant canopy toward the ground surface, with absorption and reflection of radiation by the foliage elements occurring. Solar radiation also penetrates into water bodies, snowpacks and glacier ice. Of the solar radiation reaching the Earth's surface, approximately 50% is in the visible spectral range. This also coincides with the approximate wavelength range that plants can biochemically harvest for photosynthesis. All elements in the Earth–atmosphere system also emit radiation, but at longer wavelengths (approximately 5–100 micrometers). The surface is both a recipient of the longwave radiation that is emitted by the atmosphere, as well as an emitter of longwave radiation to the atmosphere. Longwave radiation is governed by the Stefan–Boltzmann law, where the radiation is a function of the emitting surface's temperature raised to the fourth power and its emissivity. As Earth surface temperatures usually exceed the radiating temperature of the atmospheric column, the surface's net balance of longwave radiation is usually an energy loss. The net balance of solar and longwave radiation is known as net radiation (Figure M3). Daytime microclimates respond to the combined influences of solar and longwave radiation. At night the net radiation is solely a longwave radiation regime. The influence of diurnal and seasonal cycles in radiant energy input is pronounced in most microclimates (Figures M3 and M4).

The radiant energy surplus or deficit at the surface obeys the law of conservation of energy through the energy balance. In the most simple of treatments (Figure M3), net radiation is dissipated into latent heat, sensible heat and substrate heat. During the daytime, sensible and latent heat are energies employed in the convective transfer of heat and water into the air. Substrate heat is the energy lost by conduction into the underlying surface. The partitioning of available energy is primarily affected by surface moisture (Figure M3). At night, heating from the atmosphere and condensation often lead to surface-directed sensible and latent heat exchanges, although these are modest when compared to the magnitudes of the daytime regime. The substrate often serves as an energy source at night as conductive energy can flow toward the surface. Vertical profiles of temperature and humidity demonstrate the continuous coupling that exists between the surface and atmosphere in terms of energy and mass exchange (Figure M5). Simple treatments of the energy balance can be readily adapted to incorporate other factors. These could include the energy stored in surface vegetation, the energy used by plants in photosynthesis, the energy used in snow melt, the energy stored in the water bodies such as lakes, the energy contributed by anthropogenic sources, the horizontal transfer of sensible and latent energy from upwind environments, and the lateral transfer of energy to downwind environments. All of these can play significant roles in the creation and character of specific microclimates.

The input of precipitation to the surface and its routing is governed by the hydrological cycle. In the water balance the precipitation to the surface is lost to the atmosphere through evapotranspiration, to surface runoff by horizontal flow and to infiltration. The infiltrated water replenishes surface soil storage and thereafter the drainage flows horizontally or vertically into fluvial or groundwater systems. The character of the surface and substrate plays a pronounced role in the routing of precipitation (Figure M3). Precipitation input is not continuous, and the amount and timeliness is critical to the nature of the hydrological cycle across the range of spatial scales. Additionally,

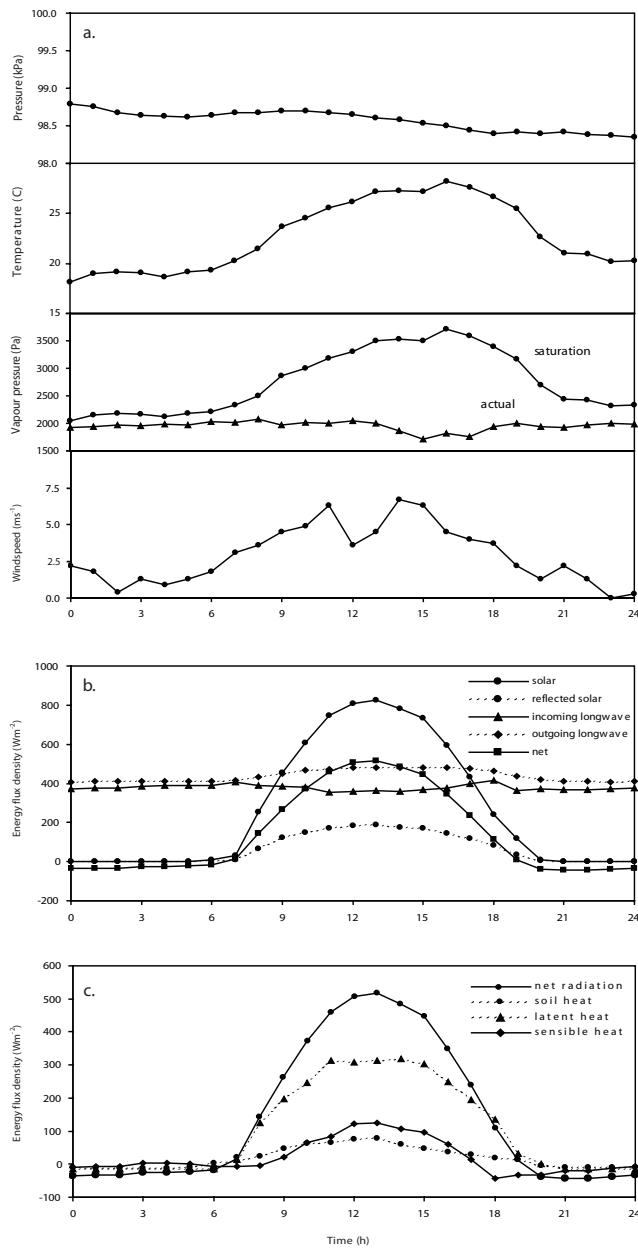

Figure M4 The diurnal trend of midsummer atmospheric variables monitored at a meteorological station and the radiation and energy balance components of a cropped surface located nearby. The day was almost cloudless and available moisture to the surface becomes slightly limiting during the afternoon period.

precipitation falling as snow may well introduce important temporal lags in the response of the hydrological system. The water balance is closely linked with the energy balance, as the transpiration from plant surfaces and evaporation from the soil are the water mass volumes represented in the energy balance by latent heat, the energy utilized in the change of phase of water from liquid to gaseous form. Analogous to the water balance, biogeochemical cycles can be defined and studied for various microclimates, with a prime example being carbon dioxide.

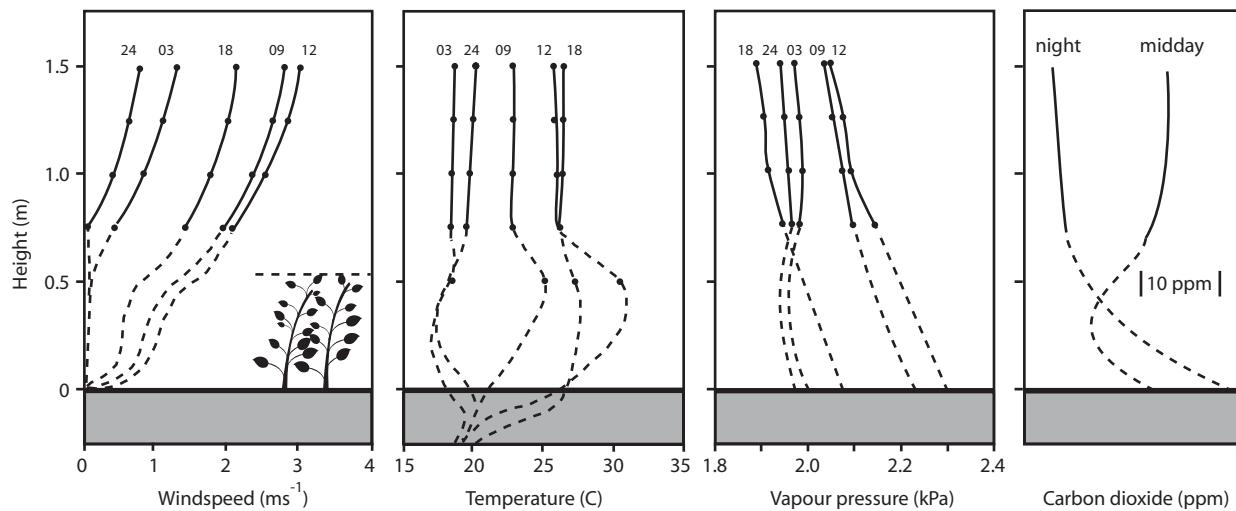

Figure M5 Hourly average vertical profiles of windspeed, temperature, vapor pressure and carbon dioxide for the near-surface layer for selected periods throughout the day (03, 09, 12, 18 and 24 hours). The profiles were measured on the day documented in Figure M5 (cropped surface in midsummer). Profiles within the plant canopy are denoted by dashed lines.

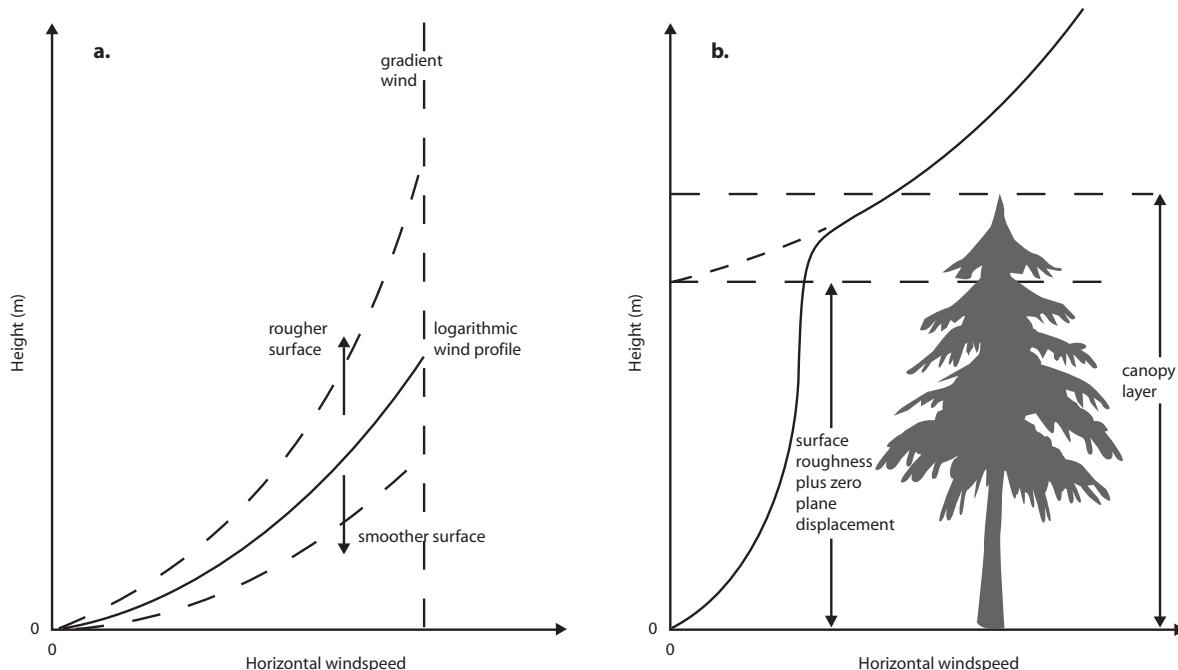

Figure M6 (a) The characteristic profile of windspeed near the Earth's surface when thermal enhancement or suppression is absent. Increasing surface roughness, from smooth (surfaces such as snow, calm water and desert sand) to rough (forests, cities), changes the profile of windspeed in the near surface layer. (b) The profile of windspeed through a plant canopy. For such three-dimensional surfaces a zero plane displacement must be subtracted from the height scale to preserve the characteristics of the logarithmic wind profile.

The flow of air above the surface, from regions of high pressure to low pressure, illustrates the combined influence of driving and steering forces. As the surface is approached, the wind velocity is reduced in response to friction effects. When no thermal gradients are present, the height variation of windspeed above the surface is logarithmic in character (Figure M6). Smooth surfaces such as water, snow and desert sand are relatively windy, but the effect of the surface extends only a short

distance above the surface. Rough surfaces such as tall forests and cities generate more turbulence and affect a much deeper layer of air. The surface roughness parameter denotes the theoretical height where windspeed goes to zero, and it is typically 10% of the average surface element height (Figure M6). If a vegetation canopy covers the surface, the effective surface height is adjusted upward to account for this. This zero plane displacement is approximately 70% of vegetation height (Figure M6).

The fundamental property of flow for a surface is momentum. The momentum aloft is extracted from the flow by the friction effects of terrain roughness. Mixing of air by turbulence results in the creation of eddies. These parcels of air are of varying sizes and, at any instant, may exhibit almost random motion. Each eddy carries the characteristics of heat, mass substances and momentum. The vertical profiles of temperature, water vapor, other gases and windspeed exhibit fundamental linkages between the surface and the atmosphere (Figure M5). Turbulence in the lower atmosphere arises from buoyancy forces (free convection) and mechanical forces (forced convection). Departures from isothermal atmospheric conditions create changes in stability; these demonstrate profound roles in turbulent mixing. During daylight hours, unstable conditions predominate with strong lapse conditions existing (temperatures decreasing with height). Turbulence and, therefore, mixing is enhanced by buoyancy. At night, stable atmospheric conditions prevail with inversion conditions existing (temperatures increasing with height). Buoyancy is minimal and mixing is suppressed.

Few surfaces on the Earth are horizontal and smooth, and microclimate variation arising from topographic influence is commonplace. Topography transforms patterns of solar radiation, temperature, wind and precipitation. North, south, east and west slopes of hills or mountains, or the sides of valleys, can have markedly different microclimates (Figure M7), with solar energy receipt and wind patterns being major contributors to these differences. In northern midlatitudes, south-facing surfaces receive more solar radiation than do other orientations. North-facing slopes may receive no direct beam solar radiation for months, depending on latitude, declination of the sun, slope and orientation of the surface and slope position (valley bottom for example). In rugged terrain, adjacent topographic features may cast shade for portions of the day or year, and some places (valleys and steep poleward-facing slopes for example), may never receive direct beam solar radiation. As a result, each facet of the terrain has a unique radiation balance and a microclimate that differs from adjacent facets (Figure M7).

The contour of the landscape also creates winds that are superimposed on large-scale circulation patterns. Anabatic winds develop along slopes that have been heated by solar radiation. Associated cloud development throughout the daytime hours often provides a visible account of the intensity of the upslope flow. These winds are best developed during anticyclonic conditions, and when coupled with subsiding air in the valley bottom, a larger local circulation system is realized. Nighttime cooling results in an increase in the density of surface air on slopes and downslope katabatic (gravitational) flow results. Such topographically induced patterns of air flow can result in marked differences in near-surface temperature. In spring and fall, frost pockets can develop where cold air drainage is impeded by topographic features (valley bottoms, earthen berms, walls of buildings, rows of trees). In these pools of cold air, near-surface air temperatures at night may be many degrees less than temperatures a very short distance away. In valleys, nocturnal temperature regimes generally increase upslope as the impacts of the frost pockets diminish with elevation. Above the height of these zones of relative warmth, adiabatic cooling prevails.

Precipitation onto any surface is determined by regional synoptic conditions, the slope and aspect of the surface, and the nature of the raindrops themselves. Changes in the trajectory of raindrops from the vertical results from wind effects, and small raindrops with lower terminal velocities are most affected. Locations with higher wind velocities have more perturbed pre-

cipitation patterns than protected sites. The intensity of precipitation at the surface depends on the angle of the wind-induced trajectories relative to the aspect and slope of the surface. A surface that is parallel to the trajectory of the raindrops, for example a wall during calm conditions, may receive no precipitation. Maximum intensities will be received on a surface that is perpendicular to the raindrop trajectory. Hence, in complex terrain and around architectural structures, significantly different precipitation amounts can occur on various slopes, and the differences can be accentuated or moderated over long periods. In winter, snow is subject to resuspension, transport and redistribution by wind. Snow accumulation zones do not necessarily coincide with the original pattern of the snowfall. Skillful design and positioning of snow fencing is a prime example of microclimate modification. The reduction of wind and turbulence around the barrier can enhance snow deposition and minimize the drifting across nearby transportation corridors.

Examples of microclimates

Examples of microclimates are plentiful and contribute significantly to the makeup of the environments that surround us: the warming of one's face as it becomes aligned with the sun's beam on a cool morning; the seeking of shade by animals and people as a respite from the harsh afternoon sun; the distinct mosaic in surface temperatures experienced during summer outings to the beach or seaside; the creative use of sunlight and shade areas for ornamental plants; the cradling of snow by conifer branches in forests; and the fresh-fallen snow in open clearings that is swept into drift patterns that are repetitive from storm-to-storm and from year-to-year. Recent advancements in the study of microclimatology have sought not only to observe the features of microclimates, but also to investigate and explain the forcings and surface responses that give rise to the distinctiveness that is found over short distances.

With high solar energy, the microclimate energy forcing in tropical forest ecosystems (Sluiter and Smit, 2001) is considerable (Figure M8a). In such environments most of the solar radiation is absorbed by the upper levels of the forest canopy, and energy availability near the forest floor is very much reduced. In adjacent forest clearings (gaps), available energy is quite abundant in the near-surface layer. Diurnal temperature and windspeed observations document the distinct differences between these forest and gap environments (Figure M8b,c,d). Additionally, the size and nature of the gaps themselves play determinate roles in the microclimates created. An abundance of solar radiation and the availability of surface moisture provide microclimate resources for forest regrowth along the gap edges and within the gaps themselves. Ecological changes in response to microclimate resource availability will not only occur, but will in turn play an active role in modifying the surface microclimates.

The spatial pattern of surface thermal and moisture regimes is usually quite complex, and the transition across the boundary between different surfaces can display sharp discontinuities. Soil temperature and moisture transects across an open clear-cut in a midlatitude forest document both of these aspects (Figure M9). Variation within the forest and clear-cut surface regimes is considerable. Generally, soil temperatures are higher in the clear-cut than the forest, and differences are enhanced during cloudless conditions. The moisture of the uppermost surface materials is lower in the clear-cut due to the strong drying regimes present when compared to the shadier forest floor environment. Transitions across the borders of the clear-cut

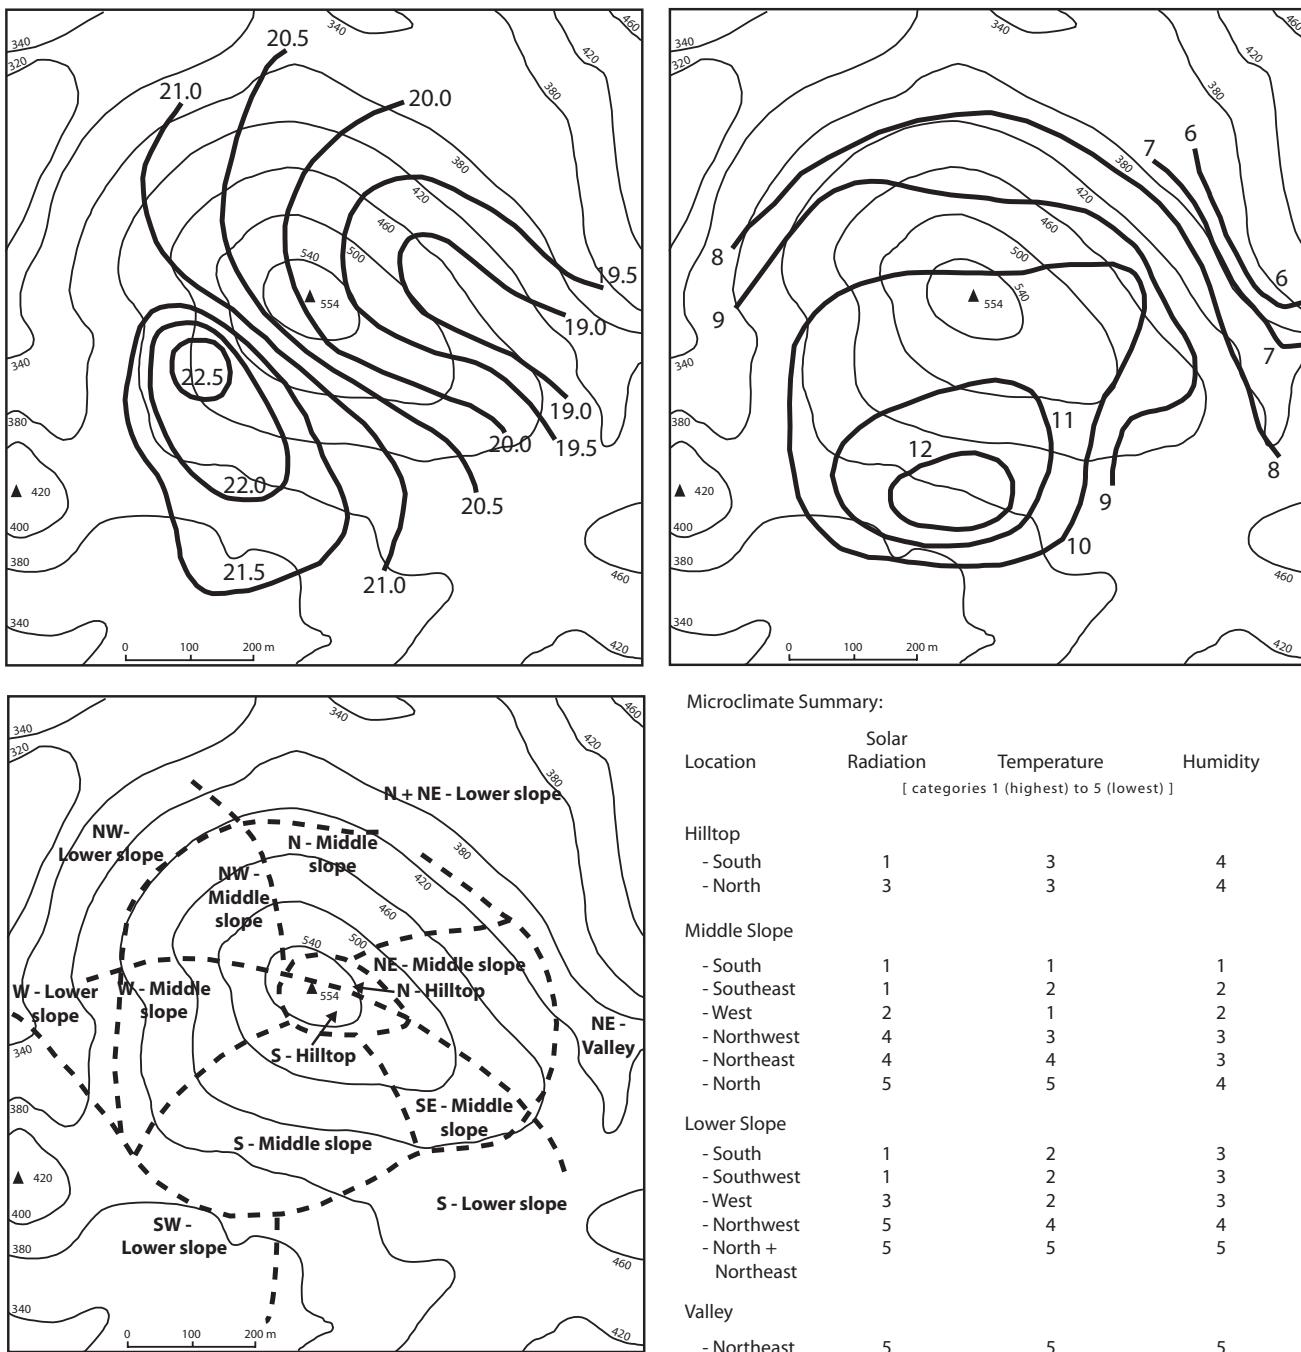

Figure M7 Topographic control of maximum and minimum near-surface air temperature for forested terrain in Germany. Isotherms are based on observations made during a series of sunny days in the month of June. Solar radiation, temperature and humidity regimes for each topographic zone are categorized from 1 (highest values) to 5 (lowest values). Adapted after Geiger (1961).

illustrate the role of south-facing and north-facing orientations in radiant energy receipt, with the latter demonstrating a sharper gradient of change.

Caves provide a means for both the assessment and interpretation of paleoclimates. Cave sediments have yielded significant archeological finds, and artistic renderings on the walls of

caves provide profound insights into early humans and their activities. In a cave with a single opening (Figure M10), the cave entrance area can be sunlit and the air relatively hot. Upon entry, passageway narrowing diminishes the effectiveness of turbulent mixing, and the temperature cools and the air becomes moister. Further from the entrance, the temperature

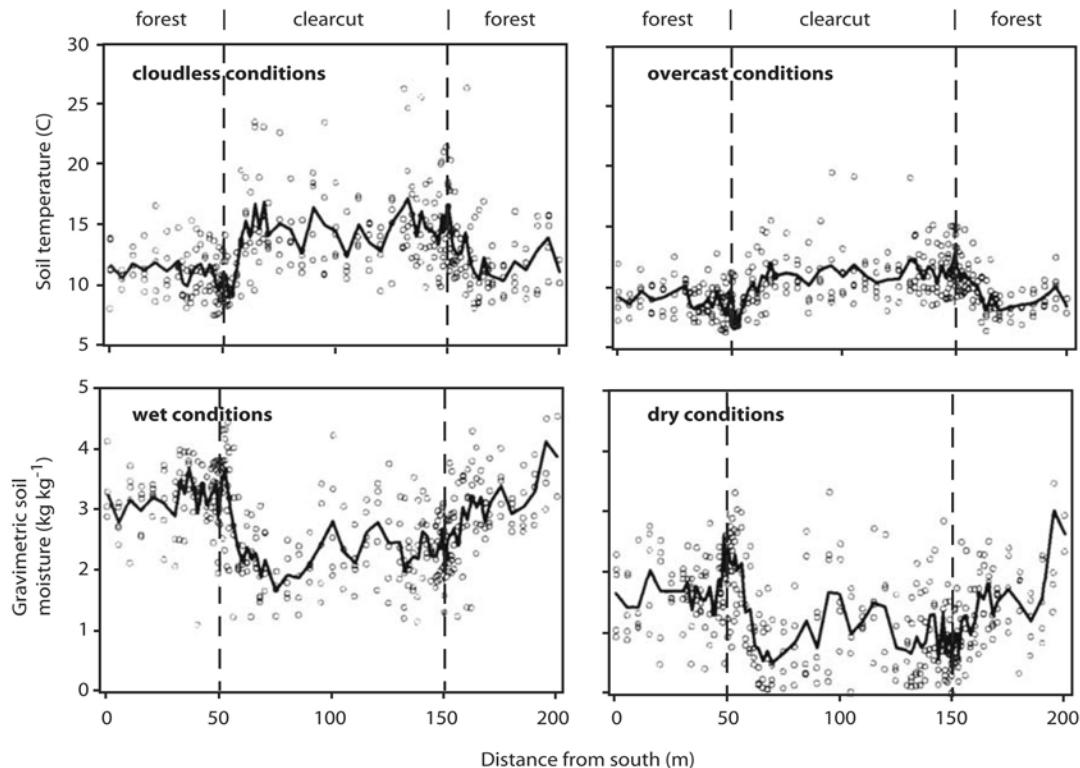

Figure M9 Transects of soil temperature and surface moisture across a 1 hectare clear-cut opening in a subalpine fir and spruce forest in British Columbia, Canada. Both average transect trends and individual site observations are presented. For soil temperature (20 mm below the surface), a comparison between cloudless and cloudy conditions is also displayed. For surface layer moisture a comparison between wet and dry conditions is exhibited. Adapted after Redding et al. (2003).

falls to near-constant values and the humidity approaches saturation. For caves with multiple openings, air circulation may develop on diurnal or seasonal timescales. Such unique crypto-microclimates have long been used by humans for shelter and security. Knowledge of such subterranean environments also has importance in understanding animal habitats, the characteristics of past and present human subsurface or hillslope dwellings, and the nature of the thermal and humidity regimes in below-surface storage facilities.

The survival and functioning of living organisms is dependent on an interrelationship between an organism and its surrounding environment. Organisms whose temperature is almost totally dictated by the surrounding environment are known as poikilotherms (so called “cold-blooded” animals such as fish, reptiles and insects). The body temperatures of poikilotherms exhibit a strong tracking and correlation with environmental temperature. Organisms that maintain near-constant deep-body temperatures are known as homeotherms (so called “warm-blooded animals” such as birds and mammals, including humans). Homeotherms exhibit near-constant body core temperatures over wide environmental temperature ranges. All animals respond to their microclimate, and heat production by animals can be separated into two distinct components: minimal heat production and regulatory heat production (Figure M11). With favorable environmental temperatures an animal will be in a thermoneutral zone and only minimal heat production will be required. Conditions will be near optimal, but perhaps with

slight coolness or warmth. As environmental temperatures deviate from this zone, heat or cold stress dictates increases in regulatory heat production. If environmental conditions further deteriorate, and regulatory heat production is unable to stabilize the thermal regime of the organism, threshold levels can be exceeded. Mortality can then result. For some organisms daily existence and survival is dependent on such microclimate circumstances (Blumberg, 2002). Aspects of animal care, husbandry and transport (Albright, 1990; Johnson, 1987; Scientific Committee on Animal Health and Animal Welfare, 1999) are but a few of the practical acknowledgements of these principles.

Human activities that reshape the landscape give rise to many microclimate regimes. The thermal and moisture conditions in a cultivated field vary markedly from furrow crest to bottom. In many ways these are analogous to features found in larger landscapes (i.e. the topographic control exhibited in Figure M7). The excavation and landscaping of slopes or embankments with orientations that favor higher solar radiation receipt usually realize greater warmth and dryness (Brown and Gillespie, 1995). Humans have created built environments for shelter, security and a host of other reasons. The walls and roofs of buildings are extreme examples of the effects of orientation on solar radiation receipt. In the northern hemisphere, east walls receive direct beam solar radiation in the morning and west walls in the afternoon. Radiant energy receipt on north walls is minimal at most times of the

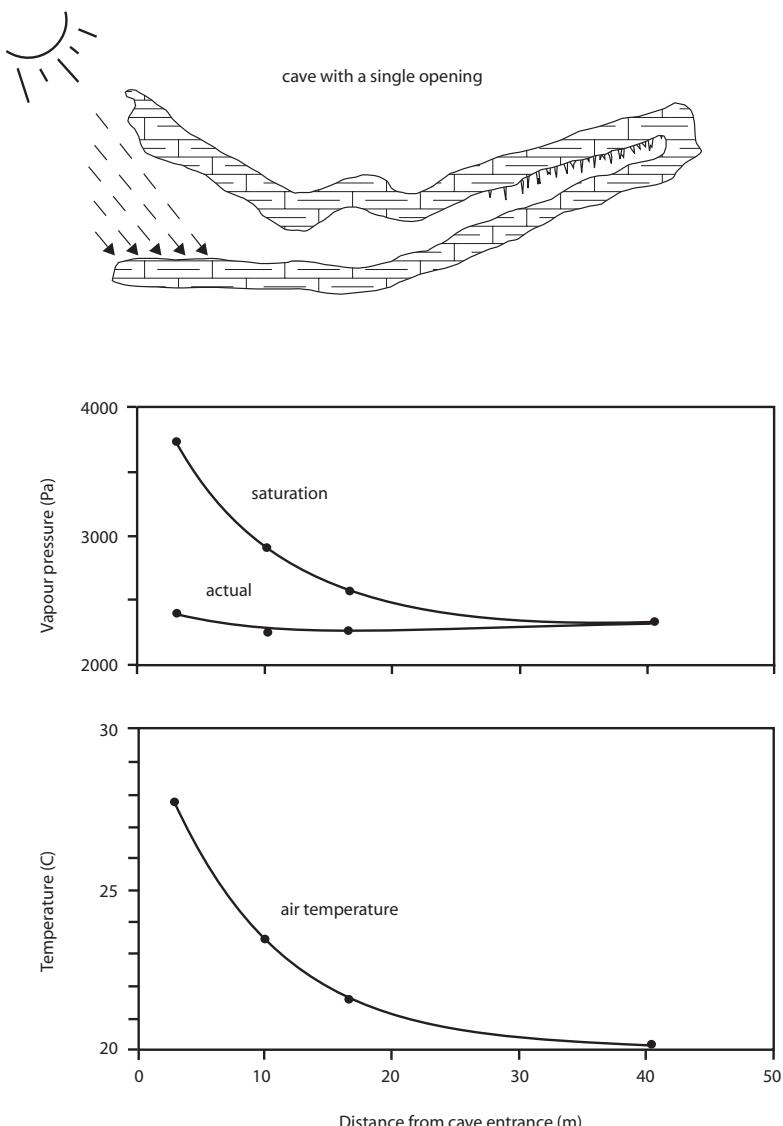

Figure M10 The temperature and humidity regime of a cave with a single opening in the eastern Mediterranean region. Adapted after Geiger (1961).

year and south walls may receive higher solar radiation during the late fall, winter and early spring. Microclimates within buildings may be linked to outside conditions (Brown and DeKay, 2001), or may have temperature, humidity and ventilation cycles that are artificially controlled. Concerns about indoor air quality and “sick buildings” are well documented, and provide challenges for architects and engineers. Humans themselves play distinct roles in the modification of the microclimates within buildings. The inhalation of oxygen and the exhalation of carbon dioxide and water vapor modify the atmospheric environment of rooms (Figure M12). The design of the best microclimate environment possible for buildings and cities, as well as a means for allowing people to modify the environment as needed, presents numerous and ongoing challenges.

The microclimatology of cultural heritage represents a unique blend of seemingly independent disciplines (Camuffo, 1998). However, knowledge of macroclimate, mesoclimate and microclimate regimes is an important factor in the location and architectural design of museums and other facilities that house cultural heritage. Within museums the monitoring and control of microclimate variables (radiation, temperature, humidity and air quality) is fundamental to the preservation of the collections as well as for the comfort of visitors (Thompson, 1990). Outdoor statues and monuments face additional complications as they are continually subject to microclimate influences, for example diurnal and seasonal heating and cooling, and dry and wet deposition arising from pollution. Pisa’s leaning tower has been the focus of tourism, public awareness, and scientific and engineering study for many hundreds of years. In addition to

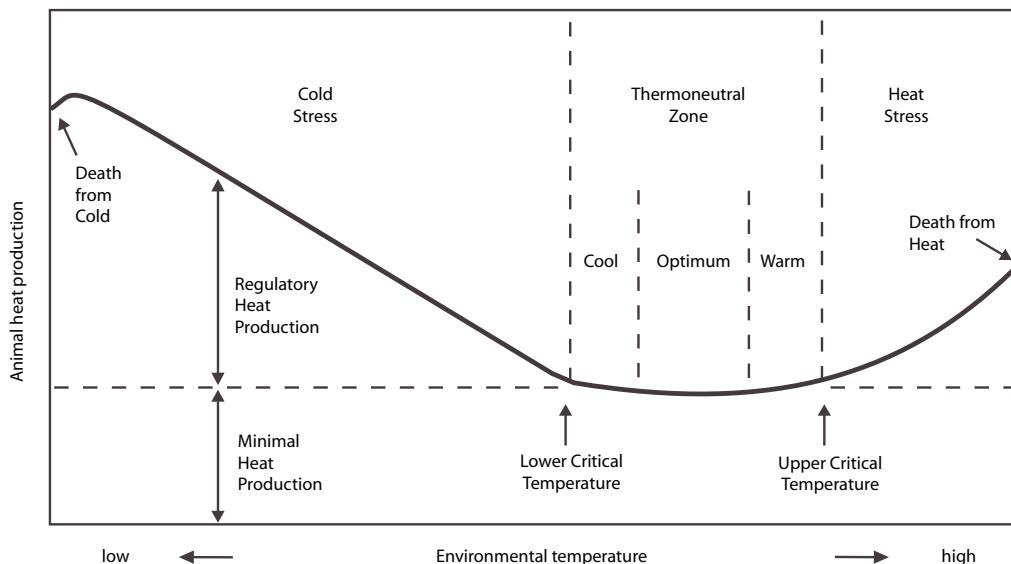

Figure M11 Schematic representation of heat production and the thermal zones of animals. Temperatures falling below the lower critical temperature results in cold stress (hypothermia), whereas temperatures rising above the upper critical temperature results in heat stress (hyperthermia). When critical thresholds are exceeded, mortality can result. Adapted after Scientific Committee on Animal Health and Animal Welfare (1999).

the tower's well-documented ballet with gravity, microclimate consequences are relentless (Camuffo et al., 1999) (Figure M13). The outer wall temperature regimes of La Tower Pendente di Pisa are closely linked to diurnal and seasonal trends in solar radiation. Throughout the day, the warmest wall temperatures move from the east-facing, to the south-facing, and finally to the west-facing walls. Expansion and contraction of the tower, and the associated diurnal twisting that is associated with this thermal warming of the stone, tracks the apparent motion of the sun in the sky. In summer, the warmed stone surfaces can exceed air temperatures by more than 10°C, and the north side of the tower is often colder than the surrounding air. The tower's splendor is continually disfigured by airborne particulate matter deposition, and a complex balance exists between deposition, the tilt and material of the tower, rainfall washout and surface runoff. Micropores on the stone surface play significant nanoclimate and picoclimate roles. The smallest micropores are always filled with water and constitute a reservoir for microbiological life, whereas condensation occurs only occasionally in the largest pores. Micropores between 4 and 5 nanometers undergo more than 250 condensation–evaporation cycles per year, and are influential in the dissolution of the material matrix of the stone and the migration of dissolved salts. Particles that are deposited on the tower can be washed away by rainfall. The washing is governed by the wind direction and the shape of the tower. Patterns in the surface washing demonstrate the direction of storms, the shielding provided by the tilt of the tower and the tower height. Rainfall washing is more effective at the top of the tower. Here airflow is less perturbed by the roughness of the surrounding urban landscape, and the trajectory of the raindrops has a greater horizontal component.

The Great Sphinx of Giza in Egypt is a globally recognized monument. Over past millennia it has been partially submerged in sand and subject to serious erosion about the neck and shoulder region. Excavation around the Sphinx has resulted in an advantageous microclimate modification as a result of altered airflow patterns (Figure M14). Wind that now sweeps across the Sphinx creates vortices on each flank of the monument, and the trajectory of abrasive granules has been altered with most falling into the excavation. As a consequence, one of the many threats to the preservation of the monument has been reduced (Camuffo, 1992, 1998).

New frontiers in the study of microclimatology are continuing to evolve. The study of the microclimatology of spacecraft, orbiting space stations and the surfaces of other planets has already commenced. In the latter, the integration of information gained from pioneer space probes, theoretical understanding and computer modeling holds the potential to yield remarkable advancements. The identification of severe microclimates on Earth, and their use as training areas for future planetary landings, is in its infancy. This attests to bold frontiers ahead for humans and their technology in the microclimates that will be visited far from Earth.

The challenges ahead

The impetus behind the advancements made in microclimatolgy knowledge during the twentieth century will continue into the twenty-first century. Knowledge about many environments exists, but only scant details are available for others. Demanding questions will continue to be posed, and the quest for insight and answers will persist. Global climate change is driven by processes that often commence with microscale

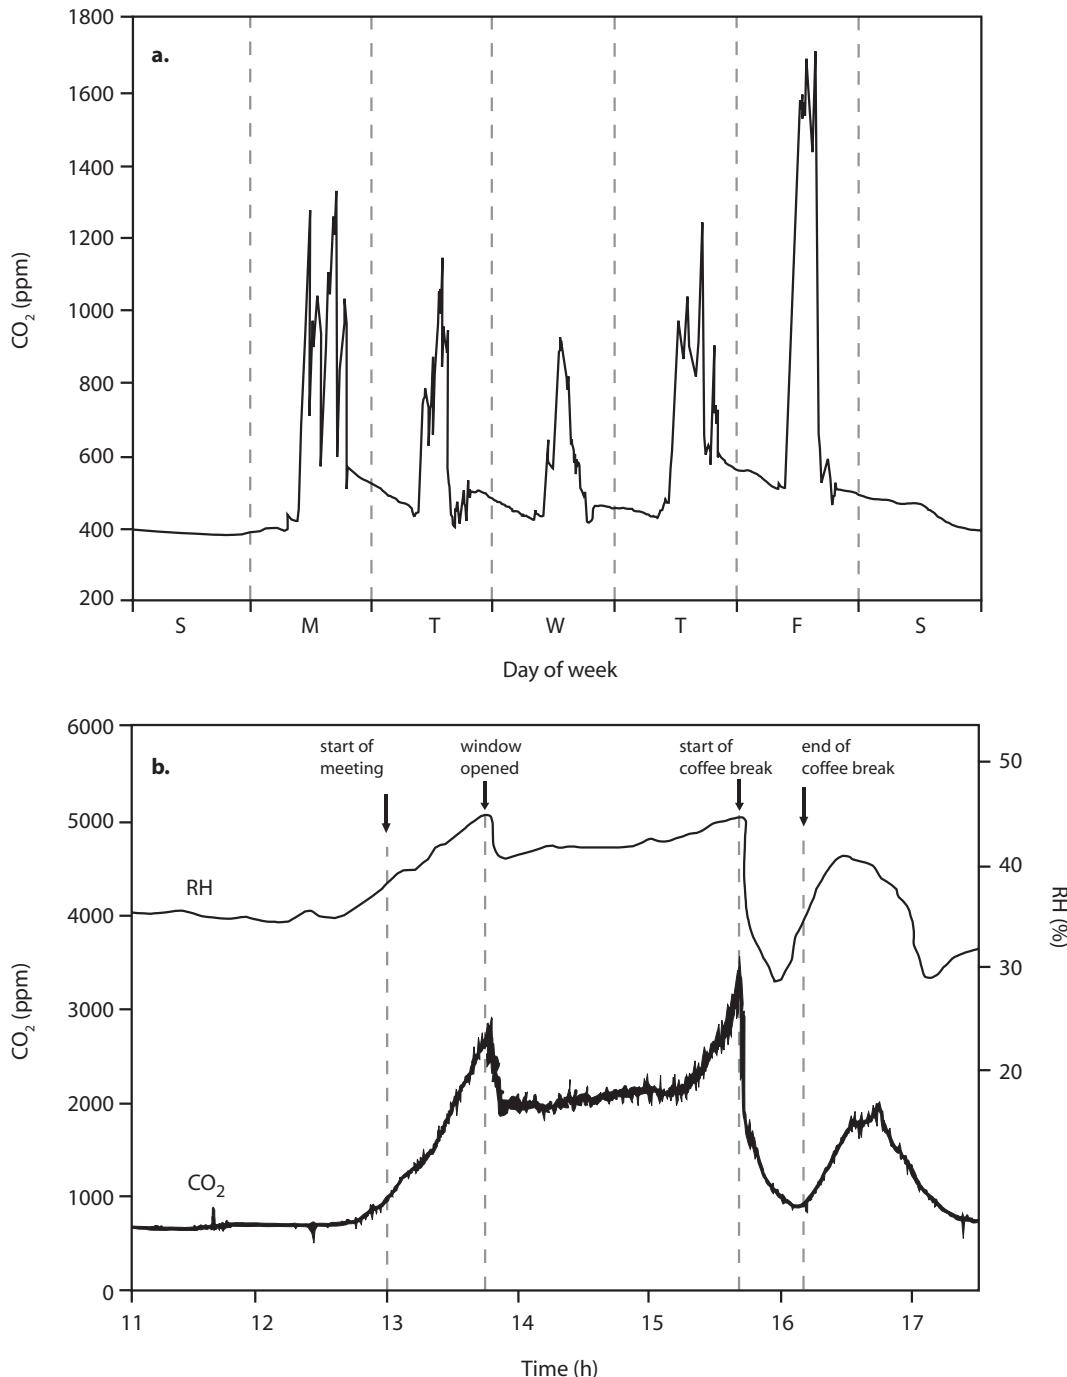

Figure M12 Variations in carbon dioxide in indoor environments. As CO₂ levels exceed 1000 ppm, tiredness and difficulties with concentration arise. Threshold values of CO₂ are approximately 5000 ppm. (a) The time-series of CO₂ in an office environment (maximum of three persons present) throughout a weekly period. Decreases in CO₂ occur during the daytime in response to windows being opened to allow the entry of fresh air. (b) The time-series of CO₂ and relative humidity during a meeting. Decreases in CO₂ and humidity occur due to window opening and the coffee break activities. Adapted after Endres (2001).

activities (IPCC, 2001c). Adequate representation and the scaling-up of important microclimate influences in numerical modeling approaches, for local and regional weather forecasting to climate change prediction and scenarios, will be an

important contribution to the advancement of overall climate science (IPCC, 2001b). Forcings that are imbedded in natural and anthropogenic climate change will impact all microclimates. The response to these changes, in many environments,

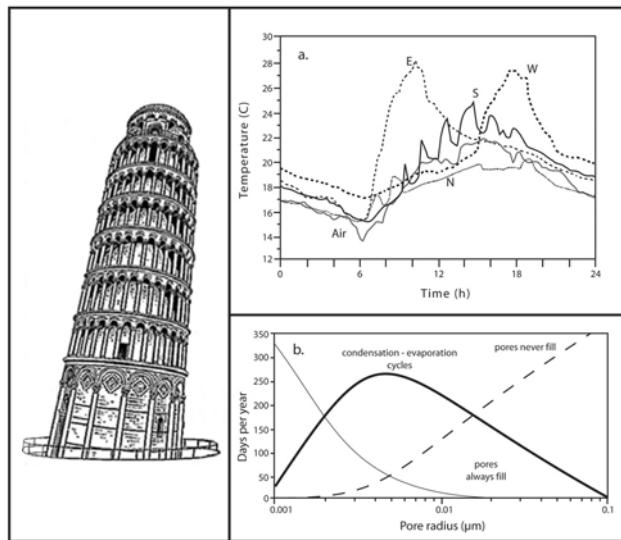

Figure M13 (a) The diurnal trend of surface temperatures on the outside wall surface of the central body of La Torre Pendente di Pisa (built from 1173 to 1370). Temperatures are given for positions facing the four cardinal directions. Air temperature was observed on the north side of the tower. (b) The influence of micropore size on the number of days each year in which condensation–evaporation cycles occur and the number of days that occur in which micropores are filled or never fill. Adapted after Camuffo et al. (1999).

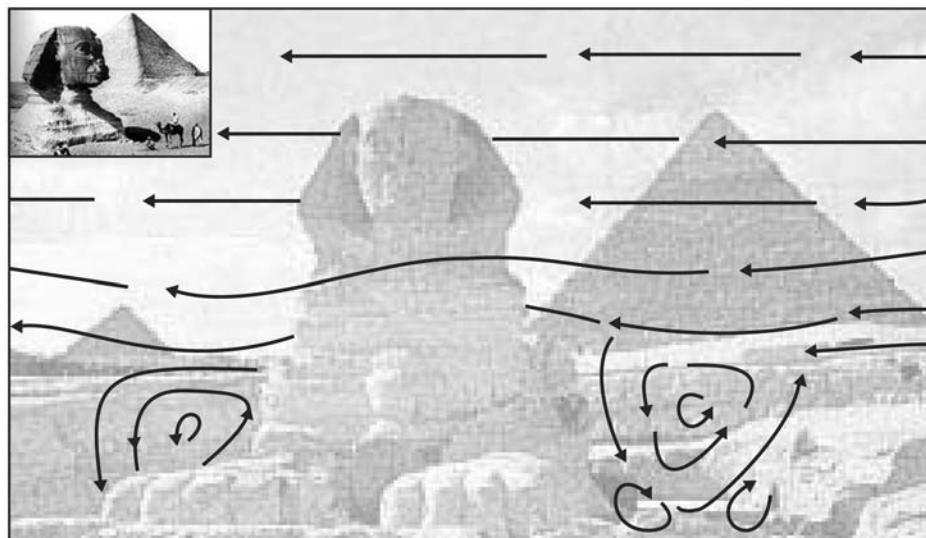

Figure M14 A schematic representation of airflow patterns across the Great Sphinx of Giza. Over the past millennia (insert), the Sphinx was often partially submerged in sand and subject to severe erosion in the neck and chest region. Excavation has resulted in the creation of a major vortex along each flank of the monument. The resultant trajectory of abrasive granules is such that most now fall into the excavation.

will have profound impacts on the organisms that inhabit them, perhaps their very survival (IPCC, 2001a).

Microclimatology is, and will remain, an inexact science. The profound challenges ahead will be the utilization of microclimate resources in the wisest and most prudent manner, and the minimization of deleterious modifications to microclimate regimes.

MIDDLE LATITUDE CLIMATES

The middle latitudes are regions of great atmospheric restlessness and variability, dominated at the surface and in the upper atmosphere by westerly winds (Hare, 1960). The climate is controlled at the surface by a succession of cyclones and anticyclones, normally moving from west to east, that are steered by the upper flow. The fall of temperature toward the poles occurs not in a uniform manner, but with the strong thermal gradients concentrated in one or more narrow latitudinal bands, or fronts. Baroclinic conditions lead to the development of jet streams just below the tropopause (Barry and Carleton, 2001).

The equatorward limit of middle latitude climates is often taken as the surface subtropical high-pressure belt. The poleward limit is more diffuse and variable, although it is often marked by the subpolar lows. The latitudinal extent of the climatic zone will vary from month to month and year to year, depending on changes in the position of the bordering centers of action, but most frequently it occupies the zone between 35 and 56 degrees N and S. As the overall equator-to-pole temperature contrast decreases from winter to summer, so does the strength of the westerlies. Day-to-day weather at a particular location is much affected by the latitude and strength of the westerly current. The upper westerlies vary between two extreme states. At times the upper flow is little deformed by waves, and the flow is

parallel to the lines of latitude. At such times of high zonal index the westerlies blow strongly over large longitudinal zones and sweep a succession of depressions eastward at high speeds with frequent rain and gales in middle latitudes. At other times the Long or Rossby waves in the upper westerlies become greatly amplified, resulting in a meridional flow, a condition described as low zonal index. If the tips of the waves become cut off, leaving cold upper pools with associated low pressure at the surface in low latitudes and warm upper highs and associated surface anticyclones at high latitudes, blocking develops.

Blocks have preferred seasonal and geographical incidences, being most common in spring and in the eastern Atlantic and over eastern Asia. Having once formed, blocks frequently are very persistent and may dominate the circulation for several weeks and on occasion for a whole season, introducing large temperature and precipitation anomalies into middle latitudes. Evidence exists of annual variations in blocking frequency and persistent anomalous climatic conditions, e.g. the mid-1970s European drought could have been caused by persistent or repetitive blocking episodes.

The strength of the circulation in any season is often expressed in relation to oscillations in the strength and position of the main centers of action, e.g. the Icelandic Low, and the Azores High. Such pressure oscillations include the North Atlantic Oscillation (NAO) and North Pacific Oscillation (NPO). In recent years the NAO, in particular, has often been strongly positive, implying strong westerlies in the Atlantic-European sector and a succession of mild winters in much of Europe (Perry, 2000).

Great differences occur in the geographical extent of land and sea areas in the two hemispheres. In the northern hemisphere midlatitudes contain the large landmasses of North America and Eurasia that lead to prominent contrasts in regional climate with important longitudinal variations. West coast locations are exposed to the predominant westerly winds and have equable temperature regimes, often with abundant precipitation throughout the year. The interiors of the continents have a more continental climate with greater annual temperature ranges and lower average precipitation totals, most of which falls in the summer season as a result of convective processes. In the southern hemisphere the much greater extent of sea area ensures that the westerlies blow more consistently and strongly (being known by a variety of names, including the Roaring Forties), and the circulation is less disturbed by periods of blocking than in the northern hemisphere. The kinetic energy of the southern westerlies is about 60% larger than the northern hemisphere westerlies. Smith (1967) has suggested that continentality and oceanicity are the principal criteria in defining subdivisions of climate in middle latitudes with general temperature levels forming a secondary subdivision. The adjective "temperate" is often applied to midlatitudes or used as a proxy term (e.g. Trewartha, 1968) but is certainly not suited to all climates in these latitudes as Bailey (1964) has shown.

Marine midlatitude climates

Along the western margins of the continents in the middle latitudes of both hemispheres, the climate is under a considerable maritime influence. In Western Europe the topography allows penetration of maritime air masses deep into the continent in contrast to the situation in both North America and South

America. A distinction is normally made between warm temperate or Mediterranean and cool temperate climates.

Mediterranean type

The approximate latitudinal extent of this type is on the order of 5–10 degrees between latitudes 30/35–40. A large proportion of the total precipitation falls in the winter when day-to-day weather is controlled by the behavior of the westerlies (Perry, 1981). During the hot dry summers the subtropical high-pressure area and its attendant ridges take control. In the type area (the Mediterranean Basin), substantial winter precipitation totals occur during low zonal index phases, when a meandering jet stream with a major trough exists over the Mediterranean, favoring cyclogenesis. Lee depressions form in the Gulf of Genoa and south of the Atlas Mountains and move in a generally eastward direction through the basin, often becoming reinvigorated in the east near Cyprus. Whereas the sea acts as a heat sink in summer, in winter it represents a heat source and cold air-masses entering the basin quickly become unstable after passage over the relatively warm water. The high intensity of rainfall is reflected in the small number of rain-days, even in the wetter areas. Regional winds, e.g. the cold Mistral and Bora, are related to meteorological and topographic factors, whereas the persistent northerly winds of summer in the eastern Mediterranean known as the etesians give this area a distinct climatic subtype. High annual sunshine totals are a feature of Mediterranean climates, with totals exceeding 3000 hours being quite common. In the northern hemisphere Southern California has this type of climate, as does the southern hemisphere coast of Chile around Santiago, the West Australian coast around Perth, and the South African coast around Cape Town.

Cool temperate

Poleward of the Mediterranean climate, on the west side of the continents, the climate is changeable throughout the year with well-distributed precipitation, brought by a series of depressions and their associated fronts and a predominance of maritime air masses. In northwestern Europe and on the Oregon and Washington coasts of North America, large positive temperature anomalies occur in winter compared with the average for the latitude, as maritime air masses cross the warm-water currents in the North Atlantic and North Pacific. Since summers are relatively cool for the latitude, annual temperature ranges of less than 20°C are common. Because depressions are deeper and more vigorous in winter near the coast, there is normally a fall or winter precipitation maximum, whereas spring and early summer have a minimum of precipitation, reflecting both the increased frequency of blocking anticyclones in these seasons and the lower moisture content of maritime air masses at this period due to the lower sea temperatures. High precipitation totals are a feature of all mountain areas and large lapse rates give such areas a short growing season and a cloudy, damp and often raw climate. A high degree of changeability from day to day is a characteristic of these climates as rapid alternations of air masses occur, although occasionally persistence of a particular synoptic situation leads to more settled conditions. The coldest winter weather and the warmest summer spells develop when continental air masses replace, for a time, the more usual airflow from oceanic sources. In the southern hemisphere sizeable belts of this climatic type occur in Chile, Tasmania, and the South Island of New Zealand.

Continental midlatitude climates

In both North America and Scandinavia the transition from maritime to continental climates is rapid due to the barrier effect of the mountains imposed on the invasion of surface maritime air-masses, but across the European Plain the transition is much more gradual. Meridional airmass movement is a particular characteristic of the North American climate and rapid changes of temperature level can occur, especially in winter, as frontal depressions cross the continent. Very severe winters occur at times with disrupting snowstorms, and are the result of strong amplification of the long waves with ridging over western North America and a deep trough in the east. This allows deployment of Arctic airmasses into the eastern states, while often in the west weather is mild and dry. Blizzard conditions develop on the cold polar side of traveling lows. In summer severe heatwaves can develop when warm air from the Gulf of Mexico is advected northward into the central and eastern states.

Over the USSR the winter circulation is dominated by the intense Siberian anticyclone, although the position and the intensity of this cold anticyclone can cause considerable departures of temperature values from the normal in individual years. Mean January temperatures below -40°C occur in parts of Siberia, accompanied by dry sunny weather. During the short summers, temperatures can rise to 35°C on occasion, even as far north as the Arctic Circle. In these continental climates the transition seasons of spring and fall are very short. Although the seasonal variation of precipitation in the interior and eastern parts of both North America and Asia can be complex, there is normally a summer maximum brought on by instability showers and thunderstorms. Local variations in precipitation totals reflect such factors as the presence of large lakes, e.g. the Great Lakes of North America enhance snowfall totals on their eastern shores. In the United States the 51 cm annual isohyet follows approximately the 100° West Meridian, and in the dry area between the Rocky Mountains and this longitude occasional drought years occur, such as those resulting in the Dust Bowl conditions of the 1930s.

MILANKOVITCH, MILUTIN (1879–1958)

Milutin Milankovitch developed the theory of orbital control of terrestrial insolation and climate change. Milankovitch was of Serbian origin, born in Dalj (Slavonia) in what is now Croatia. He obtained his PhD in 1904 in Vienna and worked as a civil engineer for 5 years before going to the University of Belgrade as Professor of Applied Mathematics. Captured during World War I, but allowed to work at the Hungarian Academy of Sciences, Milankovitch completed the insolation theory for the Earth and had also worked out a climate history for Venus and Mars.

The “Milankovitch parameters” involved in his theory are: (1) the eccentricity (or ellipticity) of the orbit e , which measures the departure of the Earth’s circumsolar orbit from a circle (with a period of about 90 000–100 000 years); (2) the obliquity of the ecliptic (or tilt), which is the angle between the equator and the plane of the orbit (principal period about 41 000 years); and (3) the precessional parameter, related to the longitude of the perihelion, which is conveniently expressed as the angular distance of the spring equinox point from the perihelion. It has two principal terms, about 19 000 and 23 000 years. This is related to the “general” precession that has been refined to 25 694 years (Berger, 1992).

After World War I, Wladimir Köppen, the famous climatologist, was working on a book with his son-in-law Alfred Wegener (of continental drift fame). This became a standard textbook on climate (1924) and carried the Milankovitch message. Unfortunately it only reached a German-speaking audience. However, a German geologist and archeologist from Breslau, Frederick Zeuner, applied the insolation theory to the central European geological record, and after moving to London in the 1930s Zeuner explained to a world audience the Milankovitch ideas (Zeuner, 1959). The “establishment” of the day responded to the Milankovitch theory with severe criticism, an outrage almost paralleled by the hostile reception of Wegener’s continental drift theory. During World War II Milankovitch worked on a complete revision of his radiation theory, which was published (in German) by the Royal Serbian Academy of Sciences in 1941 as the *Kanon der Erdbeleuchtung*.

In the post-World War II decades, however, dramatic discoveries were being made at sea thanks to sediment coring and deep-sea drilling. The sea-level record paralleled the last phase of the Milankovitch radiation curve for 65°N . During the next two decades, dating systems were expanded, deep-sea cores were obtained worldwide, and the results were conclusive: there was an exact match with the Milankovitch pattern (Fairbridge, 1967), and it was recognized as “the pacemaker of the ice ages” (Hays et al., 1976).

Milankovitch was destined to become one of those rare scientists who developed truly pivotal ideas. His inspirational conversion from engineering to orbital dynamics is elegantly told by Imbrie and Imbrie (1979), and may be followed with details and bibliography in an autobiographical work (1957). In 1979, to

mark the 100th anniversary of the birth of Milankovitch, a symposium was organized in Belgrade by the Serbian Academy of Sciences, and a conference convened at the Lamont-Doherty Geological Observatory (Palisades, NY). The evidence was overwhelming (see symposium volume, edited by Berger et al., 1984).

The acceptance of the Milankovitch theory was far more than a quantification of dynamic change for the last ice age. Geologists are now applying it to the whole of Earth history. For climatologists, long-term modeling is now feasible, and for meteorologists it carries a crucial message: the terrestrial climate machine is neither chaotic nor unpredictable – it is forced by extraterrestrial agencies. The same message must apply also to other planets.

MILITARY AFFAIRS AND CLIMATE

Today, the military is called upon for a variety of operations ranging from war fighting to humanitarian or peacekeeping missions (military operations other than war, MOOTW) to peacetime operations (for example training and research) similar to any other industry. Post-September 11 the military has also been asked to increase its role in domestic security issues and anti-terrorism special operations. All of these complex missions require timely weather and climate information. For the military, climate and weather are not distinct areas of study; rather, they flow along the entire knowledge continuum embracing strategy and tactics. Knowledge of the climatic conditions of an area is necessary in developing the strategic plans for operating in that area. Training as well as development, test, and evaluation of equipment also requires detailed climatic knowledge. On timescales up to a week, knowledge of the weather is critical in developing the tactics used during a mission. As demonstrated in Winters (1998), failure to effectively exploit this climatic knowledge, or a chance encounter with weather conditions representative of extreme departures from anticipated conditions, have resulted in disastrous defeats throughout military history. This essay will highlight many of the climatic elements that impact on the military as they perform their various missions. It will conclude with a brief look at "climates" of space and the oceans which also impact military operations. Readers interested in other areas of military geography should consult the numerous references in Collins (1998) and Plaka and Galgano (2000).

Impacts of climatic elements

A climatic element is some component of the climate system such as temperature or precipitation. Information on these elements is measured using conventional weather equipment. The (near) instantaneous values of these components is termed weather. The synthesis of these values, including not only average values but also their variability, is termed climate. Each has critical military significance. This section will relate the major climatic elements to some of their military impacts.

Temperature is the most obvious climatic element. Humans are homeotherms; they attempt to maintain a core body temperature within narrow limits. Extreme hot or cold temperatures impact the body thermoregulation system and degrade performance. In hot environments, armies will consume more fluids, and troops must be monitored to prevent heat illness. Extreme cold increases the logistical need for clothing and food to ensure good health. Equipment as well is impacted by extreme temperatures. Hot ambient conditions reduce the efficiency of engine radiators and may lead to overheating. Lubricants become less efficient at extreme temperatures causing increased wear or damage. In very cold conditions machinery may freeze if not continuously tended. In the free atmosphere temperature inversions may cause areas of anomalous propagation of electromagnetic radiation. The resulting degraded radar performance may prevent the acquisition or tracking of targets or threats. Jet engine efficiency also is a function of air temperature. Low-flying cruise missiles may have their effective range shortened in hot environments.

Humidity also impacts human comfort and performance. High humidity combined with high temperatures may produce dangerous heat stress conditions. At low humidity, drying effects can influence not only human comfort but fluid evaporation rates. A particular concern is the build-up in static charge which can make handling of fuels and munitions dangerous. Temperature and humidity determine air density, which impacts projectile performance. In tropical environments, high humidity contributes to the biofouling and deterioration of equipment. It is often necessary to artificially heat confined spaces to discourage the growth of mold or provide rust-resistant coatings to metal surfaces.

Precipitation has inspired many a soldier's lament. Heavy rains often result in trafficability problems as roads become impassable due to mud or debris flows. Floods are also a problem. Flash floods may imperil troops or equipment while riverine floods may cause delays in bridging operations. Snow or heavy rain restricts visibility and limits aircraft operations. The in-flight build-up of ice can affect aircraft control surfaces. Sensors or communication systems operating at microwave frequencies are particularly susceptible to interference from heavy precipitation.

Wind impacts include lowering of visibility due to blowing dust or sand. High winds may preclude the use of smoke or other obscurants to hide troop movements or impact the dispersal of chemical or biological weapons. Radar-absorbing chaff clouds, used as an electronic warfare countermeasure, may be quickly dispersed in high winds, thus reducing their effectiveness. High winds may also impact aircraft operations. Helicopter maneuvering in gusty winds is often problematic and launch and recovery of unmanned aerial drones is complicated by unsteady winds. Cross-winds and turbulence can impact aircraft providing low-level combat air support.

Many impacts on visibility have been listed under other climatic elements. Fog, blowing dust, and the smoke created by battle significantly impact low-level visibility. For aircraft, cloud layers may hinder target identification and weapons delivery. Many of these problems have technological solutions beyond the scope of this item. One historically important aspect of visibility has been all but eliminated by technology: night versus day. Night vision equipment and associated sensors which allow pilots and ground personnel to operate in near-total darkness have resulted in a radical change in battlefield tactics. War fighting is no longer a "sunrise to sunset" affair.

A final climatic element of military concern is atmospheric pressure. Aircraft must have oxygen systems for prolonged high-altitude flight. Troops operating in mountainous terrain need time to acclimatize to the lower pressures to avoid rapid fatigue, or in extreme cases altitude sickness. Even the often-vilified army cook must be aware of the impact of high elevation on cooking times and the boiling point of water!

Impacts of ocean and space "climates"

Most of this item has been directed toward the ground and lower troposphere. However, naval and marine units encounter another set of impacts peculiar to the ocean and the land/water interface. High winds and wave heights can make naval operations and shipkeeping extremely difficult to the point of structural damage. Personnel operating in and under the water must be protected from the effects of hypothermia. Amphibious landings must contend with tides, currents, and breaking waves. Submarine warfare is especially dependent on knowledge of

sound-velocity profiles which are largely determined by sea-water temperature. Fog and structural icing are also concerns.

With the development of space-based satellite observation and communication systems, the realm of "climate effects" has been extended to the exosphere. Periods of intense solar activity produce storms of charged particles which impact satellite operations. Multi- and hyper-spectral sensors are used to minimize the effects of clouds and water vapor on the satellite geometry.

Military weather and climate monitoring

The military maintains weather-monitoring stations at many of its facilities around the world. Part of their mission is to provide forecasting support to operational units. The US Air Force and Navy maintain detachments at the National Climatic Data Center. Here climatic data collected from weather stations around the world are used to produce climatic summaries for areas of interest to the military. During times of crisis these detachments can produce specific mission-directed products. Operational units are typically deployed with personnel trained in analyzing these weather and climate products.

Lessons learned from historical engagements are combined with advances in technology at a series of national laboratories operated by the Army, Air Force, and Navy. Research results and products from these laboratories are tested and evaluated at a series of field laboratories before being approved for use by operational forces. The testing must be done under similar climatic conditions to those in which the products will be used; therefore field laboratories are located in tropical, temperate, and Arctic locations. In addition, troops must be trained to operate in a variety of climatic conditions prior to their deployment. The goal is to exercise personnel and machinery prior to employment to maximize effectiveness and minimize loss. Climate is one consideration in this important process.

Conclusion

Weather and climate have played an important role in historical war fighting. The role continues today along with increased responsibilities for MOOTW and peacetime operations. Climate impacts all these functions. From training to development of new weapon systems to operational deployment climate considerations abound. Strategic planners and logisticians make use of climate data in deciding what mix of forces will be used in a particular area and how they will be equipped and supplied. Operational commanders can prepare tactics based on climatic knowledge and be ready to adapt those tactics to take advantage of changing weather conditions. Climatologists work with engineers and other technicians to provide new equipment and climatological summaries relevant to the evolving missions of today's military.

Human Health and Climate

MODELS, CLIMATIC

Climatic models are abstractions of climate that are used for one or more of three overlapping purposes: to explore and describe the interrelationships within and between the observed elements of climate, to predict important climatic or climate-forced events, or to explain the fundamental biophysical mechanisms that control climate. A widely accepted, comprehensive definition of climate and, subsequently, of climatic models has not been published although many climatologists would agree that climate is a synthesis of weather in which the time-period of integration often exceeds the length of a weather forecast. Climatic models, in fact, have been developed and used to investigate and describe climatic processes which are manifested over tens, hundreds and even thousands of years of Earth history as well as over but a few days. Equally variable is the geographic scale on which climate occurs and is modeled (Steyn et al., 1981).

Microclimatic models, for instance, may attempt to characterize climatic processes that function within only a few cubic meters, whereas macroclimatic models often strive to describe climate as it extends over hundreds or thousands of square kilometers and vertically from the surface to the bottom of the stratosphere and perhaps beyond (Schneider and Dickinson, 1974). From an anthropocentric vantage point, however – regardless of scale – all climatic processes and phenomena are manifested within the context of a four-dimensional (the three space dimensions plus time), circum-surface climatic environment (Figure M15). Models of climate, it follows, are chiefly formulated for and used within this context, even though application-specific requirements result in a wide variety of model forms.

A common purpose

A number of climatologists would qualify the above characterization by emphasizing that climatic models are distinct from meteorological models only when they attempt to couple terrestrial systems or oceanic processes to the lower atmosphere. Since the lower atmosphere and Earth are coupled across their contact surface, the energy and moisture crossing that interface control the equilibrium of atmosphere–Earth energy and mass exchange and, thus, have primary climatological importance. Climate at the surface also is primarily what humans experience, influencing a wide range of human activities. Climatic models, as a consequence, are mainly developed and used to explore, describe, predict or explain the integrated surface or primary interface (Figure M15) temperature and moisture states of the world's oceans, lakes, rivers, snowfields, soil, flora and fauna, as well as of people and their edifices.

As the integrated temperature and moisture states of any terrestrial or aquatic surface(s) of interest, that is climate, can only be evaluated by accounting for the fluxes of energy and mass (predominantly moisture) to and from the surface (i.e. by

solving the surface “energy [and mass] budget”), the search for improved solutions to the budget – for the myriad of disparate space and time scales as well as environments – provides the *raison d'être* for much of the development, refinement and use of climatic models. A primary reason for climatic modeling, in other words, is the establishment of good, quantitative solutions to all or parts of

$$Q(1 - \alpha) + I\downarrow - I\uparrow = H + LE + G + F \quad (1)$$

where Q is solar irradiance (W m^{-2}), α is the integrated reflectivity of the surface to solar (shortwave) irradiance, $I\downarrow$ is longwave radiation from the surrounding environment and the atmosphere which is absorbed by the surface (W m^{-2}), $I\uparrow$ is longwave radiation emitted by the surface (W m^{-2}), H is the rate of sensible heat exchange between the surface and lower atmosphere (W m^{-2}), L is the latent heat of vaporization (J kg^{-1}), E is the rate of water vapor exchange between the surface and lower atmosphere ($\text{kg m}^{-2} \text{s}^{-1}$), G is the rate of heat exchange by conduction between the surface and underlying ground or water (W m^{-2}) and F is the heat convected by the ocean, lake or river from its surface (W m^{-2}). Consistent with convention [$Q(1 - \alpha)$] and $I\downarrow$ are positive fluxes that contribute to surface warming whereas $I\uparrow$ is a positive, cooling term. On the other hand, H , LE , G and F are positive when the direction of transfer is away from the surface (cooling) and negative when they contribute to surface warming.

In order to solve the surface energy budget (equation 1), climate models must account for the ambient or representative energy and moisture states of the near-surface air, soil, snow, vegetation and so on, as well as for the states of the surface, because the magnitudes of most of the fluxes depend upon temperature, humidity and momentum gradients that exist between the surface, the atmosphere above and the terrestrial or aquatic environ below. That is, climatic models must provide supportive, quantitative characterizations of the near-surface state variables, such as air temperature, vapor pressure and soil moisture, before equation (1) can be adequately solved. Concern for the ambient states of the near-surface, in turn, leads to the related problem of evaluating those convective and radiative fluxes that take place across the climatic environment's secondary interfaces (Figure M15), for they – like the exchanges across the atmosphere–Earth interface – affect the states of the near-surface which then influence the surface energy budget. Thus, equation (1) is fundamentally nonlinear, in that the surface energy and moisture states are simultaneously required by the equation as input.

Evaluating the energy, mass and momentum fluxes into and out of the climatic environment entails modeling atmospheric dynamics and physics at the global scale. Over the last three decades, work on the development of global-scale climate models has increased dramatically, and become the main emphasis within the climate-modeling community. Our discussion, in turn, focuses on the history and status of global climate models. Although modern versions of these global climate models are both three-dimensional and time varying, important contributions to the history of global climate modeling and climatology have also been made with simpler models.

Global energy balance models (EBMs)

Global energy-balance models (EBMs) use the basic radiation laws and conservation of energy as their physical principles.

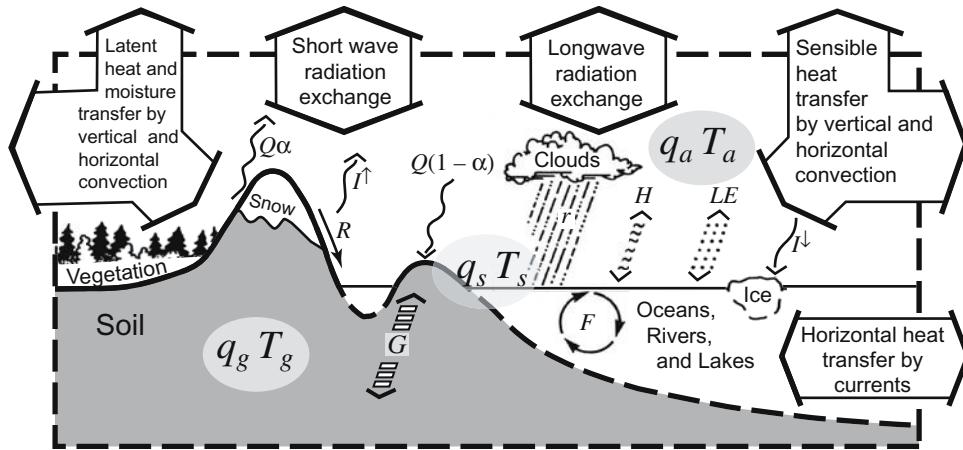

Figure M15 Schematic representation of the climatic environment represented in models. Primary fluxes occur to and from the surface (solid line), which also is referred to as the primary or atmosphere–Earth interface, and they are labeled with symbols for energy budget components (defined in text). Large symbols in oval represent temperature (T) and moisture (q) states of the atmosphere ($q_a T_a$), surface ($q_s T_s$), and near-surface ground ($q_g T_g$) respectively. Precipitation and total runoff are noted as r and R , respectively. Horizontal and vertical heat, moisture and momentum exchanges between the climatic environment and external environments are conceptually depicted by phrases within arrows crossing the secondary interfaces (dashed lines).

The balance implied is between income and outgo. On climatic timescales, whatever sunlight is intercepted by the Earth must be either reflected back to space or absorbed and reradiated as infrared radiation. A prototype for a zero-dimensional EBM is used in nearly every introductory weather and climate textbook in which the shortwave and longwave energy balances are presented for the Earth as a whole. In the textbook version, solar input is distributed between surface and atmospheric energy balances, with terms for latent heat, sensible heat, greenhouse gas warming, and albedo. All that is needed to make that into a climate model is to turn some of the ratios between energy flows into variables instead of constants, translate the percentage values into actual energy flux units, and constrain the model with the three energy balances it requires (surface, atmosphere, and space). Such a simple model can be used to provide heuristic calculations of the relative importance of the major climate forcing components, such as infrared radiation trapping (greenhouse effect) or changes in the vertical structure of the atmosphere.

Simple global EBMs reduce equation (1) to

$$Q[1 - \alpha(T, f)] = I(T, f) \quad (2)$$

in which Q is the average solar flux at the top of the atmosphere, T is temperature, f is cloud-cover fraction, and α and I are functions representing the variation of planetary albedo and infrared output to space, respectively, with temperature and cloud-cover fraction. Simple linear relationships for α and I – derived from satellite data (Bintanja, 1996; Graves et al., 1993) – allow equation (2) to be inverted to solve for temperature.

In the most famous use of a zero-dimensional climate model, Arrhenius (1896) explored the role of carbon dioxide in the Earth's radiation balance. As early as the end of the nineteenth century, Arrhenius noted that carbon dioxide levels were rising from human use of fossil fuels, and he projected that a doubling of carbon dioxide levels in the atmosphere could produce a 1.5–3°C warming in the average surface temperature of the

Earth. A century later, Arrhenius's calculation is still within the mainstream of climate model projections – neither alarmist nor contrarian.

Global energy-balance models have been usefully extended to higher dimensions, most notably to one-dimensional models. These zonal EBMs add a latitudinal component to the energy balance. In addition to the vertical energy balance implied by equation (2), a meridional transport term must be added, as in

$$\begin{aligned} QS(\varphi)[1 - \alpha(T(\varphi), f(\varphi), \varphi)] - I(T(\varphi), f(\varphi)) \\ = F(T(\varphi), f(\varphi), \varphi) \end{aligned} \quad (3)$$

in which φ is latitude, S is a distribution function for solar energy, and F is a function representing the net meridional flux of energy, and all the other functions now vary with latitude. A direct dependence on latitude is included for the albedo and meridional flux functions, in addition to their indirect dependence on latitude via the latitude-dependence of temperature and cloud cover. The direct dependence of albedo on latitude allows for variation of vegetative cover and continental extent with latitude. The direct dependence of horizontal flux convergence on latitude reflects the fact that models of this simplicity do not adequately simulate the high meridional transport in the Hadley circulation without some numerical assistance.

Two particular versions of equation (3), published nearly simultaneously, hold a place of high importance in the history of climate models. Budyko (1969) and Sellers (1969) independently presented simple versions of (3) with slightly different formulations for F and a similar formulation for $\alpha(T)$ in which the albedo of the land surface jumped sharply if the zonal temperature went below -10°C , representing the onset of a snowline. Both found that a small decrease in solar input, amounting to just a few percent, would raise the planetary albedo sufficiently to cause runaway cooling. This runaway positive feedback raised considerable interest in this kind of

modeling through the 1970s. Through that decade, considerable knowledge of the Earth's stability, sensitivity, and feedback systems was gained via exploration of zonal EBMs (North et al., 1981).

Schneider and Dickinson (1974) reviewed a wide range of modeling activities and concluded that a hierarchy of climate models ranging from zero-dimensional, steady-state models through fully three-dimensional general circulation models had a role to play in understanding climate. Within a short time after that, however, zonal EBMs had been found to be too sensitive to describe global sensitivity to solar radiation variations, too insensitive to produce a realistic ice-age cycle from orbital parameter variations, too parameterized to produce a useful greenhouse-gas-change simulation, and generally not competitive for cutting-edge research. Today, zonal EBMs remain an important heuristic tool: they are well worth using as exploratory tools in an introductory course, and building a simple model can illustrate a variety of climate principles and numerical modeling techniques for an advanced student. A few research problems make good use of simple models when coupled with ocean models (Egger, 1999) or glacier models (Sakai and Peltier, 1999) for long-term climate experiments. Beyond these specialized uses, EBMs have mostly faded from view in research.

General circulation models (GCMs)

General circulation models (GCMs) share with global EBMs the idea that physical principles drive the system, rather than atmospheric data. Beyond that commonality, GCMs are both genetically and morphologically different from EBMs. The core of the modern GCM is the atmospheric GCM (AGCM).

AGCMs grew out of weather-forecasting models. The early history of numerical weather prediction has been told elsewhere (Thompson, 1978). The first useful weather simulations were developed in the years immediately after World War II as a project led by John von Neumann at Princeton, the inventor of the stored-program computer. The size and complexity of weather and climate models has been closely tied to improvements in computing technology ever since (Hack, 1992, figure 9.1). The transition from weather model to climate model occurs when a model's statistical behavior approaches the statistical behavior of weather over a long enough period that we may consider climate statistics from the model output to be comparable to climate statistics from weather data. Phillips (1956) ran a baroclinic model long enough to produce a climate simulation in what is often called the first general circulation model.

Six partial differential equations define an atmospheric general circulation model: three for conservation of momentum (one for each dimension of physical space), two for conservation of mass (one each for air and for water), and one for conservation of energy. The six independent field variables in this system are the three components of atmospheric velocity, temperature, specific humidity, and pressure. Thus, nominally, we have a system that can be solved. In practice, the effort required to create such a model is huge.

Because of the complexity and scale of AGCM building, most state-of-the-art models bear institutional names, such as the NCAR CAM (the National Center for Atmospheric Research Community Atmospheric Model, Boulder, Colorado),

the GFDL GCM (Geophysical Fluid Dynamics Laboratory, Princeton, New Jersey), or ECHAM model (European Center for Medium Range Weather Forecasting – Hamburg, Germany). Each of these has an evolving version history from over 30 years of continuous development involving hundreds of scientists and programmers. The most-developed models from large institutions coexist with a plethora of other models, but most share some common origins. What AGCMs have in common is the concept of simulating weather using a grid. The entire global atmosphere is broken up into boxes, both in the horizontal and vertical dimensions. Within each vertical column of boxes, all of the *subgrid-scale* processes must be evaluated. Between vertical columns of the model, most horizontal transfer processes proceed by advection, which requires a prediction of wind. For this prediction the equations of motion are solved approximately.

More difficult to understand, but currently more popular in use, are *spectral* methods (Bourke et al., 1977). In these methods, the fields that require horizontal derivatives are subjected to a generalized Fourier transform, so that they may be represented by a set of coefficients of the spherical harmonics. Some of the advantage of this method arises because the truncated Fourier series of spherical harmonics used to represent the horizontal fields is intrinsically smooth.

Grid scales have been decreased as computational power has increased. Up to a limiting point that we are far from approaching, decreasing the grid size so that fewer things need to be relegated to the subgrid-scale parameterizations will always be an improvement. However, halving the grid size requires an increase in computing power of more than a factor of 100, so grid sizes have not decreased at a rate that might be expected from a simple understanding of how fast computers have improved in recent decades. A common grid scale now would be roughly 3°latitude/longitude boxes, 20 layers in the vertical, and a 20-minute time step.

Climate system models (CSMs)

Climate system models (CSMs) are AGCMs within which boundary conditions at the land and ocean surfaces respond to the changing atmospheric conditions. In the earliest AGCM climate experiments a land model may have consisted of a simple parameterization of soil-moisture availability beneath each grid box and a specified vegetation albedo that could be raised if snowcover were predicted. A number of more realistic land-surface formulations have been developed since then, and they incorporate important vegetation and soil characteristics, as well as human-modified aspects of the land surface (Dickinson, 1984; Sellers et al., 1986). These land-surface models have been widely applied within CSMs, and they have improved significantly CSMs estimates of land-surface albedo, evapotranspiration and soil moisture. Dickinson (1984), in particular, raised the level of land modeling from a parameterization to a significant submodel with the Biosphere–Atmosphere Transfer Scheme (BATS). Continued development of BATS and similar models has led to land models which can be considered independent models in themselves, to be run either in conjunction with an AGCM or in standalone mode using atmospheric data (Bonan et al., 2002).

Just as land-surface boundary conditions have become more interactive and sophisticated, oceanic boundary conditions have matured. From “swamp” models in which the oceans were flat

surfaces with unlimited thermodynamic capacity and moisture availability, we now recognize that for realistic long-term climate simulations, an oceanic general circulation model (OGCM) must be coupled to an AGCM. Such coupled experiments still have not been entirely successful in reconciling the energy and moisture fluxes between the atmospheric and oceanic components into a stable equilibrium. Usually, a flux correction field must be applied, a nonconservative difference between the energy leaving the top of the ocean and that entering the bottom of the atmosphere. Models have come close enough to equilibrium to avoid using the flux correction, but these still show long-term drift (Bryan, 1998).

Another boundary condition model required for coupling into a CSM is one for sea ice. Sea ice has an importance in climate systems well out of proportion to its mass, both because of its sharp albedo effect and because its role as an insulator with respect to both thermal and moisture fluxes between the oceans and the atmosphere. Although the thermal prediction of freezing or melting is fairly simple, and the simulation of the effects of sea ice on the atmosphere–ocean fluxes is also straightforward (Curry et al., 1995), sea ice moves in a complicated response to wind action, modulated by ocean currents. Errors in sea-ice prediction may be the largest identified, systematic problem with current CSM simulations.

Models of everything

Climate modelers have long dreamed of complete models of the climate system – models of “everything” which couple all of the related components of the climate system. The coupling of human activities to climate (Terjung, 1976), however – owing to its complexity, will continue to remain indirect for the foreseeable future. Nonetheless, all of the components of new CSM suites are available for simulating decadal to century-scale climatic variations. Specific improvements in nearly every aspect of atmospheric, oceanic, and land-surface models are being discussed widely and implemented. Even with dramatic improvements in these components, however, climate simulations will remain restricted to medium-term variations, perhaps up to the scale of a millennium, because the simulated climate system is still not complete.

The largest climatic changes of the last several million years have involved the advance and retreat of large ice sheets from North America and northern Eurasia, on time scales for which 1000 years is a high-speed fluctuation and 100 000 years appears to characterize a complete cycle. The pioneering ice-sheet model of Weertman (1976) demonstrated that such cycles could be controlled primarily by the lagged response within the ice sheet. The eventual model of everything will need to include an ice GCM for resolving problems on that scale. Ice-sheet models in current use are not quite ready for full coupling. The best continent-scale ice models are still map-plane models that have sub-grid scale weaknesses with important problems such as ice streams (Fastook and Prentice, 1994), whereas the fully three-dimensional ice sheet models that can simulate ice stream convergence cannot readily be scaled up to continental scales (Hanson, 1995; Blatter, 1995). Nevertheless, some interesting uncoupled simulations using ice-model-generated boundary conditions in an AGCM have been attempted (Bromwich et al., 2001). Full coupling of an ice-sheet model into a CSM is probably a few model generations away, but the path to that eventual coupling is at least being followed.

Another component that will eventually need to be dealt with is the vegetational response. When dealing with the last 20 000 years of climate, going from full glacial conditions to the present, we see significant vegetational responses. For example, the current Amazon rainforest was probably mostly savanna during the last ice age, with a few refugia of forests, from which the current rainforest was created by slow species migration as the climate changed. One of the first things specified into any paleoclimate simulation, immediately after the pattern of continents and oceans, is the vegetation types that will cover each grid box. No model currently presupposes the ability to modify those vegetation types in response to climate change, nor should models bother trying so long as a CSM is restricted to a relatively short simulation. We expect that such a vegetation model will be needed before the model of everything is truly complete, and we expect that building it will be a very difficult problem.

Outlook for the future

There is every reason to believe that the sophistication of our climate models will continue to increase over the next decades. Ongoing improvements in our computational resources will allow climatic models to incorporate increasingly realistic levels of detail at the same time that a burgeoning corps of climatologists is uncovering those essences of climate which will provide the bases for the models of the future. Vast and continuing increases in our stores of climatic and climate-related data – owing significantly to advances in remote sensing technology – will contribute many of the terrestrial and oceanic observations necessary to determine boundary and initial conditions for future models. With these advances in climatic theory and computational resources, as well as in the type and quantity of available data, climatologists will develop, refine and apply a hierarchy of CSMs. These CSMs will couple the oceans, vegetation, ice and sea ice to the atmosphere, and they will be used to describe, predict and explain climatic processes and phenomena over a wide range of geographic scales.

MONSOONS AND MONSOON CLIMATE

Monsoon regions

The monsoon broadly refers to an atmospheric phenomenon in which the mean surface wind reverses its direction from summer to winter. However, the monsoon is popularly used to

denote the rains without reference to the winds. The term “monsoon” has its origin from an Arabic word meaning season. In English, the original Arabic word is spelled in several ways, such as, “mausam”, “mausem”, “mausim”, “mawsim” and “mausin”. The term was used by seamen, several centuries ago, to describe southwesterly wind during summer, and northeasterly wind during winter over the Arabian sea. Along with progress in meteorological sciences, more regional circulations have been categorized as “monsoonal”; they are based on both wind and rainfall characteristics. Monsoonal regions over the globe are generally identified by certain characteristics of surface circulations in January and July as laid down by C.S. Ramage. These include a shift in wind direction by at least 120°, average frequency of prevailing wind directions exceeding 40%, mean wind strength in at least one of the months greater than 3 m/s and fewer than one cyclone–anticyclone alternation in either month in every 2 years. Although these monsoon criteria do not include the rainfall explicitly, the seasonality in rainfall is the most important manifestation of the monsoon circulation. Most of the countries lying between 35°N and 25°S and between 30°W and 170°E (Figures M16a,b) satisfy the criteria of monsoons and, hence, are widely accepted as a part of the single most important monsoon domain on Earth. The monsoon is primarily an Asian phenomenon. However, numerous studies have established that monsoon circulation occurs in some other parts of the world, such as western Africa, northern Australia and North America at varying intensities. In the monsoon regions, wind blows inland from the cooler oceans toward warm continents in summer and from cold continents toward the warm oceans in winter (Figures M16a,b). Thus, broadly speaking the summer monsoons of both the hemispheres are very wet (Figures M17a,b) and winter monsoons are dry. Comparison of seasonal wind directions in Figures M16a and M17b demonstrates that the monsoon conditions are best developed in east and south Asia, with winds from southwest in summer and from the northeast in winter. Accordingly, those are known as the southwest and northeast monsoons respectively. The Asian summer monsoon consists of the Indian monsoon, and the east Asian monsoon, both of which are responsible for abundant summer rainfall in the region shown in Figure M17a. The Indian monsoon is effectively separated from the east Asian monsoon by the massive Himalayan mountain range. About 80% of the annual rainfall over India occurs during the southwest monsoon from June to September. Consequently, the summer monsoon is very important for the economy of India, which is predominantly an agricultural country. Usually, in eastern Asia, the winter monsoon wind is stronger than the summer monsoon wind while the opposite happens in south Asia.

West Africa also experiences a wind reversal to some extent, from southwesterly in summer (Figure M16a) to northeasterly in winter (Figure M16b). In the west coast of Africa there is heavy rainfall from June to August, although the rains actually commence in March–April. In some parts of eastern Africa near the equator there are two rainy seasons, one during March to May, popularly known as the “long rains”, and the other from October to November, which is termed as “short rains”. These rainy periods fall between the two African monsoon circulations.

Over north Australia there is a northwesterly flow of humid maritime air in the southern hemisphere summer (Figure M16b) from December to February, and the southeast trades in the southern hemisphere winter (Figure M16a). The east Asian winter monsoon and the north Australian summer monsoon are

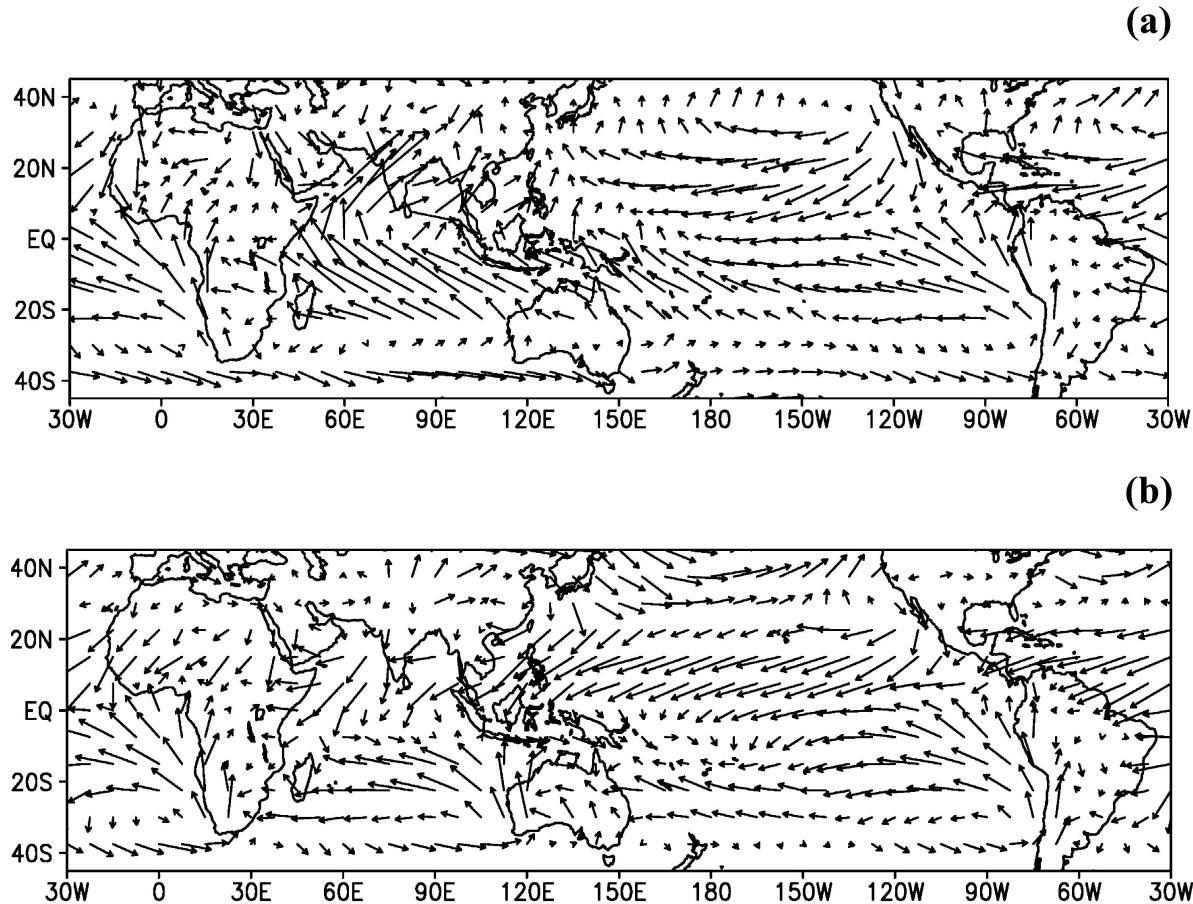

Figure M16 Surface wind (m/s) in the tropical belt (a) June, July and August average; (b) December, January and February average based on NCEP/NCAR reanalysis.

intermingled because the dry winter air of the northern hemisphere flows across the equator toward the southern hemisphere continents, picking up moisture from the warm tropical oceans to become the wet monsoon over north Australia.

The southwestern part of North America is also considered to be monsoonal. Here the surface zonal wind is observed to change from an easterly in January to westerly in July. There is a pronounced increase in rainfall over large areas of southwestern North America and southern Mexico from June to July, although the summer rains may last till September. This region also experiences significant winter rainfall.

Based on recent data, studies justify the existence of summer monsoon circulation over the subtropical south American highland. In southern hemisphere summer, distinct rainfall enhancement occurs over the central Andes and the southern parts and north coast of Brazil.

Important features of planetary scale monsoon

In 1686 Edmund Halley explained the Asiatic monsoon as resulting from thermal contrasts between the continent and oceans. In simple terms one may compare the monsoon circulation to a land-sea breeze occurring on larger spatial and temporal scales. In summer the continents surrounding the Arabian

sea begin to receive large amount of heat, due both to solar insolation and the heat emitted from the Earth's surface; consequently, by the end of May, a trough of low pressure develops over a large area from Somalia to Pakistan and northwest India. This is usually known as the heat low. It is accompanied by subsidence and hence fine weather in general. The southerly wind, after crossing the equator, turns to the east under the influence of the Coriolis force and blows over the Indian subcontinent as a southwesterly monsoon wind (Figure M16a) in summer. This current appears to originate in the southeast trades. George Hadley in 1735 incorporated the concept of the Coriolis force, which arises due to the rotation of the Earth around its own axis from west to east.

In the northern hemisphere summer, prior to the arrival of monsoon, a low-pressure zone forms around 5°N and 5°S on either side of the equator. This is referred to as a near-equatorial double trough. During the Asian summer monsoon the trough is located north of 15°N and is associated with cyclonic vortices. Surface air converging into these troughs ascends, accompanied by moist convection, and gives rise to unsettled weather, mainly clouds and rain. Climatologically, the heat low and the near-equatorial trough in the northern hemisphere form a continuous low-pressure belt, although the two systems give rise to opposite weather. Hence, the location of the low-pressure

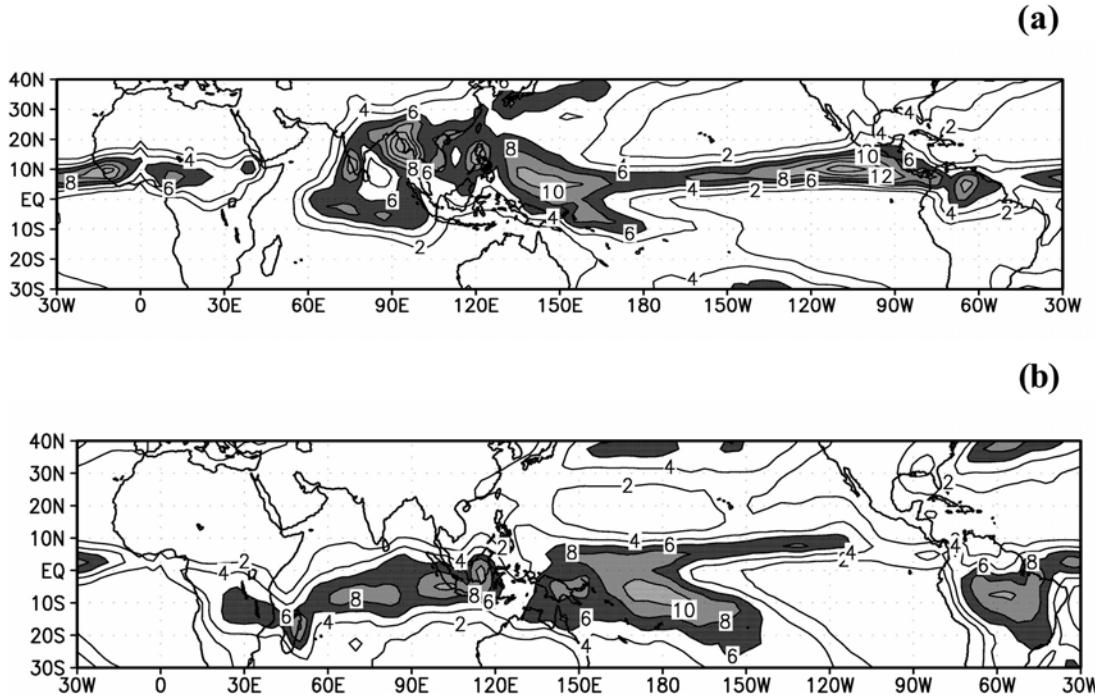

Figure M17 Accumulated rainfall (mm/day) in (a) northern (southern) hemisphere summer (winter) monsoon and (b) southern (northern) hemisphere summer (winter) monsoon based on Global Precipitation Climatology Project (GPCP) data updated by NCEP/NCAR.

belt over the Asian continent does not always coincide with maximum cloud and rains. Nevertheless, the huge land-mass of the Asian continent with wide east–west extension in the north and, primarily, an ocean to the south makes it geographically the most favorable for dominant summer monsoon flow compared to the other monsoons of the world.

The difference in the global distribution of heating gives rise to planetary-scale quasistationary waves in the tropics and subtropics, which form the most important component of both the summer and winter monsoons. The convective latent heat released forms the most important part of the differential heating, and globally the course of maximum rainfall follows that of convective heating. As shown in Figures M17a and M17b, the maximum precipitation bands occur at around 10°N and 10°S in the northern and southern hemisphere summers respectively. The monsoonal regions receive most of the rainfall due to the seasonal migration of the Intertropical Convergence Zone (ITCZ). This is a relatively narrow low-latitude zone in which the northeast and southeast trade winds originating in the northern and southern hemispheres respectively converge. The mean position of the ITCZ is somewhat north of the equator and it moves northward in the northern summer and southward in the southern summer. The ITCZ may not be the zone of organized moist convection always, especially over the Asian region. In this context it is convenient to use the term maximum cloud zone (MCZ) which is a bright cloud band of about 10° longitude width spreading along the latitude circles. There are two favorable locations of the MCZ; one within 15°N and 25°N latitudes over the land and another over the equatorial region (Figure M17a) at about 5°N have been identified. Successive generations of northward epochs of MCZ in the equatorial region pushes it to about 20°N in July–August from its mean

position near 5°N. The northward progress of MCZ in surges is akin to that of monsoon rains over India.

Convection is best represented by low values of outgoing longwave radiation (OLR). A comparison of Figures M18a and M18b indicates the seasonal variation of low values of OLR, which is large over the monsoon regions. Specifically in the case of the Asian summer monsoon between the meridians 70°E and 110°E, the belt of low OLR extends over a large area from 5°S to 35°N, while for the rest of the monsoonal region it is confined to a narrow latitude belt (Figure M18a).

Each monsoon appears to have a dominant circulation either in a north–south or in the east–west direction, with a rising branch located near a heat source, and is associated with upper-level divergent circulation. Similarly, the descending branch lies over a heat sink. The north–south and east–west dominant circulations are popularly called the Hadley and Walker circulations respectively. Generally, the velocity potential field is used to depict divergence and convergence centers in the atmosphere. As shown in Figure M19a, in July the upper-level divergence circulation is prominent over the Asian monsoon region accompanied by convergence centers on both sides in the east–west direction as a part of the Walker circulation. This center of divergence is responsible for spillover of mass from the Asian summer monsoon region in all directions. Thus the Asian summer monsoon is supposed to have a profound impact on the global atmospheric circulation. In the northern hemisphere winter the center of divergence shifts to the south over the north Australian region, as shown in Figure M19b. In the northern hemisphere the Walker and Hadley type overturnings are observed to be prominent in summer (Figure M19a) and winter (Figure M19b) respectively.

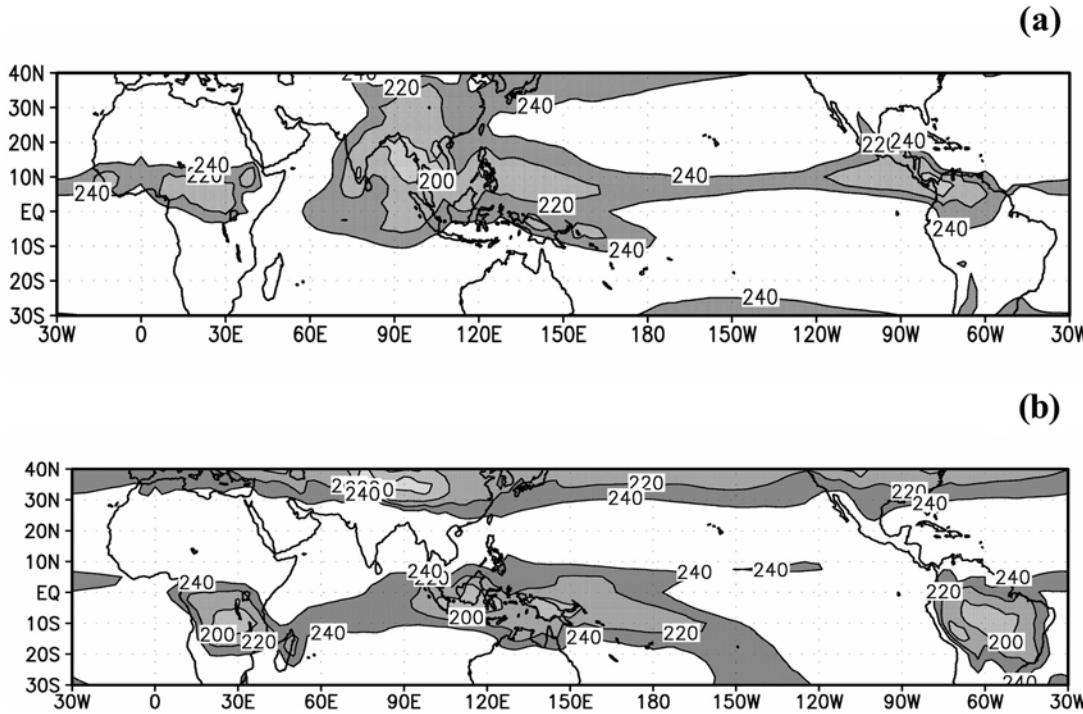

Figure M18 Same as in Figure M16 except for outgoing longwave radiation (W/m^2).

Important features of regional monsoons

The principal components of the Indian summer monsoon are the monsoon trough, the cross-equatorial low-level jet over coastal Africa, the Mascarene High, the Tibetan anticyclone and the tropical easterly jet stream at the upper level, monsoon disturbances and the cloud cover which gives rise to rainfall. The Western Ghats and the Himalayan mountains help in the ascent of moist air, and this gives rise to heavy orographic rains. Around July the monsoon activity is most pronounced, and the low-pressure area is intense, extending from north Africa to northeast Siberia. At this time a trough lies over north India with its axis extending from a place in northwest India to the northern tip of the Bay of Bengal running almost parallel to the Himalayas. This is referred to as the *monsoon trough*. The pressure gradient is strong south of this trough. Simultaneously, in the southern hemisphere, off the coast of Madagascar, a region of high pressure persists giving rise to anticyclonic circulation. This is known as the *Mascarene High*. The *cross-equatorial low-level jet* is most pronounced at a height of about 1.0–1.5 km and its major part penetrates into east Africa during May. Subsequently, it crosses the Arabian Sea and reaches the Indian west coast. Due to significant boundary layer exchange processes between the ocean and the atmosphere, there is an abundant supply of moisture to the Indian summer monsoon. The Tibetan plateau acts as a source of heat in summer and as a sink in winter. The heating of this elevated landmass in summer leads to the development of an intense anticyclone in the upper troposphere, which is popularly known as the *Tibetan Anticyclone* with strong east-northeasterly flow over north India. Here deep convection exists along with strong vertical wind shear. Monsoonal circulation is also accompanied by a

variety of cyclonic disturbances; especially over the Indian and adjoining oceanic region one observes the *onset vortex*, *mid-tropospheric cyclones*, *offshore vortices*, *lows*, *monsoon depressions* and other cyclonic disturbances of higher intensity. Observations show that most of the remnants of tropical cyclones from the South China Sea under favorable atmospheric conditions intensify to monsoon depressions. Studies also show that the horizontal and vertical wind shears of the mean monsoon flow in the presence of deep convection supply energy for the growth of monsoon disturbances.

The east Asian monsoon consists of a monsoon trough in the South China Sea and western Pacific, a cross-equatorial flow around 100°E, the cold anticyclone in Australia, the subtropical high in the western Pacific, the upper-level northeasterly flow, the convection along the monsoon trough and the midlatitude disturbances. In the middle of June the ITCZ is normally prominent over India, corresponding to an active phase of the Indian monsoon, and at the same time the subtropical convergence, which is called *Mei-yu* in China or the *Baiu* frontal zone in Japan, is most active, especially around Japan.

For the west African monsoon, the major components are the low-level southwesterly wind over the coastal areas of the Gulf of Guinea flanked by northeasterly winds to its north. The African easterly jet and tropical easterly jet are the dominant middle- and upper-level atmospheric flows in this region. With the change of season from summer to winter, there is no complete reversal of wind direction over the west coast of Africa (Figures M17a and M17b) as in the case of the Indian monsoon. The boundary between the southwesterly and northeasterly winds is known as the intertropical discontinuity in west Africa. The major rainfall in the east African monsoon is due to the north-south movement of the ITCZ.

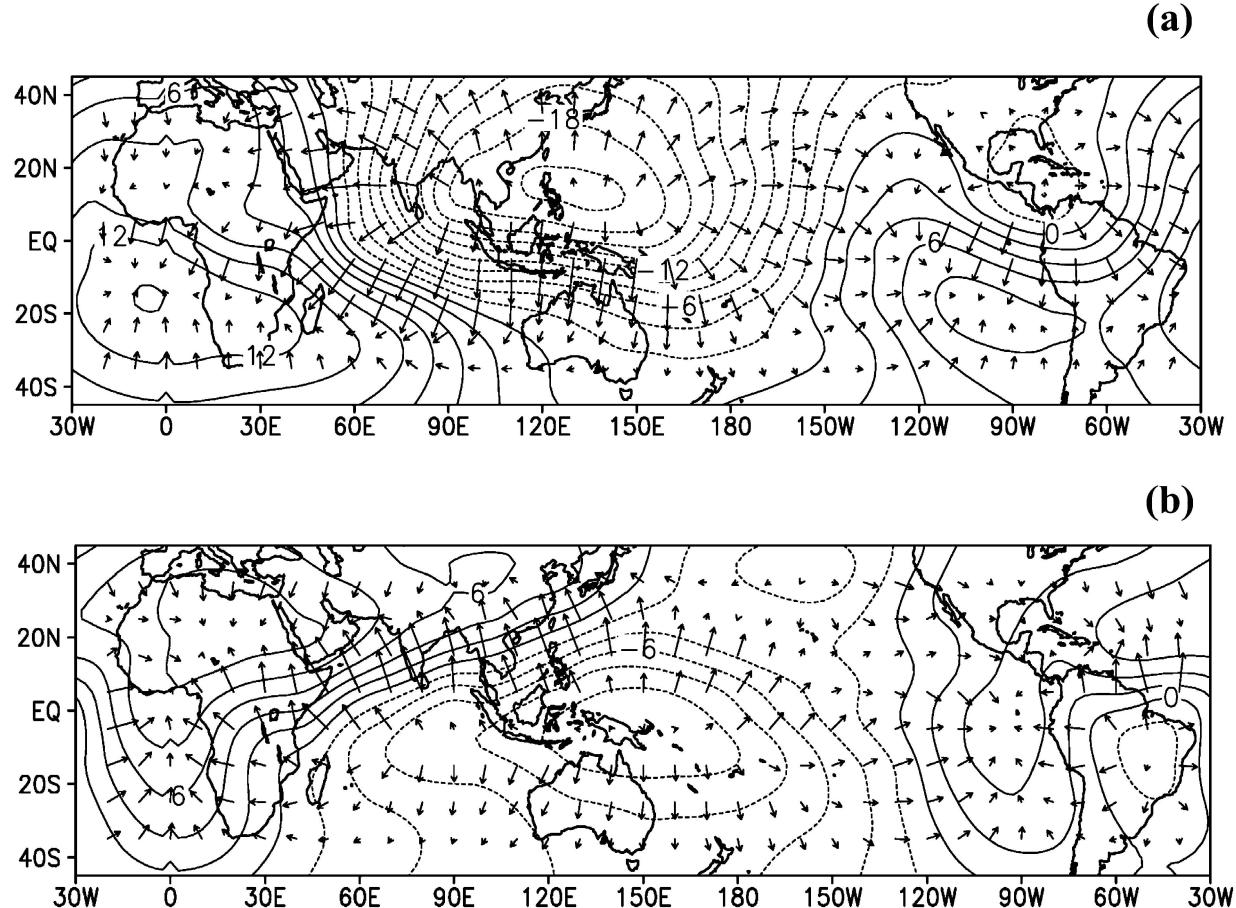

Figure M19 Divergent wind and contours of monthly mean velocity potential ($10^6 \text{ m}^2 \text{ s}^{-1}$) at 200 hPa (a) July and (b) January based be NCEP/NCAR reanalysis.

There are many similarities between the Asian summer monsoon and the northern Australian monsoon, although in general the latter is less intense. The ITCZ across northern Australia, near-equatorial upper-level easterlies and lower-level westerlies, cross-equatorial flow, tropical cyclones and monsoon depressions are the important components of the Australian monsoon. The southern hemisphere near-equatorial low lies to the south of the ITCZ over northern Australia. This low-pressure area is referred to as the monsoon trough and the corresponding westerlies are the north Australia monsoon winds.

The North American monsoon domain is considered to be large, as it spreads over much of the southwest United States, northwest Mexico and even Central America. The eastern north Pacific ITCZ between 120°W and 80°W migrates northwards (Figures M17a and M17b) in summer and the corresponding zonal wind becomes westerly at the lower level. At the upper level the zonal wind is easterly. The opposite happens in the winter. Over the North American Arctic region there is a seasonal reversal of wind direction and technically it may be considered to be monsoonal.

The occurrence of South American summer monsoon circulation can be shown by considering the difference between the prevailing surface wind and its annual mean. In the southern

hemisphere summer this anomaly flow from the sub-Saharan region, after crossing the equator, becomes northwesterly along the eastern side of the Andes. In winter the anomaly flow reverses its direction. The seasonality of surface wind over this region is not normally noticed because of the fact that the easterly trade winds prevail over the tropical Atlantic throughout the year (Figures M16a and M16b).

Intraseasonal and interannual variabilities

The monsoon passes through different phases, such as its onset, active periods, breaks and withdrawal, which do not have any regularity. There are annual variations in the dates of onset and withdrawal of the monsoon at a place, and also in the duration and intensity of the active and break conditions of monsoon. The normal duration of the Indian summer monsoon is about 4 months starting from 1 June. It begins to withdraw from the northwest part of India by the middle of September. The extreme dates of onset of India summer monsoon is found to be as early as 11 May and as late as 15 June. Based on the temporal rainfall distribution at a particular place, there is a statistical method for delineating the normal dates for onset and withdrawal of monsoon at that place. The date of onset of monsoon over the southern tip of India every year is based on a

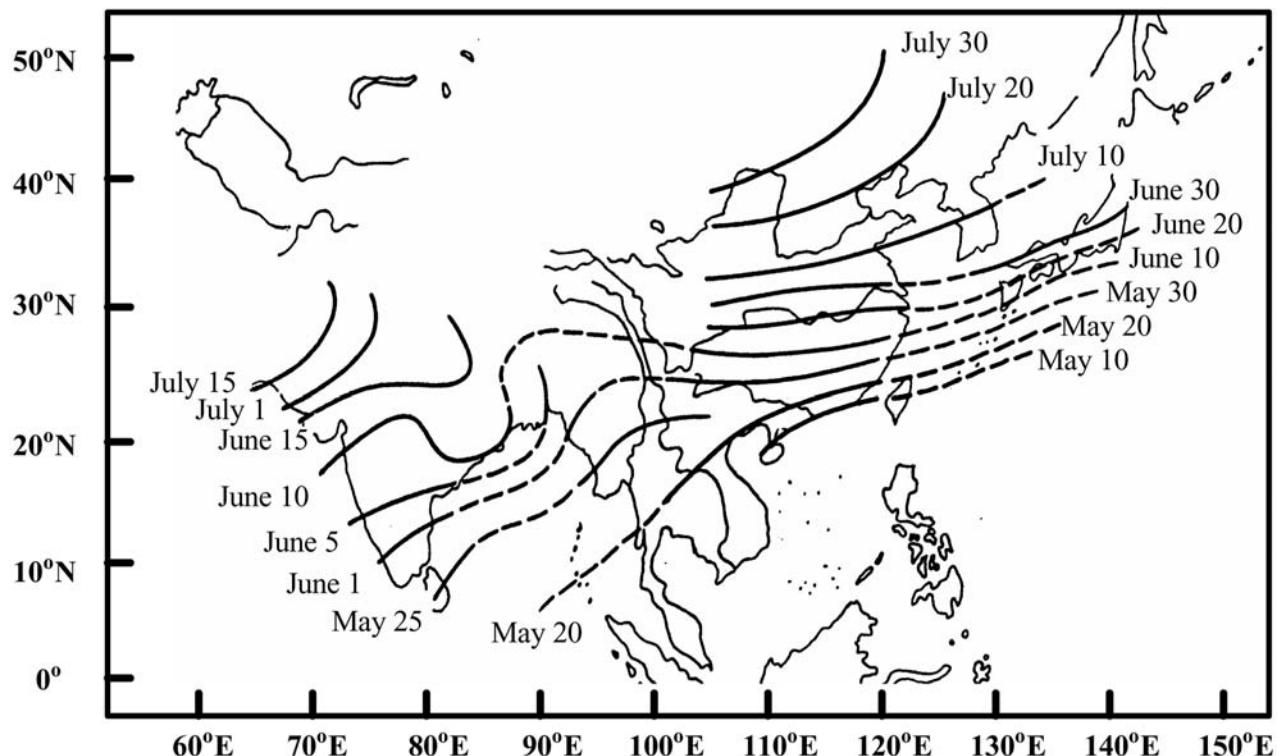

Figure M20 Mean dates of onset of Asian summer monsoon (based on Figures 3.1 and 3.9 in Rao (1976) and Chang and Krishnamurti (1987) respectively).

working rule by taking into account the continuously accumulated rainfall for certain days over certain meteorological stations in the west coast of southern India. Figure M20 shows the normal dates of onset of the summer monsoon at different places along with the northward progress of the rain belt over the Asian landmass. By mid-July the whole of India is observed to be covered by the summer monsoon. The withdrawal of the monsoon from India is slower than the onset; in fact it is difficult to know when southwest monsoon ends and the northeast monsoon begins over the extreme southern part of India.

The entire duration of the monsoon does not exhibit any uniformity or regularity in weather systems. During a season there are periods of active rainfall and also there are continuous days of no rainfall, called a “break”. Normally, monsoon breaks are accompanied by cessation of rainfall in central and the adjoining parts of India, and an increase in rainfall over northeast India and foothills of the Himalayas. Observations show that, during breaks, the monsoon trough usually shifts northward to the foothills of the Himalayas and surface pressures are above normal over central parts of India. Prolonged monsoon breaks may lead to severe droughts and hence have disastrous effects. Thus, during a monsoon season, the characteristics and duration of weather systems and the amount and distribution of rainfall vary. Such intraseasonal variations in the Indian summer monsoon circulation and rainfall are the most important aspects of the monsoon.

The monsoon of a year is not identical with the monsoon of another year in all aspects. There are year-to-year variations in the strength of circulation and also in the associated rainfall at

a place. It is observed that the mean rainfall over India during June to September in a year is about 88 cm with a coefficient of variation of 10%. Thus the amount of Indian summer monsoon rainfall (ISMR) equal to or more than 110% and less than 90% of the mean value are taken as excess and deficient rain respectively, and that equal to or more than 90% and less than 110% is normal. This annual variation in ISMR averaged over the whole of India may seem to be small, but its impact is high because of large spatial variations in the annual rainfall. The coefficient of variation of annual rainfall between different parts of India varies between 12% and 45%. There are occasions when some parts of the country experience deficient rain and drought, although the mean monsoon rainfall over the country as a whole is normal or in excess. The opposite also happens. Such temporal and spatial variations in the rainfall make the agriculture and the economy of India most vulnerable to the summer monsoon.

Variabilities of the Indian summer monsoon in the interannual and intraseasonal scales are scientifically intriguing. The exact reasons for such variations are not yet known. It is well known that changes in weather occur due to atmospheric instabilities. It is also known that the dynamic processes occurring in the atmosphere are nonlinear in nature, involving interactions between different spatial scales starting from few kilometers to hundreds of kilometers. Thus, “internal dynamics” play a very important role in the interannual variations of the seasonal mean circulation and rainfall. Secondly, the slowly varying “surface boundary conditions”, such as the sea surface temperature (SST), soil moisture, sea ice, snow extent and

depth, and land surface conditions play very important roles in the interannual variations of the ISMR. The exact physical processes responsible for the interannual variation of ISMR are not yet known. General circulation models (GCM) are increasingly used as convenient scientific tools to design and conduct sensitivity experiments on state-of-the-art computer systems for understanding the nonlinear processes leading to such variations. Large-scale field experiments using sophisticated sensors fitted to ships, aircraft, balloons and weather satellites yield good-quality meteorological data which help in understanding the evolution of weather systems. They are also needed for preparing reasonably accurate initial data for numerical weather prediction (NWP) models.

The Asian summer monsoon circulation is very different from other monsoons in its intensity, accompanying rainfall and its intraseasonal and interannual variabilities. A detailed analysis of satellite imagery indicates that the Asian summer monsoon is peculiar in having the double MCZ (one over the continents and the other over the seas) and also in the large meridional extent of low OLR spanning over 30° to 40° latitudes. It is believed that understanding the relationship between the continental MCZ and the oceanic MCZ may help a great deal in understanding the interannual and intraseasonal variations of ISMR.

Forecasting the Indian summer monsoon rainfall

Although the Indian summer monsoon is the most dominant feature of the atmospheric circulation, and although its annual appearance is certain, the most challenging task is forecasting its onset dates at different places, for active and break periods, withdrawal dates and above all the amount and spatial distribution of rainfall. Forecasts of rainfall at all time scales, such as short-range (up to 2 days), medium-range (between 3 and 10 days) and an extended range (a month to a season) are important. These involve the detailed understanding of the interaction between different physical processes, vast network for data collection, improved data assimilation procedures, sophisticated coupled ocean atmosphere models and the availability of immense computing power. The accuracy of the initial atmospheric variables is very important for the short-range forecasts, while both the initial atmospheric conditions and changes in the surface boundary conditions play very crucial roles in the forecasting of monsoons in the medium-range. In the long-range forecasts the variations in the slowly varying boundary conditions matter the most. Efforts are going on to forecast the Indian summer monsoon and its associated rainfall with reasonable accuracy by numerical weather prediction models at least a week in advance. As the mesoscale phenomena are very crucial, high-resolution regional models are nested to global models. They are best suited for forecasting monsoon rainfall up to few days with greater skill.

Forecasting the seasonal mean monsoon rainfall a couple of months ahead is very useful for farmers and planners as well. Based on the information of favorable and unfavorable predictors, a parametric model is generally used for a qualitative forecast of seasonal mean rainfall. Other statistical models, such as multiple-power regression models, dynamic stochastic transfer models, principal component regression models and models based on neural network technique are being tried for quantitative forecasting of ISMR for the whole of India, as well as for some of its homogeneous regions, such as northeast, northwest and peninsular India. These models depend on the long time

relationship of some well-identified predictors such as the El Niño, Southern Oscillation Index, Eurasian and Himalayan snow covers, South Indian Ocean and Arabian Sea SST, Indian Ocean Equatorial Pressure, Central India temperature, northern hemisphere temperature and pressure, etc. with ISMR. The statistical models play a very important role in the long-range forecast of ISMR because the interannual variation of ISMR has not been successfully simulated by most of the NWP models. However, statistical models have their limitations, especially when the predictors are large in number as in case of ISMR. Changes in the global and regional circulation patterns may generate temporal variations of several predictors and hence affect their relationship with ISMR.

Because of the chaotic nature of the atmosphere there is a limitation of about 2 weeks in the deterministic prediction of weather. However, the seasonal mean monsoon circulation is potentially more predictable because of the slowly varying surface boundary conditions. The internal dynamics also affects the monsoon circulation. This makes the prediction of Indian summer monsoon very difficult. Intercomparison of the results of a number of GCM indicates that the simulation of ISMR is more difficult than the rainfall over the rest of the tropics. This is attributed to the occurrence of the double MCZ over the Indian summer monsoon region, one above the continent and the other over the Indian ocean. The successive fluctuations of the MCZ between these two favorable positions is found to be a major limitation for most of the GCM.

Oceans cover about three-fourths of the Earth's surface, and water has a much greater capacity for absorbing and storing heat energy than any other material on Earth. Thus the oceans have large memory. Hence, the interactions between the ocean and atmosphere have a crucial role in determining the state of the atmosphere. Results of sensitivity experiments show that the Pacific SST influences monsoon circulations more than other surface boundary conditions. Therefore, coupled ocean-atmosphere models are very essential for extended-range monsoon forecast by numerical methods. Such models also need proper parameterization of the land surface processes and cloud-radiation feedbacks. Ensemble simulations obtained from a combination of different GCM may help to yield reasonable forecasts of Indian summer monsoon.

The influence of global warming on the monsoons in general, and the Indian summer monsoon in particular, is not very clear, since the former occurs in the time-scale of a century. In general, global warming is expected to intensify the hydrological cycle and hence the monsoon rainfall. However, considering the limitations of GCM in simulating ISMR and the large time-scale of model integration, the different projections of Indian summer monsoon arising due to global climate change should be interpreted intelligently.

MONTREAL PROTOCOL

An international agreement for the protection of the ozone layer was initiated in 1985 in Vienna, Austria. Details were defined in the *Montreal Protocol on Substances that Deplete the Ozone Layer* that was signed in 1987 and ratified in 1989.

The substances defined are CFC, HCFC, HBFC, halons, carbon tetrachloride, methyl chloroform, and methyl bromide. The phase-out time for these was defined in the Montreal Protocol, with appropriate changes made at Vienna in 1995, Copenhagen in 1996, and Beijing in 1999. In all cases different schedules were applied to developed and developing countries.

The agreement to reduce production of ozone-depleting substances has been successful. Public concerns, political action, and industrial innovation, including the identification and production of appropriate alternative chemicals, has, in most cases, seen the phase-out meet or exceed the provisions of the Montreal Protocol.

The complete text of the Protocol including adjustments and amendments is available at the UN Environment Program site listed below.

MOUNTAIN AND VALLEY WINDS

There is a special category of local or tertiary winds that are directly related to the topography. Sir Harold Jeffreys called them *antirropic winds* because of the dominance of friction in their thermodynamics. Known as mountain and valley winds or breezes (Figure M21), they are diurnal in character and most obviously operative in otherwise calm, clear weather.

At night on the high mountain slopes, the air cools rapidly by radiation and thus becomes denser; it flows downhill into the valleys, gaining velocity and momentum, as a *katabatic wind*. A similar cold wind often flows down the surface of a glacier. This nightly drainage of cool air from mountain slopes may lead to important temperature inversion in the high plains, e.g. of Colorado or central Switzerland, leading to extremely cold nights. In high plains of the central Rockies the basins at 2500–2800 m elevation are treeless and known as *parks*, although the actual tree line is much higher (3000–3400 m), and the slopes carry forests of conifers and aspen: the cold layer below the inversion predicates what might be called an *inverted tree line*.

In the daytime the mountain slopes are warmed by insolation and the breeze begins to flow upslope, usually beginning about half an hour after sunrise and continuing until half an hour before sunset. It may reach a maximum of 6 m/s (12 knots) up sunny slopes but much less on the northern slopes. In depth the air flow may exceed 150 m increasing uphill. This type of flow is called an *anabatic wind*.

According to Defant (1951), an additional factor was suggested by Wagner. A pressure gradient from the plain to the valley must exist during the day, whereas a reverse gradient must develop at night. Equalization of the pressure differences must

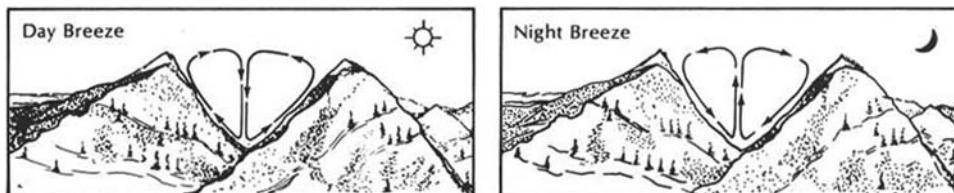

Figure M21 Schematic diagram illustrating mountain wind (breeze) and valley wind (breeze).

obtain at effective ridge altitudes, so that largest differences can be expected in valley floors. The pressure gradient is then due to the combined effects of the valley bottom slope and the effective ridge altitude; in practice one has two wind systems, a thermal slope circulation and a valley wind.

The following sequence of mountain and valley winds may be identified:

1. Sunrise: onset of upslope winds; continuation of mountain wind. Valley cold, plains warm.
2. Forenoon (about 0900); strong slope winds, transition from mountain wind to valley wind. Valley temperature same as plains.
3. Noon and early afternoon; diminishing slope winds, fully developed valley wind. Valley warmer than plains.
4. Late afternoon; slope winds have ceased, valley wind continues. Valley continues warmer than plains.
5. Evening; onset of downslope winds, diminishing valley wind. Valley only slightly warmer than plains.
6. Early night; well-developed downslope winds, transition from valley wind to mountain wind. Valley and plains at same temperature.
7. Middle of night; downslope winds continue, mountain wind fully developed. Valley colder than plains.
8. Late night to morning; downslope winds have ceased, mountain wind fills valley. Valley colder than plains.

MOUNTAIN CLIMATES

Mountain climates show great variation in the values of climatic elements over a short distance due to elevational differences, complex topography, and the physical presence of the mountains themselves. Whereas mountain climates are usually characterized by their spatial variety, the same causes often lead to large temporal variation as well.

It has been estimated that mountains or high plateaus occupy 20.2% of the Earth's land surface (Louis, quoted by Barry, 1992) and influence the life-support systems of 400 million people (Ives, 1981). Messerli (personal communication, 2001) claimed

that 10–26% of the world's population lived on or within 50 km of mountains. The most prominent mountain areas include the Cascade–Sierra Nevada and Rockies of North America, the Andes of South America, the Alpine system of Europe, the Himalayas and Tibetan Plateau and Caucasus of Asia, the east African Highland, and the mountain backbones of Central America, Borneo, New Guinea, and New Zealand. There are many less prominent highland areas that should be recognized, such as the ice plateau of Greenland and Antarctica and the mountain ranges in both, together with elevated regions of older geologic materials, exemplified by the Appalachians of North America and the uplands of Great Britain and Scandinavia.

The variety of climates in mountain areas leads to confusion in climatic classification, therefore such areas are usually either excluded or grouped together under a broad category such as "highland climate". Modern versions of the Köppen classification, for example, use the letter H for mountain climates (Christopherson, 2002); the H standing for the German *hochgebirge* (high mountain). No quantitative definition of mountain climates has ever been given but, if one were needed, it would include the characteristic of rapid spatial change of climate classes within complex terrain. Such a characteristic would include not only areas currently classified as H but also areas such as the central highlands of Madagascar, which sometimes are attributed to other classes in the Köppen system.

Although humans have noted some of the effects of mountain climates whenever they have had contact with elevated areas, the scientific study of them dates only from the eighteenth century. The investigations of H.B. De Saussure, started in 1787, assured him of recognition as the first mountain meteorologist (Barry, 1978). Numerous mountain meteorological observatories were established in the nineteenth century, many of which were later closed due to lack of funds or for other reasons. Barry (1992) lists 30 of the most important observing stations, many of which have long records and continue to collect data through to the present time. The continuing importance of mountain climates is demonstrated by the appearance of excellent reviews of the subject such as those of Barry (1992) and Whiteman (2000). Additionally, there are more frequent conferences on the subject both in Europe and in North America (American Meteorological Society, 2000), and a number of national and international research programs into mountain meteorology are currently operating or planned.

Variety in mountain climates

Geographic variety in mountain climates is seen both on the global scale and on meso- and local scales. On the global scale the nature of mountain climate is determined by the latitude of the site as well as other factors that influence most climates, such as proximity to the ocean or features of the general circulation of the atmosphere. Table M4 gives some idea of the range of temperature and precipitation values found at high-altitude stations at different latitudes. La Paz at 16°S has a very small annual temperature range, whereas the range at Lhasa (29°N) is rather larger and similar to the midlatitude station at Longs Peak, Colorado. The Antarctic station of Vostok (which might also be regarded as a high-latitude climate) has an even larger annual temperature range but is more noteworthy for its extremely low temperatures. The precipitation regime at La Paz is influenced by the southward movement of the Intertropical Convergence Zone giving a maximum of rainfall between December and February. The same phenomenon in conjunction with the Asian monsoon system is

Table M4 Monthly mean temperature (°C) and total precipitation (mm) at selected high-altitude stations

responsible for the maximum of precipitation at Lhasa between June and September. Longs Peak shows a summer maximum of precipitation owing to the frequency of thunderstorms at this season. There is very little measurable precipitation in Antarctica where the annual value is believed to be less than 6 in (150 mm; Trewartha and Horn, 1980).

On smaller geographic scales mountain climates are affected by the rapid change of temperature with height, aspect, particular wind systems, and the barrier effect of mountains as they act with respect to precipitation values. The complexities of mountain climates are represented by surface energy budget values. All of these factors will be discussed below.

Characteristic features of mountain climates

Radiation

The amount of global solar radiation received at the Earth's surface increases with altitude due to the decreased radiation through the atmosphere and atmospheric water vapor that is concentrated at the lower part of the atmosphere. Sauberer and Dirmhirn (quoted by Barry and Van Wie, 1974) note an increase in global solar radiation in the Austrian Alps from 650 ft (200 m) to 9840 ft (3000 m) of 21% in June and 33% in December. The increase is approximately exponential and occurs in both cloudy and clear skies. However, varying cloud amounts in mountain areas can sometimes disturb this pattern (Greenland, 1978). The increase in radiation is most marked in the shorter wavelengths. Reiter and Munzert (1982) observed that total ultraviolet radiation could be increased 1.4 times in January and 1.5 times in June, accompanying an altitude increase from 2296 ft (700 m) to 9840 ft (3000 m), using a 5-year observing period in the northern European Alps. The large variety of slope orientations and gradients give rise to a whole spectrum of different aspects in mountain areas, and it is the varying degree of radiation receipt on these slopes that essentially leads to the importance of aspect in mountain climates. At latitude 50°, for example, there is a fourfold difference in the radiation receipt on 45° slopes facing north and south (Barry and Van Wie, 1974). Variation of radiation receipt due to aspect can overshadow that due to any other cause, and leads to variation in temperatures, evaporation rates, and processes of the soil and vegetation growth. The specific location of long-lasting snow and ice patches is also associated with aspect.

Temperature

Since the atmosphere is heated principally by infrared radiation from the Earth's surface, air temperature usually decreases with altitude. The decrease varies in the free atmosphere from about $-2.7^{\circ}\text{F}/1000 \text{ft}$ ($-5^{\circ}\text{C}/\text{km}$) for saturated air to $-5.5^{\circ}\text{F}/1000 \text{ft}$ ($-10^{\circ}\text{C}/\text{km}$) for dry air and averages about $-3.2^{\circ}\text{F}/1000 \text{ft}$ ($-6^{\circ}\text{C}/\text{km}$). The air above mountain slopes is also influenced by latent and sensible turbulent heat flows and so the temperature changes with altitudes, or lapse rates, on slopes are often different from those in the free air (Coulter, 1967). Average lapse rates in mountain climates have also been shown to vary with season, global climatic zone and with airmass frequency (Barry, 1992).

The rapid change of temperature with height leads to a climatic zonation that, in some parts of the world, has been given a special nomenclature. Trewartha and Horn (1980) point out that in tropical Latin America four zones are recognized; these are Tierra Caliente (hot lands), Tierra Templada (temperate lands), Tierra Fria (cool lands), and Tierra Helada (land of

Figure M22 The west coast of the South Island of New Zealand from the top of Mount Tasman. The snow-covered mountain peaks give way to subtropical rainforest before sea level is reached.

frost). Each of these zones is associated with different types of vegetation or agricultural crops. Figure M22 displays a similar kind of zonation in the New Zealand Southern Alps. From the perpetually snow-covered slopes of Mount Tasman one descends through rainforest vegetation before reaching sea level.

Another important feature of temperature in mountain climates is related to the sinking downslope of radiationally cooled, relatively dense cold air that accumulates at the bottom of valleys and in mountain basins. The colder air at the lower elevations, and the relatively warmer air above, result in increasing temperatures with height, a situation known as a temperature inversion. Inversions are commonly formed at night but can last through the whole day, especially in winter, when radiative heating is not strong enough to disperse them. Stagnating cold air in valley bottoms can have the effect of trapping air pollutants.

The frequency of temperature inversions and the consequent higher temperatures at some distance up the slope can be so great as to cause generally warmer areas in midslope. These are called thermal belts and have been used to advantage by agriculturalists in many parts of the world (Dunbar, 1966). The center of the thermal belt in the European Alps is found to be between 330 and 1310 ft (100–400 m) above the valley in areas of relief under 1650 ft (500 m). In higher mountains the thermal belt is centered 1150 ft (350 m) above the valley floor in summer and 2300 ft (700 m) above it in winter (Barry, 1992).

Precipitation

A general global pattern of precipitation change with altitude has been noted by Lauscher (quoted by Barry, 1992). There is a general decrease of precipitation with elevation in equatorial latitudes, which is also seen, to a lesser degree, at polar stations open to a maritime influence. In the tropics, however, there is a maximum of precipitation at about 3000 ft (900 m). In midlatitudes there is a general increase of precipitation up to the highest altitudes at which observations are made at about 12 000 ft (3660 m).

This global pattern is often superceded by the effect of mountain barriers on the vertical flow of air and subsequent increase or suppression of precipitation formation processes. When air is forced to higher altitudes in its passage over a mountain, the air is cooled and condensation of water vapor often gives rise to precipitation formation on the windward side. This is sometimes

called orographic precipitation. Descending air on the leeward side of the barrier is accompanied by warming of the air, an increase in potential for evaporation, a decrease in relative humidity, and a decrease in the likelihood for precipitation formation. Dry areas on the lee side of mountain barriers are called rainshadow areas. These phenomena are found in many of the mountain areas of the world. The South Island of New Zealand is a good example of such orographic effects. On the windward side of the island at Milford Sound, annual precipitation is 245 in (6233 mm), whereas on the lee side in the interior plateau of central Otago the value decreases to 13 in (330 mm) at Alexandra (Garnier, 1958).

A complicating but important feature of mountain precipitation is the fact that much of it falls in the form of snow. The difficulty of measuring snowfall makes values of precipitation from the higher elevations of mountain climates less accurate than their lowland flat-terrain counterparts. In both environments it is hard to design a shield for precipitation gauges that suppresses local wind eddy currents and permits representative assessment of snowfall but, in addition, mountain observational sites are seldom representative of larger geographic areas. As a result it is often expedient to sample the water content of the mountain snowpack over snow courses set up in a systematic manner. As much accuracy in snowpack measurements as possible is necessary because many lowland areas depend on this water source for agricultural, industrial, hydroelectric energy, and domestic purposes. The frozen form of precipitation in mountain areas also adds immensely to their esthetic qualities in terms of such features as long-lasting snow cover and glaciers.

Wind

The decrease of the effect of friction between the Earth's surface and the movement of air in the free atmosphere causes wind velocities to increase with altitude. This effect is also noted from wind observations at high mountain stations although Wahl (quoted by Barry, 1992) found that for the European Alps mountain summit wind velocities are about half those at corresponding altitudes in the free atmosphere. Nevertheless, mountain areas exhibit some of the highest wind velocities anywhere on the surface of the planet – a gust of over 231 mph (103 m/s) having been recorded on Mount Washington, New Hampshire, where the annual average wind speed exceeds 31 mph (15.7 m/s; Smith, 1982).

More important than high wind velocities is the topographic influence of mountain barriers on winds. These barriers impose wavelike motion on airflow both in the horizontal and in the vertical planes. On the global scale, downwind of major mountain barriers, horizontal waves with wavelengths on the order of 3000 miles (4800 km) are established with their troughs to the lee of the mountain range. This is most pronounced in the northern hemisphere, resulting from the presence of the Rockies in North America and the Himalayas in Asia. A similar smaller-scale effect is noticed, however, east of the Andes in South America and in the New Zealand Southern Alps. In all cases the presence of the mountains has a marked effect on the climates downwind of them, particularly in causing rainshadow areas and, further downwind, regions of cyclogenesis or formation of cyclones. Waves are also imposed on airflow over mountains in the vertical plane. These vertical undulations or waves created by gravity acting on local variations in air density are sometimes called gravity waves (Whiteman, 2000). The effects of these waves can sometimes be noticed when lee wave, or

Figure M23 Lee wave clouds near Aviemore, South Island, New Zealand.

lenticular, clouds are formed on their crests, as illustrated in Figure M23. Wind phenomena in the lee of mountains are not limited to lee waves, however. Another interesting feature is a rotor effect that can give air movement at the surface back toward the mountain. This effect sometimes carries snow that can feed alpine glaciers and maintain their existence at latitudes that would otherwise be impossible (Johnson, 1980).

High-velocity winds in the lee of mountain ranges are also common features of mountain climates. These downslope winds may be warm or cold. The warm variety are called chinook winds in North America and föhn winds in Europe, and their warmth is due to compressional heating as the air moves downward to more dense parts of the atmosphere. "Chinook" is a North American Indian term meaning "snow eater", and signifies the large amounts of snow that can be melted by the wind, especially when it occurs in the spring (Brinkman, 1970). The wind storms at Boulder, Colorado, originally studied by Brinkman, have been found to be difficult to predict because of lack of upstream observational data but also because more than one synoptic-scale pressure situation can give rise to the storms (Leptuch et al., 2000). As in the case of the chinook winds, particular synoptic-scale pressure patterns are required for the establishment of the cold winds. These winds that have several local names are exemplified in Europe by the Bora winds of Croatia and Slovenia (parts of the former Yugoslavia). Besides a strong pressure gradient, their formation occurs when there is a damming up of cold air east of the mountains in the type area (Petkovsek and Paradić, quoted by Barry, 1992). Locally, under certain conditions, downslope winds can give rise to intense windstorms, causing much damage in populated areas (Miller et al., 1974). A windstorm in 1972 caused \$2.5 million damage in Boulder, Colorado (Whiteman, 2000).

The modification of wind flow direction is another important aspect of wind in mountain climates. Modifications include the lateral movement of air around obstacles, the channeling of air through topographically formed tunnels, and the altering of wind direction between that found in valleys and that above the ridge line. The fact that it is possible to have different wind regimes in different parts of mountainous topography is another noteworthy feature of mountain winds. When two or more regimes influence each other they are said to be coupled, but when they act as separate entities they are said to be uncoupled.

Some of the most frequent kinds of mountain winds are thermally induced. Downslope movement of cold air at night is

called katabatic flow, whereas upslope movement of a warm air during the day is termed anabatic flow. In the absence of strong synoptic-scale winds, mountain-valley wind systems can develop. The classic description of these involves the combined results of katabatic nighttime winds, giving rise to a downvalley wind best marked in the early morning. This is gradually stilled when radiative heating of slopes gives rise to anabatic winds. Air to feed these is drawn up the valley, leading to an upvalley wind system that is most noticeable in the early afternoon. More recent observational studies show the phenomenon to be very complex and involving compensatory winds at different levels and characteristic fluctuations in wind velocity (Barry, 1992). The theory of these wind systems has yet to be completely worked out but Whiteman (in American Meteorological Society, 1981) has made an important contribution to it in his study of the breakup of valley temperature inversions. Whiteman (2000) distinguishes four components of the overall mountain wind system; namely slope winds, along-valley winds, cross-valley winds, and mountain-plain winds. He comments that it is difficult to study the pure form of any one of these components because they interact with one another in various combinations and also with the winds of the larger-scale synoptic situation.

Surface energy budgets

The energy budget of the surface is an estimation of heat flow to and from the surface by radiation and by sensible and latent heat flows to and from the atmosphere, and by conduction of heat into and out of the submedium. The estimation of surface energy budgets often helps our understanding of a climate under consideration. Reiter (1982) has drawn attention to the importance on global climate particularly of sensible heat fluxes from the Tibetan Plateau, where a resulting large-scale wind circulation may be established. Reiter has described how anomalies of heat flowing from the Tibetan Plateau could set off significant interannual variability of monsoon circulation systems. Complete energy budgets of snow- and ice-free mountain area surfaces are difficult to estimate for any length of time and hence very few exist. Barry (1992), for example, while giving information on several others, tabulates only six studies, and all of these are for short periods. One of the few long-term studies (daily values for 1 year) for the New Zealand Southern Alps shows a positive net radiation to be used more or less in equal parts by sensible and latent heat flows, whereas ground heat flow is rather small (Greenland, 1973). These results, which relate to a shrub and grass surface, have been paralleled by shorter-term studies in similar environments such as Alaska (Wendler, 1971). However, the effect of aspect plays a large role in determining the radiation receipt, and therefore the energy budgets, of mountain areas, as has been demonstrated by Brazel and Outcalt (1973) for another Alaskan site. Cline (1997a) performed pioneering work on measuring the energy balances of melting snow surfaces at Niwot Ridge, Colorado. He found that, besides net radiation, surface flowing turbulent fluxes were an important source of energy for snow melt and could provide 25–54% of the energy needed. He has also developed a point energy and mass balance model of a snow cover (called SNATHERM) for use in alpine conditions (Cline, 1997b).

The energy budgets of snow and glacial surfaces of mountain areas are better known partly because their details are important for practical hydrological purposes. A summer study of the Peyto glacier in the Canadian Rockies indicates that heat flows are

generally toward the ice surface. These heat flows are used in melting the ice; 71% of the ice melt was from net radiation, 23% from the downward transfer of sensible heat, and 6% was from the downward transfer of latent heat in the form of condensation (Munro, quoted by Oke, 1987). These values appear to be generally representative as judged by the reviews presented by Patterson (1994). The difficult problems of aspect and surface heterogeneity still remain, however, and because of this several investigators have turned their attention to attempting to model the energy budgets of such surfaces. Dozier and Outcalt (1979) performed pioneering work in this area. With the advent of satellite data the heterogeneity of mountain areas becomes more approachable. Duguay (1994) has used remote sensing data to map the growing season radiation of the Niwot Ridge alpine site in Colorado. Researchers at the Institute for Computational Earth System Science at the University of California, Santa Barbara, are leaders in handling the large datasets of energy budget values and other data that result from the remotely sensed products. In another advance, Kumar et al. (1997) have extended the process of modeling topographic variation in solar radiation for use within a GIS environment. It is with respect to their surface energy budgets that mountain climates show one of their greatest degrees of variability.

Applied aspects of mountain climates

The increasing use of mountain areas by humans has stimulated the field of applied climatology in mountain regions. Studies have taken a wide variety of forms. These forms include the study of climate change and tourism, hydro-electric power potential, and marginal agriculture (Beniston, 1994), investigations of weather-related mountain hazards such as avalanches (Mock and Birkeland, 2000) and lightning (Peterson, quoted by Barry, 1992), examination of forest fire weather and smoke management, air pollution dispersion, and aerial spraying (Whiteman, 2000).

One topic of increasing importance is the development of systems to interpolate and extrapolate values of climatic variables in mountain environments. Such an endeavor is extremely useful in almost all applied aspects related to mountain climates. This development is particularly important because there will never be enough actual meteorological observations in mountain areas. Indeed there are fears that increasingly mountain observatories are being closed down for budgetary reasons (Beniston et al., 1997). Pioneering work has been performed on interpolation and extrapolation by researchers at the University of Montana who first developed a methodology called MT-CLIM and later refined it into a system called Daymet. These methodologies permit the interpolation and extrapolation of such variables as air temperature, solar radiation, and surface humidity from sparsely distributed observation sites to other parts of the terrain (Running et al., 1987; Glassy and Running, 1994; Kimball et al., 1997; and Thornton and Running, 1999). This work has been complemented by the development of a methodology, called PRISM (Parameter-elevation Regressions on Independent Slopes Model). PRISM is an analytical tool that uses point data, a digital elevation model, and other spatial datasets to generate gridded estimates of monthly, yearly, and event-based climatic parameters, such as precipitation, temperature, and dewpoint for interpolating precipitation values in mountain (and other) terrain (Daly et al., 1997). Ollinger et al. (1998) have also used regression techniques to establish the spatial variation of temperature and precipitation in the complex terrain of the northeastern United States.

Research programs in mountain climatology

Our knowledge of the characteristics of mountain climates has been achieved by the painstaking research of many individuals. However, in recent decades, as in many branches of the atmospheric sciences, it has been realized that significant further progress could be made by employing large integrated research programs in addition to the work of individuals and small groups.

Some noteworthy early programs of the 1980s included ALPEX that was focused on the European Alps and ASCOT that was developed in the United States in order to investigate the potential of mountain areas for air pollution. In more recent years the Special Observation Period of the Mesoscale Alpine Programme (MAP) in the European Alps was completed in the fall, 1999. MAP was possibly the most comprehensive field program to date documenting the influence of mountains on the atmosphere. MAP is likely to provide data and the development of new theory in years to come. The following are the goals of MAP as outlined on the website of the programme

- (1a) To improve the understanding of orographically influenced precipitation events and related flooding episodes involving deep convection, frontal precipitation and runoff.
- (1b) To improve the numerical prediction of moist processes over and in the vicinity of complex topography, including interactions with land-surface processes.
- (2a) To improve the understanding and forecasting of the life-cycle of Föhn-related phenomena, including their three-dimensional structure and associated boundary layer processes.
- (2b) To improve the understanding of three-dimensional gravity wave breaking and associated wave drag in order to improve the parameterization of gravity wave drag effects in numerical weather prediction and climate models.
- (3) To provide data sets for the validation and improvement of high-resolution numerical weather prediction, hydrological and coupled models in mountainous terrain.

Another recent field program was the Intermountain Precipitation Experiment (IPEX). This program, focused in the US Rocky Mountains, also had detailed and complex goals as described by the program leaders.

IPEX is a research program designed to improve the understanding, analysis, and prediction of precipitation over the complex orography of the Intermountain West of the United States. The goals of IPEX are to advance knowledge of the structure and dynamics of Great Salt Lake-effect and orographic precipitation, especially in and adjacent to the Wasatch Mountains of northern Utah; to better understand the relationships between orographic circulations and cloud micro-physics; to verify and improve data assimilation, numerical weather prediction, and radar-derived quantitative precipitation estimates over the Intermountain West; to explore the electrical structure of continental winter storms; and to raise awareness of mountain meteorology and the associated scientific and forecasting challenges at the public, K-12, undergraduate, and graduate levels (Schultz et al., 2002).

Programs such as MAP and IPEX clearly demonstrate the areas of concern and depth of investigation in modern-day studies of mountain climatology.

The future outlook

In mountain climatology, as with many other fields, the more that is discovered, the more new questions arise. In addition,

recent discoveries in mountain climatology have highlighted the increasing importance of the topic. For example, evidence suggests that late twentieth-century global-warming signals may be amplified in mountain climates. Temperature increases in parts of the European Alps of up to 2.0°C have been recorded. It has also been shown for the European Alps that temperature extremes shift by a factor of 1.5 for a unit shift in the global means of the twentieth century (Beniston et al., 1997). Beniston and colleagues have outlined the most pressing needs for further activities in the field. They advocate the encouragement of field studies including monitoring programs, an increase in the depth and breadth of the paleo-database, and more attention to the downscaling of climate models. The future appears to continue to be closely tied to the increasing human populations in and near mountains and the particular kinds of uses to which mountain lands are being put. The main activities include: (1) recreation; (2) timber production and watershed management; and (3) mining for mineral and energy production. Each of these activities carries with it particular, although sometimes interrelated, problems of mountain climatology.

Recreationists demand clean air and this, together with clean air legislation in some countries, provides the incentive for air-quality studies that examine pollutant transport, chemical reaction, and visibility studies. Avalanche potential prediction is another item of interest to recreationists. Mountain forest land management requires knowledge of mountain microclimate and climatic factors affecting growth rates and forest fire. Overall, whereas projection of future climates is a difficult task in itself, the task becomes even more complicated in mountain areas because of the complex nature of mountain climates. Increasing population growth, however, continues to raise the importance of understanding mountain climates.

NATIONAL CENTER FOR ATMOSPHERIC RESEARCH*

The National Center for Atmospheric Research (NCAR) was established in 1960 to serve as a center for atmospheric and related science problems. Its major sites are in Boulder, CO, at the I.M. Pei Mesa Laboratory and the Foothills Laboratory. It is operated by University Corporation for Atmospheric Research (UCAR) under a cooperative agreement with the National Science Foundation (NSF).

*The article is derived mainly from www.ncar.ucar.edu, where much additional information is given.

NATIONAL CLIMATE DATA CENTER/DATA SOURCES*

The National Climatic Data Center (NCDC) is part of the Department of Commerce, National Oceanic and Atmospheric Administration (NOAA), and the National Environmental Satellite, Data and Information Service (NESDIS).

The Weather Bureau, Air Force and Navy Tabulation Units in New Orleans, LA were combined and formed into the National

*This article is derived from information provided by the NCDC. The web source www.ncdc.noaa.gov provides much additional information.

Weather Records Center in Asheville, NC in November 1951. Authority to establish the joint Weather Records Center was granted under section 506(c) of the Federal Records Act of 1950 (Public Law 754, 81st Congress). The Center was eventually renamed the National Climatic Data Center. Data are received from a wide variety of sources, including satellites, radar, remote sensing systems, NWS cooperative observers, aircraft, ships, radiosonde, wind profiler, rocketsonde, solar radiation networks, and NWS Forecast/Warnings/Analyses Products.

The NWS's Cooperative Network, composed mainly of 8000 volunteer observers, has been recording daily records since the 1880s. Ships at sea have also been observing the weather essentially the same way for over 100 years. However, new observing systems have presented themselves as technology has advanced. As aircraft began to fill the skies, information on the upper atmosphere was needed. Balloon-borne instruments radioed data; radars began to probe clouds; rockets reached the fringes of the atmosphere; and weather satellites, both geostationary and polar orbiting, now continuously watch the weather. These data are all archived by the National Climatic Data Center.

Global weather and climate

The global weather and climate community has established a communications network to flash observations around the world in a matter of seconds. These data are supplied to NCDC by the National Weather Service's National Meteorological Center, the Air Force's Global Weather Center, and the Navy's Fleet Numerical Oceanography Center. NCDC also maintains World Data Center for Meteorology, Asheville. The four World Centers (US, USSR, Japan, China) have created a free and open atmosphere in which data and dialogue are exchanged.

The World Meteorological Organization, through its Resolution 35, has established the mechanisms whereby marine observations are exchanged among participating countries. This exchange is perhaps the prime example of country-to-country cooperation over several decades. However, to supplement all of the exchanges already listed, NCDC also maintains cooperative agreements with individual countries. In exchange for US

data and information, countries are glad to exchange their own data and information.

Publications

Climatological publications have been produced and disseminated for over 100 years and include:

Local Climatological Data (LCD) is produced monthly and annually for some 270 cities. The *LCD* contains 3-hourly, daily, and monthly values. The annual issue contains the year in review plus normals, means and extremes.

Climatological Data (CD), also produced monthly and annually, contains daily temperature and precipitation data for over 8000 locations. The *CD* is published by state or region (New England), with a total of 45 issues produced each month.

Hourly Precipitation Data (HPD) is produced monthly. It contains data on nearly 3000 hourly precipitation stations, and is published by state or region.

Storm Data (SD) documents significant US storms and contains statistics on property damage and human injuries and deaths.

Monthly Climatic Data for the World (MCDW) provides monthly statistics for some 1500 surface stations and approximately 800 upper air stations.

In addition to routine publications, NCDC also generates many nonperiodicals including normals, probabilities, long-term station and state summaries, and several atlases covering the land areas, coastal zones, and oceans of the world.

NORTH AMERICA, CLIMATE OF

The climate of North America ranges from the frost-free tropical of southernmost Florida to the perennial ice and snow of the northernmost islands of the Canadian Archipelago, from the rain-drenched mountains of the northwest coast to the drought-ridden deserts of the southwestern United States. Within the limits set by these extremes is a variety of climates that results from the interplay of atmospheric systems with the complex geography of this large landmass. Its great size (about 25 million km²), the span of latitudes from about 25° to 80°, "the configuration and alignment of its shorelines, plus the distribution of major landform regions have generated a diversity of climates that very closely resemble those of the much larger continent of Eurasia within the same latitudes.

The scattering of persistent ice fields in the Canadian Arctic from the northern Ellesmere southward to Baffin Island may be viewed as a fragmented extension of the north polar ice cap that dominates most of Greenland's elevated mass to the east and the surface of the Arctic Ocean to the north. These ice fields are only a negligible component of North America's climatic array, but it is a reminder that past climates have permitted continental glaciers to spread over much of North America during earlier geological epochs.

Organization rationale

Given the vast amount of climatic literature pertaining to the continent, it is possible to take a number of approaches to describe North American climates. Certainly, the best description of climate would be a genetic one that relates each climate to a particular set of causes. One approach that assesses climates by cause draws upon airmass climatology (e.g. Oliver and Hidore, 2002). In this approach source regions are identified (Figure N1) and their characteristics are related to prevailing conditions (Table N1). Airmass climatology is examined in related articles in this volume. Similarly, reasons for the distribution of temperature (Figure N2) and precipitation (Figure N3) and other climatic elements are also dealt with in other entries.

It is also possible to delineate the climates according to a descriptive classification scheme, such as that of Kōpen, and use the identified regions as the basis for discussion. This approach has been used in a number of textbooks (e.g. Trewartha and Horn, 1980), and it is the approach adopted herein. Figure N4 identifies the location of the regions described on the following pages, along with a number of climographs showing mean monthly temperature and precipitation for a few selected stations. The stations in Figure N4 were selected to illustrate gradients in climatic conditions that are not always reflected by the categorization of the Kōpen system. Some stations may be mentioned in discussions of climates different from the climate class in which they reside simply because the climograph illustrates an important trend. For example, Amarillo is used to illustrate the westward decrease in precipitation in C climates, yet it is a BS climate. Similarly, generalization has eliminated some geographic variation and Kōpen subtypes.

Tundra climate (ET)

The northernmost of the continent's major climates is ice-free only during the summer, a region of rolling, virtually treeless plains stretching eastward from the shores of the Bering Sea to the coast of Labrador. Long, severely cold winters alternate with short, cool summers. Sunless darkness prevails for several weeks before and after the winter solstice around 22 December. Lowest temperatures are normally reached in February, except near the sea after oceanic ice has attained its maximum extent, where March is the coldest month. February averages between -15° and -30°C (Inuvik, Figure N4). From time to time, values drop to -50°C or lower. At this season precipitation diminishes to about 1 cm a month over the interior and falls mainly in the form of fine, light, dry snow, brought by the fairly rapid passage of small, intense frontal storms from the north Pacific. Occasionally, when clear, transparent air is calm and intensely cold, showers of minute ice crystals fall from the cloudless sky. Normal yearly precipitation throughout the tundra is usually less than 25 cm, although coastal stations may average up to 50 cm or more.

Summer is a season of prolonged daylight when temperatures average above freezing for 3–4 months at most stations. The warmest month is commonly July when readings are above 5°C but not above 10°C. Comparatively high temperatures are not unknown at numerous inland sites where values exceeding 30°C have been reached. However, it is the sporadic occurrence of subfreezing temperatures from June to September that characterizes the luminous summer of the tundra. This is the season of maximum precipitation for most of the region, mainly falling as light, steady drizzling rain of frontal origin. Monthly values are typically around 5 cm. Thunderstorms are rare. By

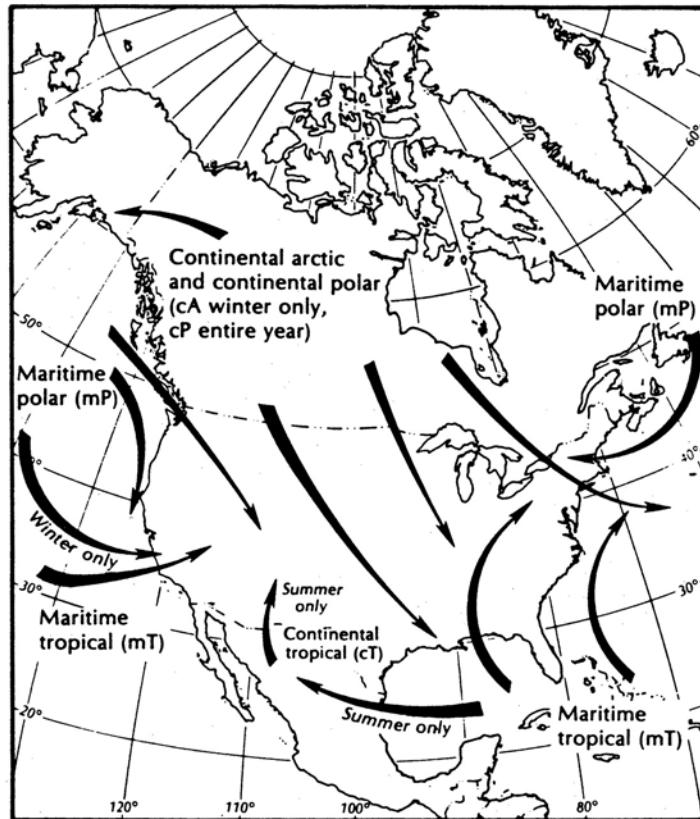

Figure N1 Source regions and paths of airmasses influencing the North American continent.

midsummer, landscapes are released from the grip of frost, streams flow, lakes and ponds are ice-free, and the low-lying plant life engages in the year's brief period of vegetative growth. Very few plant species tolerate the lengthy dormancy of winter and the short, cool, frost-threatened growing season. The assemblage of mosses, lichens, a few flowering herbs and ligneous shrubs that spread laterally close to the surface, plus isolated clumps of hardy spruces, a few meters high in sheltered depressions, are the commonest plant forms making up the tundra vegetation and giving this climate its unique name.

Snow climates (Dfa, Dfb, Dfc)

Along the southern margins of the tundra, treeless barrens give way gradually and unevenly to forest. Southward through the interior of the continent, these forests become more lush and the trees larger, changing in character from the coniferous boreal forest to mixed types, and eventually to subtropical species along the Gulf of Mexico. The largest portion of this forest contains the D or snow climates, those that have one or more months with average temperatures below -3°C . The Kpen system's various modifiers succinctly indicate that all seasons of the year receive significant moisture (the "f" in Dfa), and the length and warmth of summer decrease from south to north (Dfa, Dfb, Dfc). It is this climate that offers the widest annual temperature range as well as the greatest geographic variation in temperature in North America.

Variability is the hallmark of the snow climates. The northern portion of the D climates is in the Arctic, and the southern portion verges on the subtropics. Besides the extreme variation in solar radiation caused by this latitudinal extent, the variability is also caused by the seasonal variation in the location of the polar front and its attendant airmasses and cyclones. During the summer the westerly jet stream retreats to the margin of the Arctic, while in the winter it may frequently reach to the Gulf of Mexico. The resulting storm tracks (Figure N5) are somewhat seasonal, with the Alberta track being occupied largely in summer and the Gulf Coast track in the winter. The Colorado storm track may see activity in all seasons, but cyclone activity as a whole decreases during the summer months.

The length and severity of winter are noteworthy characteristics of the Snow Climates. In the Dfc, (Anchorage) deep cold settles over the land from October through April. January is usually the coldest month when normal temperatures average near -10°C , and thermometer readings often plunge to less than -50°C . In northwest Canada, interior stations have recorded values below -60°C . The high frequency of anticyclonic weather is chiefly responsible for lengthy, intensely cold periods, when the calm, dry, crystal-clear atmosphere settles over the land permitting rapid radiative heat loss to proceed from the surface with exceptional effect.

Farther south (Dfb, Winnipeg), winter extends from November through March. But monthly and daily temperatures may be every bit as extreme as in Dfc, since the relatively flat,

Table N1 Characteristics of North American airmasses

Airmass	Source region	Temperature and moisture characteristics in source region	Stability in source region	Associated weather
cA	Arctic basin and Greenland ice cap	Bitterly cold and very dry in winter	Stable	Cold waves in winter.
cP	Interior Canada and Alaska	Very cold and dry in winter	Stable entire year	Cold waves in winter. Modified to cPk in winter over Great Lakes bringing "lake-effect" snow to leeward shores.
		Cool and dry in summer		
mP	North Pacific	Mild (cool) and humid entire year	Unstable in winter	Low clouds and showers in winter. Heavy orographic precipitation on windward side of western mountains in winter.
			Stable in summer	Low stratus and fog along coast in summer; modified to cP inland.
mP	Northwestern Atlantic	Cold and humid in winter	Unstable in winter	Occasional "northeaster" in winter.
		Cool and humid in summer	Stable in summer	Occasional periods of clear, cool weather in summer.
cT	Northern interior Mexico and southwestern US (summer only)	Hot and dry	Unstable	Hot, dry, and clear, rarely influencing areas outside source region. Occasional drought to southern Great Plains.
mT	Gulf of Mexico, Caribbean Sea, western Atlantic	Warm and humid entire year	Unstable entire year	In winter it usually becomes mTw moving northward and brings occasional widespread precipitation or advection fog. In summer, hot and humid conditions, frequent cumulus development and showers or thunderstorms.
mT	Subtropical Pacific	Warm and humid entire year	Stable entire year	In winter it brings fog, drizzle, and occasional moderate precipitation to NW Mexico and SW United States. In summer it occasionally reaches western US providing moisture for infrequent conventional thunderstorms.

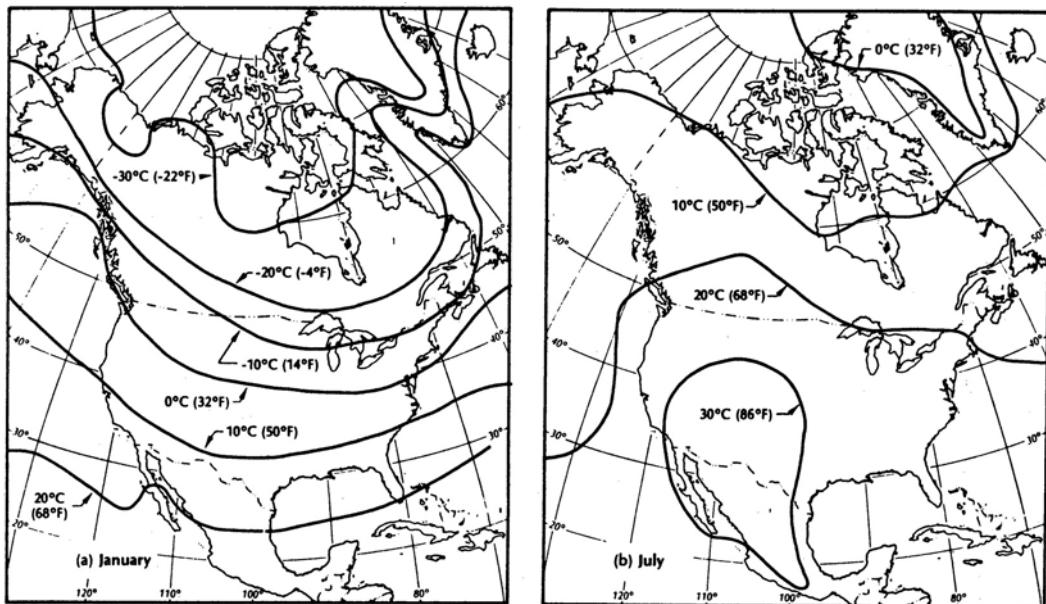

Figure N2 Mean January and July temperatures over North America.

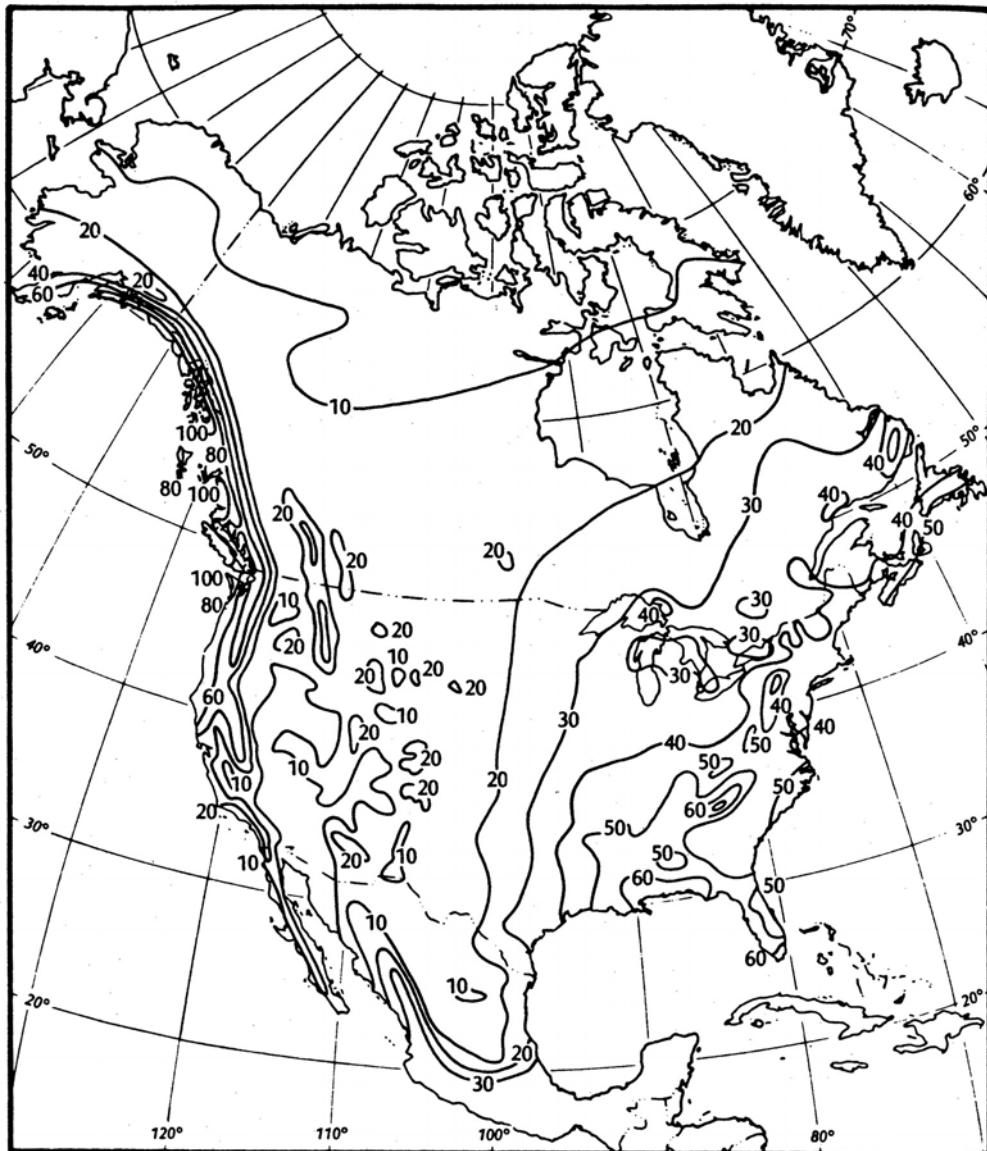

Figure N3 Distribution of precipitation in North America.

snow-covered continental interior offers a breeding ground and easy transit for cold Arctic and polar air masses. By the time these air masses reach the Dfa region, however, they warm considerably, as snow cover is usually less continuous and the sun is more intense. Average winter temperatures in the Dfa region are therefore nearer to 0°C (Springfield), and the cold season persists only from December through February.

Winter is the season of diminished precipitation when most frontal disturbances move rapidly over the surface at about twice the speed of summertime. The seasonal decrease is largely controlled by the expansion of drier air polar and Arctic masses in winter, and it becomes more pronounced as latitude increases. Longitudinal variation also occurs, as winter storms increase in frequency from west to east. In the Dfc climate the storms yield a snow that is light, fine, and dry, while along the

southern boundary of Dfa, wet, heavy snow combined with rain and sleet is common. Within the Dfc climate the incidence of snowfall rises from about 50 days per year in the Yukon Valley to over 100 days in northern Quebec and Labrador. Mean yearly snowfall increases from around 100 cm in central Alaska to over 500 cm in easternmost Labrador. Around the Great Lakes in the Dfb climate, snowfall values average between 200 and 300 cm, except for lake effect snow which may double or triple that amount for a region within a few miles of the lakes. Snowfall values are between 50 and 100 cm for most of the Dfa region but the geographic and annual variation can be extreme during any particular year.

The retreat of the polar front jet stream to the north in the summer allows maritime tropical airmasses from the Gulf of Mexico and continental tropical airmasses from the southwest

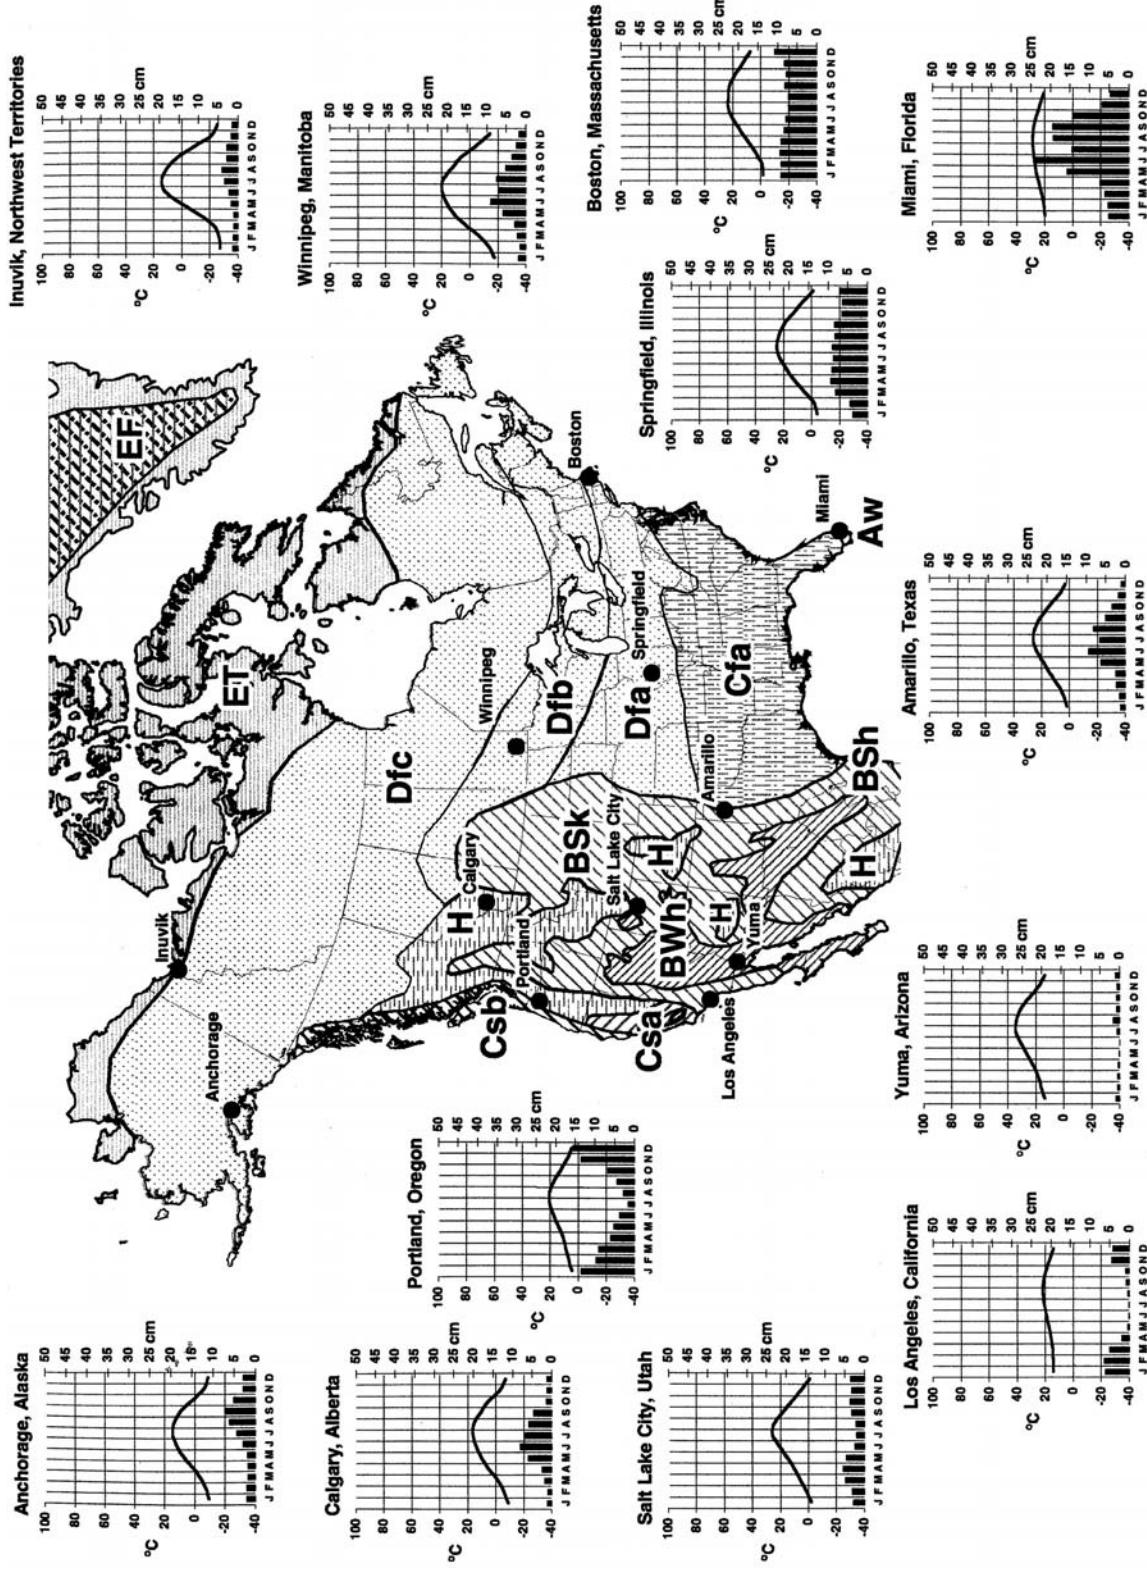

Figure N4 Köppen climate distribution.

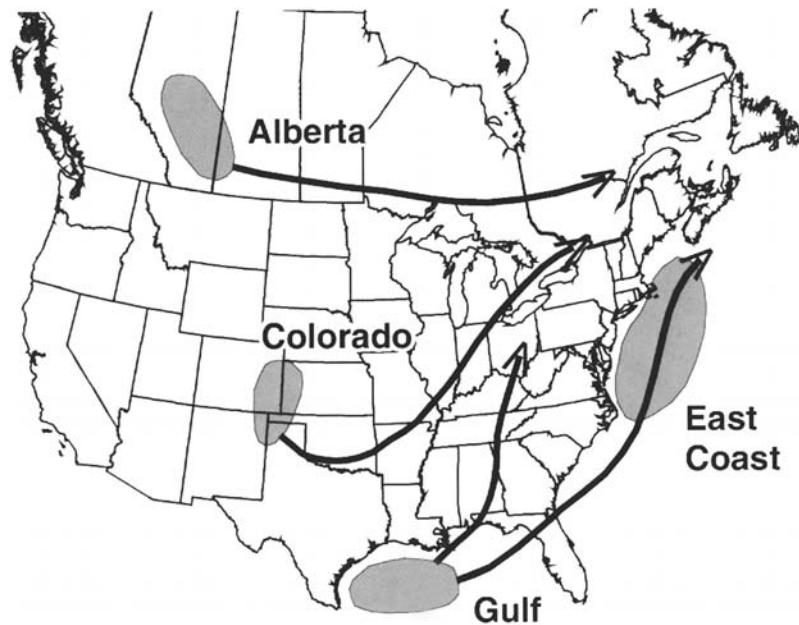

Figure N5 Major storm tracks over North America.

to expand into the D climates bringing heat, humidity, and a decrease in extratropical cyclone activity. Summer in the D climates brings a growing season which varies from about 75 days in the northern portion of the Dfc to about 180 days on the southern margin of the Dfa. Although frost may occur sporadically in the north, mean monthly temperatures in the Dfc are above 10°C for 1–3 months. July is commonly the warmest month with average readings above 18°C but never above 22°C. Extreme temperatures in excess of 38°C have been recorded at some inland stations, although prolonged hot spells do not occur. Summers are longer and warmer in the Dfb climates: 4 months have average temperatures over 10°C, although none exceeds 22°C, and prolonged hot spells are common. Long, hot summers are the norm in the Dfa climate. July temperatures average over 22°C, and at least 4 months have average temperatures over 10°C. Daily maximum temperatures over 38°C, sometimes for days at a time, have been recorded in the Dfa climate.

Summer is the season of maximum precipitation when about two-thirds of the normal yearly amounts are received, except along the northeast coast which records a winter maximum (Boston). Most summer precipitation is produced by slow-moving extratropical cyclones and fronts. In the Dfc climate light, steady rains are the norm, but farther south the increased humidity allows fronts to trigger convective showers. Annual thunderstorm frequency varies from 5 to 10 days in the Dfc to as many as 50 days per year in the Dfa. The increase in convective activity also leads to tornadoes, and although the causes and distribution of tornadoes are quite complex, the southwest corner of the Dfa climate in North America occupies the northern portion of "Tornado Alley". Within this portion of the Dfa, annual tornado frequency may reach seven tornadoes per 27 000 km². May, June, and April, respectively, are the months of highest tornado frequency.

Significant regional variability in this picture is introduced by the Great Lakes, mountainous terrain and proximity to oceans.

The Appalachian mountains in the east and the various ranges in the west all impart thermal and precipitation gradients dependent on altitude and location relative to prevailing winds on a rather fine scale. Similarly, within a few miles of the Great Lakes, thermal and precipitation gradients can be severe, most notably in the form of lake-effect snow in the winter. Location near the ocean generally causes warmer, wetter winters and cooler summers in the D climates, which can be seen by comparing, for example, Winnipeg and Boston, or Anchorage and Inuvik.

Humid subtropical climate (Cfa)

The polar front jet stream frequently inflicts winter storms on the Cfa climate, sometimes bringing rain, sometimes snow, and sometimes a mix of rain, snow, sleet, thunder, lightning, and tornadoes. Arctic airmasses following behind cyclones bring days of temperatures below 0°C, and then give way to warmer maritime tropical airmasses from the Gulf of Mexico ahead of the next winter storm. As the polar front retreats in the spring, the trade winds blowing out of the Bermuda extension of the Azores subtropical high-pressure system, and southerly winds from the Gulf of Mexico, blow warm, humid airmasses over the eastern portion of the region, providing the heat and humidity so typical of this climate. Peak summer temperatures are usually somewhat cooler in the east because the increased presence of water and lush vegetation forces the use of solar radiation for evaporation and transpiration rather than heating. Along with the heat and humidity come convective storms, some triggered by extratropical cyclones and fronts, some accompanying tropical cyclones, and some just random, convective storms. Any convective storm may initiate tornadoes, and the Cfa climates bear the distinction of having both the highest frequency of tornadoes recorded in North America and the highest frequency of damage from hurricanes.

The four seasons become much less distinct farther south in all climates, a result mainly of increasing nearness to the

equator. Annual possible sunshine increases from about 40% in southeastern Canada to over 65% in Florida: mean daily solar radiation rises from less than 300 Langleys in the north to more than 450 in the south, and the growing season lengthens from under 80 days in northern Canada to more than 350 days along the Gulf Coast. This change is particularly evident within the Cfa climate, as the growing season ranges from 180 days in the north to 350 days in the south. January temperatures during the coldest winter months remain substantially above freezing, and mean monthly temperatures in winter are all above -3°C (Amarillo). Summers are long and hot, with daily temperatures over 38°C common, and for months at a time the daily maximum temperature may reach 32°C . In the western portion of the region (Amarillo), drier continental tropical airmasses may persist for days, bringing temperatures over 45°C .

In the subtropical region snow is expected on fewer than 10 days and does not normally exceed 10 cm. But the gradient is a steep one, as snow is common in the northern portion of the Cfa but a rarity in the southern part. Winter precipitation may increase during El Niño years as a result of increased high-level moisture advected into the area by the subtropical jet stream. Because of the tendency for El Niño events to displace the polar front jet stream farther north over much of North America, this precipitation generally falls as rain rather than snow.

Mean annual precipitation increases southward and eastward from about 100 cm in the north to over 160 cm along the coast, largely because of greater atmospheric moisture content the closer proximity to the Gulf of Mexico or Atlantic Ocean. Because of these humid airmasses, summer experiences significantly more precipitation than winter even though winter has the higher frequency of synoptic-scale storms. Thunderstorms account for a much larger percentage of yearly precipitation in this climate, occurring on 50–100 days per year, and reaching a maximum between May and October. This convective precipitation is frequently intense and of a short duration; throughout the region, between 70% and 90% of the annual precipitation falls from storms dropping greater than 12.7 mm of water per day.

June through October is the peak season of tropical cyclone activity which accounts for 15% or more of annual precipitation along the Gulf Coast and the Atlantic seaboard. Many tropical cyclones develop into hurricanes, and the landfall of any one of these intense tropical storms is usually a disaster. In North America the greatest proportion of hurricane landfalls occurs in the Cfa climate.

Tropical climate (Aw)

The southern tip of the Florida peninsula contains the only tropical climate in North America (Miami). The average temperature of the coldest month (January) is over 18°C , and freezing temperatures do not occur, as the intensity of sunlight, and the proximity of the warm ocean waters, keep the area hot all year. Summer daily temperatures are usually in the range of $27\text{--}30^{\circ}\text{C}$. The summertime maximum in precipitation is the result of frequent and intense airmass thunderstorms. Approximately 90–100 thunderstorms per year bring monthly precipitation values over 15–20 cm, and an annual average precipitation of 190 cm. For much of the summer a daily thunderstorm is the rule. In the winter, though, drier continental polar airmasses spread south, and precipitation drops to 5 cm per month or less for 4 months.

Dry climates – steppe (BSk and BSh)

In the United States and southern Canada the westward decrease in precipitation eventually produces the dry climates, where potential evaporation exceeds precipitation. Potential evaporation is defined as the amount of water that could potentially evaporate, assuming it was available. On the average, then, the dry climates experience a water deficit. Within the dry climates, BS refers to steppe-type climates, where grasses were the originally the dominant vegetation, and BW is desert. The boundary between steppe and desert is where potential evaporation is double the annual precipitation. The modifiers "h" and "k" indicate whether the average annual temperature is above 18°C (h) or below 18°C (k), and their presence on the map generally reflects the north-south temperature gradient across the continent.

The greatest expanse of dry climates is largely the result of three factors: distance from oceans, prevailing winds, and rain-shadow of mountains. The prevailing westerly winds across the United States, combined with the rainshadow of the large, western cordillera, creates a large expanse of dry land interfingered between mountain ranges in the west. Dry climates can be found even on the coast of the Gulf of Mexico because of the prevailing westerly winds. On the west coast (Los Angeles), however, the situation is somewhat different, as an area of steppe and desert climate reaches all the way to the Pacific ocean. In this region the proximity of the subtropical high-pressure system, the freshly subsided airmasses, and the cold California current combine to create very stable airmasses in the summer. This situation is similar to the west coast of Africa and South America at the same latitude.

The steppe climates are distinctly continental in character, featuring four well-defined seasons, a large annual temperature range, and a pronounced summer precipitation increase. From 65% to 80% of yearly precipitation occurs in the period April through September, maximum amounts commonly falling early in the growing season. Summer rains are mainly in the form of thermal convective showers of short duration and highly variable distribution. Summer convection is initiated by the intense solar heating, but most of the region is far from a water source, and so the precipitation coverage is spotty. Tornadoes can accompany these storms.

Skies during summer are predominantly cloudless or partly cloudy, and from April through September over 60% of possible sunshine is recorded, with a maximum of 70% in July and August. During July and August thermometer readings above 32°C occur on more than 15 days per month in the central portion of the region, more than 25 days per month in Texas, but fewer than 10 days in the Canadian provinces. Evaporative moisture loss to the atmosphere is notably high in the steppe, especially along the drier western margins, attaining values in excess of 250 cm per year in southern sections and over 140 cm per year in the north. The growing season varies in length from about 240 days in central Texas to fewer than 120 days in the prairie provinces of Canada. July is the warmest month as a rule, averaging above 27°C in the south, diminishing to about 22°C in North Dakota, and to less than 18°C in Alberta.

Winter is dominated by airmasses originating in the higher latitudes, most of which are continental in character and thus are often very cold and very dry. Moisture arrives mainly from the north Pacific, and frontal storms bring most of the season's precipitation. Snow, usually fine, light, and dry and easily drifted, is the chief form, occurring on over 60 days per year in the north and amounting to about 125 cm in depth. Snow is

expected on fewer than 10 days per year in southern sections and rarely amounts to more than 25 cm. The cold wave, blizzard, and chinook are also characteristic of winter in the steppe. The cold wave arrives when a very cold, dry airmass moves rapidly southward, causing a temperature drop in 24 hours of more than 12°C to a value of lower than -18°C . When deep cold, dry air moves rapidly into a developing low-pressure system, a blizzard results. This is usually when wind speeds within the frontal system reach between 15 and 20 m s^{-1} . Accumulations of more than 60 cm from a single storm have been reported, with drifts to more than 300 cm, the open plains allowing winds to attain speeds of up to 130 km h^{-1} . Much of the surface is laid bare by the winters' winds and ground frost may reach depths of 250 cm in northern areas.

The chinook provides one of the more dramatic phenomena of winter's weather. It is essentially a downslope wind, variable in strength and persistence, but capable of attaining speeds exceeding 130 km h^{-1} . Moving rapidly down the east slopes of the Rockies, it may bring a temperature rise of more than 20°C in 3 hours and usher in a period of higher than normal temperatures lasting for several days. Through sublimation, snow on the ground may diminish at the rate of 2.5 cm h^{-1} . The chinook may develop at any hour of the day or night throughout the year, but it mainly appears in January and March. January is the coldest month of winter and the chinook offers an ameliorating effect, especially since January temperatures average -20°C or lower in northern sections and may drop to -50°C .

Dry climates – desert (BWh and BWk)

Desert in North America is geographically discontinuous, as mountain ranges disrupt the apparent continuous coverage on Figure N4. Deserts above 1500 m elevation such as in the region known as the Colorado Plateau may be cold desert (BWk). Adjoining this region to the south, and at a somewhat lower elevations, are fringes of the Sonoran Desert and the Chihuahua Desert, both hot deserts (BWh). The detailed distribution of actual desert climates is greatly complicated by the extremely variable topography of the intermountain west which causes a widespread scattering of steppe and the forested highland climates (H).

Clear, cloudless skies from dawn until dusk are the overriding atmospheric condition of the desert climate. In summer most of the western deserts receive more than 80% of all possible sunshine from day to day; in southern California more than 90% is the rule. During the winter months clear skies are less frequent, although even then southern deserts receive more than 70% of possible sunshine. Under clear skies the sun's rays at dawn rapidly heat the bare ground and the overlying air begins to warm at once. Air temperatures rise to a maximum in midafternoon, falling more slowly with the approach of evening. At Yuma, Arizona, on a typical August day, air temperature reached a minimum of 26°C during the calm interval at dawn, but by 1000 hours had risen to 32°C and by 1500 hours reached a maximum of 44°C . The dry soil at the same location registered 64°C . Relative humidity was 8% at noon and remained below 10% during the early afternoon. High temperatures and low humidities after midday are strongly characteristic of desert climates.

Extremes of summer heat are well known in desert situations of low altitude. At Greenland Ranch (el. -54 m) in Death Valley the mean July temperature is 38°C , at Yuma (el. 61 m) it is 35°C and at Brawley (el. -30 m) in the Imperial Valley it is 34°C . Extreme summer temperatures are frequently above

38°C . At Greenland Ranch the thermometer has reached 56.5°C , at Yuma 49°C and at Las Vegas, 47°C . Winter temperatures tend to remain above freezing except at higher elevations.

Mean yearly precipitation is generally less than 25 cm over most North American desert regions. Of far greater importance than the normals, however, are the degree of variability, the kinds of precipitation, and the seasons of their occurrence. In the northern portions, and in southern California, precipitation falls mainly in winter and is produced by cyclonic storms from the Pacific. In the southern deserts of Arizona and New Mexico, snow falls infrequently and in trifling amounts. Summer experiences higher precipitation values in a monsoon-type circulation: the intense desert heat causes widespread convection leading to the development of a thermal low pressure on the synoptic weather map. Humidity, perhaps in the form of clouds, is advected in from the Gulf of California, and the resulting convective showers are the chief rain-generating mechanisms for these deserts. In the areas of summer maximum, departures from normal are over 20%. In winter precipitation regions, variability averages between 25% and 35%. The random scattering of precipitating clouds is a common cause of variability. A notable phenomenon, known as *virga*, is the appearance of showers falling from a cloud base that fail to reach the surface because of the low relative humidity.

Mountain climates (H)

The western reaches of North America are dominated by high mountain ranges and intermontane plateaus and basins that create a climatic pattern of great complexity totally different from the rest of the continent. The Rocky Mountains extend from west Texas northwestward some 4500 km to Alaska. The Pacific mountain system is a series of narrower ranges reaching southward from the Alaska archipelago to include the Cascades of Washington and Oregon and the Sierra Nevada of eastern California. Less prominent coastal ranges overlook the Pacific from Mount Olympus in Washington to the peninsula of Baja California in Mexico. Between the Pacific system and the Rockies are broad tablelands such as the Colorado Plateau and extensive elevated depressions such as the Great Basin of Nevada and Utah.

Among the western mountains, maximum climatic diversity is encountered within short distances. Differences in altitude alone impose pronounced changes in atmospheric properties. With increasing altitude, moisture and dust content diminish, as well as atmospheric density and barometric pressure. The atmosphere's heat capacity also decreases, resulting in lower air temperatures. Along the Front Range in Colorado, for example, the mean annual temperature at Colorado Springs (el. 1860 m) is 8.9°C , whereas at Pike's Peak (el. 4300 m) about 15 km west, it is -7.2°C . As density decreases, there is an increase in the intensity of solar radiation, particularly in the ultraviolet range of the spectrum. Wind speed also increases with altitude as well as the proportion of precipitation that falls as snow.

Perhaps the chief effect on the atmosphere of mountain features is the barrier they interpose on the movement of airstreams over the Earth's surface. Airflow deflected upward is cooled adiabatically and encounters increasingly cooler atmospheric strata in the process. The visible result of these movements is the development of cloud formations along windward mountain slopes that offer one of the more striking features of the skies over mountain terrain. Precipitation is commonly produced by such deflection and is known as orographic rain or

snow. Thus precipitation increases with altitude, reaching a maximum at heights that vary with latitude, but in western North America range from 1200 m to 2400 m. Convective motions that generate the cumulus clouds of mountain regions are often intensified and prolonged sufficiently to produce spectacular cumulonimbus forms that yield extremely heavy showers. Such cloudbursts, added to meltwater runoff from higher snow fields, often cause sudden, destructive freshets to rush swiftly down through the lower stream courses with disastrous consequences to life and property.

With increasing altitude, most of the year's precipitation falls as snow. As latitude increases, snow fields are seen at ever lower elevations, approaching sea level in the coastal ranges of southern Alaska. Snow is without doubt one of the more significant products of atmospheric activity in mountain country. With its esthetic value is coupled its usefulness in winter sports and in the annual release of meltwater to mountain streams in spring and summer. Mountain runoff is indeed the chief source of water supply for streams in arid regions of the west. On the other hand, mountain snows can bring sudden death and destruction through rapid accumulation during unusually severe winter storms or through the sudden, swift downward rush of an avalanche. On mountain tops above 3000 m snow has been observed during every month of the year.

The greatest amounts of snow are normally recorded in the coastal mountains of British Columbia, the Cascades, and the Sierra Nevada. In the state of Washington, at levels from 1200 m to 1700 m, normal wintertime snows amount to between 1000 cm and 1500 cm during the period from November to June. In Oregon, amounts average between 760 cm and 1400 cm at levels from 1400 m to 1800 m, and in California mean amounts are around 1000 cm in the central Sierra Nevada between 1800 m and 2400 m. Similarly high values are reported from British Columbia and are several times greater than the normal amounts reported outside the mountainous west. Some exceptional amounts have been measured during a single winter season. At Tamarack, California (el. 2438 m) 1200 cm (over 22 m) fell during the winter of 1906–1907. At the Paradise Ranger station (el. 1676 m) on Mount Rainier in Washington, 2540 cm were recorded in 1953–1956. At Silver Lake (el. 2600 m) about 35 miles northwest of Denver, 220 cm of fresh snow fell in 27½ hours in April of 1921.

Atmospheric turbulence is commonly intensified in mountain regions as a product of the barrier effect on normal air movement. Hazardous turbulence not infrequently occurs in clear, cloudless air over mountain terrain and is most noteworthy over middle and upper slopes. This is partly due to wind speeds increasing with altitude. The levels at which maximum wind speeds are attained vary widely, but one example suggests this common tendency. At the summit of Old Glory Mountain (el. 2347 m), British Columbia, average wind speeds during April have been 26 km h⁻¹, with a maximum for 1 h of 100 km. During the same period at Carmi (el. 1245 m) average wind speed was 8 km h⁻¹, with a maximum for 1 h of 71 km.

West coast climates (Csa, Csb)

From northwestern Mexico to southern Alaska the coastal climates of western North America are uniquely elongated and narrowly confined to within 80 km to 160 km of the sea. Within this narrow region exists a large north-south temperature gradients (although not as great as in the continental interior), and an extreme north-south precipitation gradient unlike any other

on the continent. In summer the subtropical high-pressure system immediately offshore expands northward, bringing warm, dry, stable air on to the margins of the continent. As the polar front jet stream moves poleward, frontal systems develop less frequently and are less vigorous, and precipitation is substantially reduced. In winter the anticyclonic subtropical circulation contracts and moves southward, allowing more humid air from the Pacific to encroach. Cyclones and frontal systems develop much more frequently, and are usually larger and more intense. They pursue paths that lie much farther south than in summer and dispense the greater part of the year's precipitation. This is the only part of North America where winter precipitation is such a pronounced climatic characteristic.

The feature common to both of these climates is the precipitation regime of dry summers and wet winters. The dry summer becomes more pronounced farther south (Los Angeles), and less visible farther north (Portland), while the winter becomes wetter farther north. Csa is the classic Mediterranean climate with summers that are long and hot, whereas the companion climate, Csb, has long, cool summers.

In the Csb, cool, damp summers alternate with moderate, cloudy winters with much fog and frequent rain and snow. In summer, mean temperatures for the warmest month are 13°C in Eureka, California,. Extreme maximums have rarely exceeded 30°C. Inland, sheltered stations are somewhat warmer. Portland records a July mean of 19°C, Vancouver 18°C, and Seattle 17°C. In the Puget Sound–Willamette Valley most stations have recorded extreme maximums of more than 38°C. The growing season is about 240 days from Vancouver to Eureka.

Even though summer is the dry season, some rain falls in every month of summer. During the 3 months June through August, normal amounts increase northward, with less than 2.5 cm at Eureka, Portland 6.6 cm, Seattle 7 cm, and Vancouver 14 cm.

The increased frontal activity of winter brings a higher number of depressions to the Gulf of Alaska than anywhere else in the northern hemisphere at any time of the year. December is thus the wettest month at nearly all stations in the region. Although most of the year's precipitation occurs in winter, the actual percentage decreases northward. From October through March, Eureka receives 83%, Portland 77%, and Vancouver 73%. Snowfall accounts for an increasing proportion of winter's precipitation. However, at sea-level stations it is usually less than 25 cm. Greater amounts of precipitation fall on higher elevations. In general, drizzling rain is the chief source of annual precipitation, which averages over 200 cm from northern California to southern Alaska. On seaward slopes just a short distance inland, amounts may range from 250 cm to 500 cm. The annual departure from normal averages about 15%.

Winter temperatures are unusually high for the latitudes: Eureka averages 8°C and Seattle about 7°C in January. Occasionally in winter a mass of cold, dry continental air from the deep-frozen interior spills out over the sea, producing very low thermometer readings at low-lying stations. Portland has reported –19°C and Vancouver –17°C.

The Mediterranean climate (Csa) is one of warm to hot, dry summers and mild, wet winters, with an abundance of cloud-free, sunny skies. Mean annual precipitation averages between 40 and 90 cm. An important climatic characteristic is that about 95% of the normal yearly amount falls during the 7-month period from October through April. Most stations record only negligible amounts the rest of the year. In southern areas the rainy season lasts for only 5 months.

Winter precipitation is produced almost entirely by frontal disturbances off the Pacific. Thunderstorms are rare, seldom occurring more than three or four times yearly, and are usually small, weak and of short duration. Winter rains ordinarily begin before the end of October and increase to a maximum for the season in December at most stations, although February is the wettest month around Los Angeles. During El Niño years the subtropical jet stream may contribute increased moisture and energy to polar front storms and enhance precipitation greatly. Average amounts for December are largest toward the north. Redding, far up the Sacramento Valley, averages 20 cm; the Russian River Valley, north of San Francisco, averages between 20 cm and 23 cm; and Placerville (el. 575 m) in the Sierra Nevada foothills also records 20 cm. Elsewhere, normal December amounts are about 10 cm. From year to year the total amount of winter's precipitation may vary widely around the arithmetic mean, especially during El Niño years. Red Bluff, in the northern interior, averages 64 cm, but during a recent year received 175 cm, followed a few years later by a total of 26 cm. San Francisco records a normal of 52 cm, but has received as little as 23 cm and as much as 90 cm. Variability rises to more than 40% in southern sections. During the 1997–1998 El Niño, San Francisco and Los Angeles received over 200% of their normal annual rainfall.

Snow seldom falls in the Mediterranean region, except on the coastal mountains where it is a common occurrence at altitudes above 1200 m. At Sandberg (el. 1377 m) less than 80 km northwest of Los Angeles, winter snowfall averages about 70 cm. High in the Sierra Nevada, however, heavy snows accumulate each winter, creating an annual reserve of water that is released in spring and summer, adding meltwater to the rain-fed streamflow.

Despite the high frequency of precipitating disturbances during winter, the sun shines much of the time. About one-third of the days of each winter month are sunny, dry, and pleasant. Under clear skies, nocturnal temperatures sometimes drop well below freezing. Red Bluff in the north has recorded –8°C in both December and January, Sacramento –6°C in January, and San Diego –2°C. January is without exception the coldest month and mean values are usually well above 2°C in the north and above 4°C elsewhere in the region. In February winter begins to wane as frontal activity diminishes and precipitating storms retreat northward.

Summer weather is controlled for the most part by the expanded oceanic high-pressure fields. Except for the coast, most of southern California is under clear, dry, cloudless skies from May to October. More than 90% of possible sunshine prevails from June through August. Temperatures rise rapidly after sunrise each day, reaching close to 30°C by midafternoon. July is the warmest month, when mean temperatures are largely in the mid to upper 20s Celsius. Red Bluff averages 28°C, Sacramento 24°C, and Bakersfield 29°C. The thermometer rises above 32°C in July on 28 days at Red Bluff, 20 days at Sacramento, and 30 days at Bakersfield. Relative humidity by midafternoon during July drops to low values, usually less than 30%. The average at Red Bluff is 18% and at Sacramento 28%. In the drier southern sections of the central valley, under the desiccating influence of hot, dry winds, called Santa Ana, values often drop to between 5% and 10%. The period May through October accounts for over 75% of annual evaporation, which amounts to about 180 cm in the north and over 230 cm in the south. The growing season at interior locations averages between 240 and 270 days, whereas along the coast it increases to more than 330 days.

The summer weather of coastal California is cooler, more cloudy, and more humid than areas that are sheltered from chilly air off the Pacific, even though many are only a few miles inland. The south-flowing California Current, coupled with upwelling deep water, brings sea surface temperatures of about 15°C past San Francisco, and up to 20°C south of Los Angeles, from June through August. The warmest month is usually either August or September at most seaside stations. San Francisco averages 17°C in September, Santa Cruz 17°C from July through September, and Santa Barbara 19°C in July and August.

Warm air off the open Pacific, 130 km to 160 km offshore, passing over the cool coastal waters, produces frequent low stratus clouds and dense fog. Only about 60% of possible sunshine is recorded at shoreline stations, and most observe more than 60 days per year with dense fog. Cool, humid maritime air penetrates inland through the Golden Gate providing lower temperatures and higher humidities over much of the San Francisco Bay area. A similar effect is seen in the Los Angeles Basin, which is exposed to the sea. In both areas combustion effluents frequently combine with stable, humid air to develop into California's notorious *smog*.

NORTH AMERICAN (CANADIAN) HIGH

The North American High consists of one or two semipermanent cells of high pressure that develop over the interior of the continent during winter. The Siberian (Asiatic) High represents an analogous situation in the northeastern interior of Asia.

The influence of the North American High is rarely felt above 2500 m (8200 ft), as it is made up of cold, dense air. At 3000 m (9800 ft) the high loses its identity (Petterssen, 1969).

The weaker thermal influence of the smaller North American landmass ($24\,063\,000 \text{ km}^2$; $9\,291\,000 \text{ miles}^2$) as contrasted to the much larger landmass of Asia ($44\,134\,000 \text{ km}^2$; $17\,040\,000 \text{ miles}^2$) results in a weaker and divided anticyclone. The southern center, the Plateau High of the western United States, represents a moderate poleward displacement of the subtropical high-pressure belt. The northern center, the Canadian or Alaskan High, is primarily caused by continental cooling.

As shown in Figure N6, the Canadian High has a January mean sea-level pressure of 1020 mb (30.12 in) in contrast to the mean pressure of 1035 mb (30.56 in) of the Siberian High. The Canadian High is located just to the east of the Rocky Mountains, where it is most protected from heat transfer from the Pacific. The highs generally move southeastward and then eastward toward the Atlantic coast. Coming over the warm Atlantic, the high loses its identity and becomes absorbed in the Azores High. The Canadian High also tends to build a bridge between the polar high and subtropical belt of high pressure. Continental cooling is so strong that the subpolar low-pressure belt, which would occur on a uniform Earth, is almost entirely eliminated (Petterssen, 1969).

During periods of strong circulation the Plateau (or Great Basin) High that is located over the southern portion of the Rocky Mountain states increases in size. A rapid inflow of relatively mild Pacific airmasses occurs north of this high-pressure area, and rapid air movements eastward prevail over the northern United States. Thus, maritime Pacific air from the southwest characterizes weather conditions during the time of strong circulation. The Pacific coast can then expect to receive some precipitation.

The Canadian High develops and the Plateau High tends to disappear as the zonal circulation of middle latitudes weakens and reaches a minimum value. The strong continental anticyclone extends a wedge of high pressure southward into the United States. There is now little air motion in the surface layers from west to east across North America. Alaska and British Columbia may now experience an outflow of cold, dry continental air from the east.

Continental heating during the summer causes North America to become an area of relatively low pressure. Figure N7

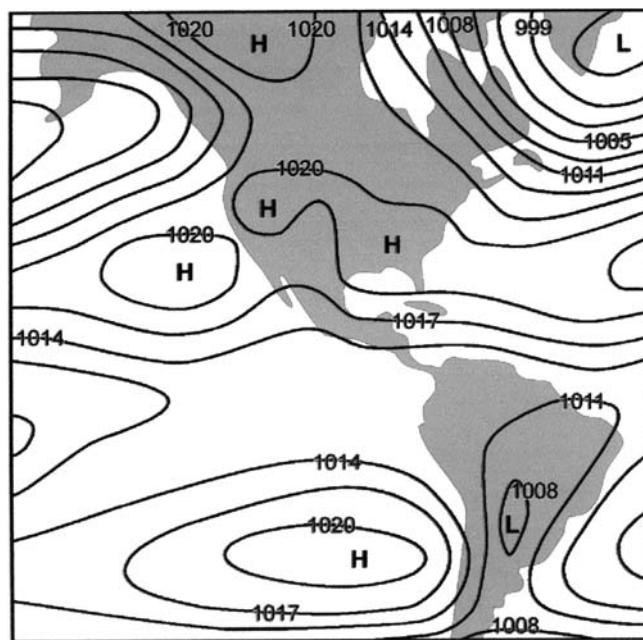

Figure N6 Mean January sea-level pressure (mb).

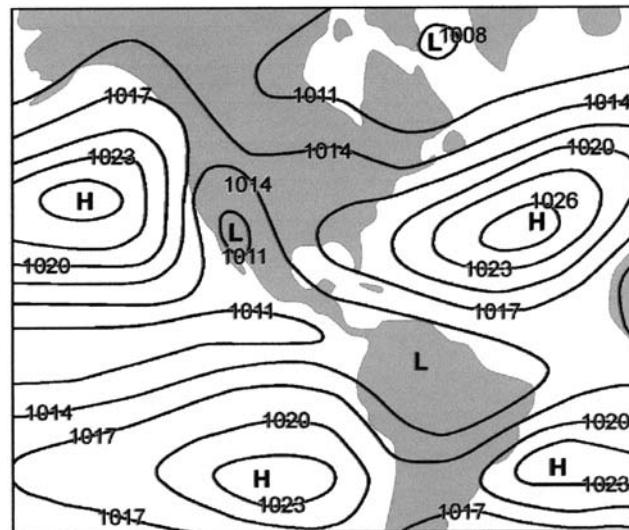

Figure N7 Mean July sea-level pressure (mb).

clearly shows a small low-pressure center with a July mean of 1011 mb (29.86 in) in the hot desert regions of southern California, Arizona, and northern Mexico. Note how the low breaks the subtropical high-pressure belt existing over the oceans.

NORTH ATLANTIC OSCILLATION

Introduction

Simultaneous variations in weather and climate over widely separated points on Earth have long been noted in the meteorological literature. Such variations are commonly referred to as “teleconnections”. In the extratropics, teleconnections link neighboring regions mainly through the transient behavior of atmospheric planetary-scale waves. Consequently, some regions may be cooler than average, while thousands of kilometers away warmer conditions prevail. Though the precise nature and shape of these structures vary to some extent according to the statistical methodology and the dataset employed in the analysis, consistent regional characteristics that identify the most conspicuous patterns emerge.

Over the middle and high latitudes of the Northern Hemisphere (NH), many teleconnection patterns have been identified, although there are only a few that are truly independent (Kerr, 2004). One of the most prominent is the North Atlantic Oscillation (NAO), which refers to changes in the atmospheric sea-level pressure difference between the Arctic and the subtropical Atlantic (Hurrell et al., 2003). Although it is the only teleconnection pattern evident throughout the year in the northern hemisphere, the climate anomalies associated with the NAO are largest during the boreal winter months (November–April) when the atmosphere is dynamically the most active.

A time-series (or index) of nearly 150 years of wintertime NAO variability and the spatial pattern of the oscillation are shown in Figures N8 and N9. In the positive index phase, higher than normal surface pressures south of 55°N combine with a broad region of anomalously low pressure throughout the Arctic. Because air flows counterclockwise around low pressure and clockwise around high pressure in the northern hemisphere, this phase of the oscillation is associated with stronger-than-average westerly winds across the middle latitudes of the Atlantic onto Europe, with anomalous southerly flow over the eastern United States and anomalous northerly flow across western Greenland, the Canadian Arctic, and the Mediterranean.

Impacts of the NAO

Swings in the NAO produce changes in wind speed and direction over the Atlantic that significantly alter the transport of heat and moisture. During positive NAO index winters, enhanced westerly flow across the North Atlantic moves relatively warm and moist maritime air over much of Europe and far downstream across Asia, while stronger northerlies carry cold air southward and decrease land and sea surface temperatures over the northwest Atlantic (Figure N10). Temperature variations over North Africa and the Middle East (cooling), as well as North America (warming), associated with the stronger clockwise flow around the subtropical Atlantic high-pressure center are also notable.

This pattern of temperature change is important. Because the heat storage capacity of the ocean is much greater than that of land, changes in continental surface temperatures are much larger than those over the oceans, so they tend to dominate average northern hemisphere (and global) temperature variability. Given especially the large and coherent NAO signal across the Eurasian continent from the Atlantic to the Pacific, it is not surprising that NAO variability accounts for about one-third of the year-to-year changes in average northern hemisphere winter surface temperature. Moreover, the long-term changes in atmospheric circulation associated with the upward trend in the NAO index have contributed substantially to the winter warming of the northern hemisphere in recent decades (Thompson et al., 2000). Changes in the mean circulation patterns over the North Atlantic associated with the NAO are also accompanied by changes in the intensity and paths of storms (atmospheric disturbances operating on time scales of about a week or less). During boreal winter a well-defined storm track connects the North Pacific and North Atlantic basins, with maximum storm activity over the oceans. Positive NAO index winters are associated with a northeastward shift in the Atlantic storm activity, with enhanced action from southern Greenland across Iceland into northern Europe and a modest decrease in activity from the Azores across the Iberian Peninsula and the Mediterranean. Positive NAO winters are also typified by more intense and frequent storms in the vicinity of Iceland and the Norwegian Sea (Hurrell et al., 2003).

The ocean realizes the effects of storms in the form of surface waves, so that it exhibits a marked response to long-lasting shifts in the storm climate. The recent upward trend toward more positive NAO index winters, for example, has been associated with increased wave heights over the northeast Atlantic and decreased wave heights south of 40°N (Kushnir et al., 1997). Such changes have consequences for the operation and safety of shipping, offshore industries, and coastal development.

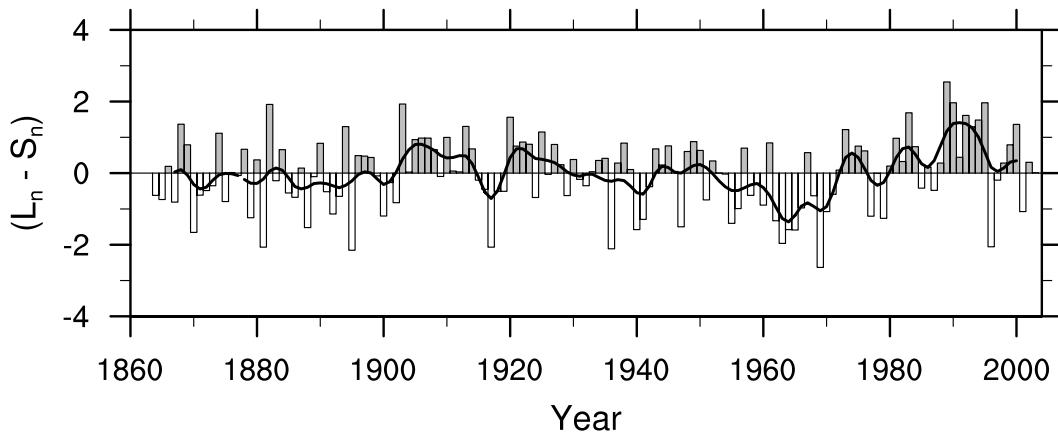

Figure N8 Index of the boreal winter (December–March) mean NAO constructed as the difference in sea-level pressure between Lisbon, Portugal and Stykkisholmur/Reykjavik, Iceland from 1864 through 2003. The mean winter sea-level pressure data at each station were normalized by division of each seasonal pressure by the long-term mean (1864–1983) standard deviation. The heavy solid line represents the index smoothed to remove fluctuations with periods less than 4 years. The indicated year corresponds to the January of the winter season (e.g. 1990 is the winter of 1989/1990). See <http://www.cgd.ucar.edu/~jhurrell/nao.html> for updated time-series.

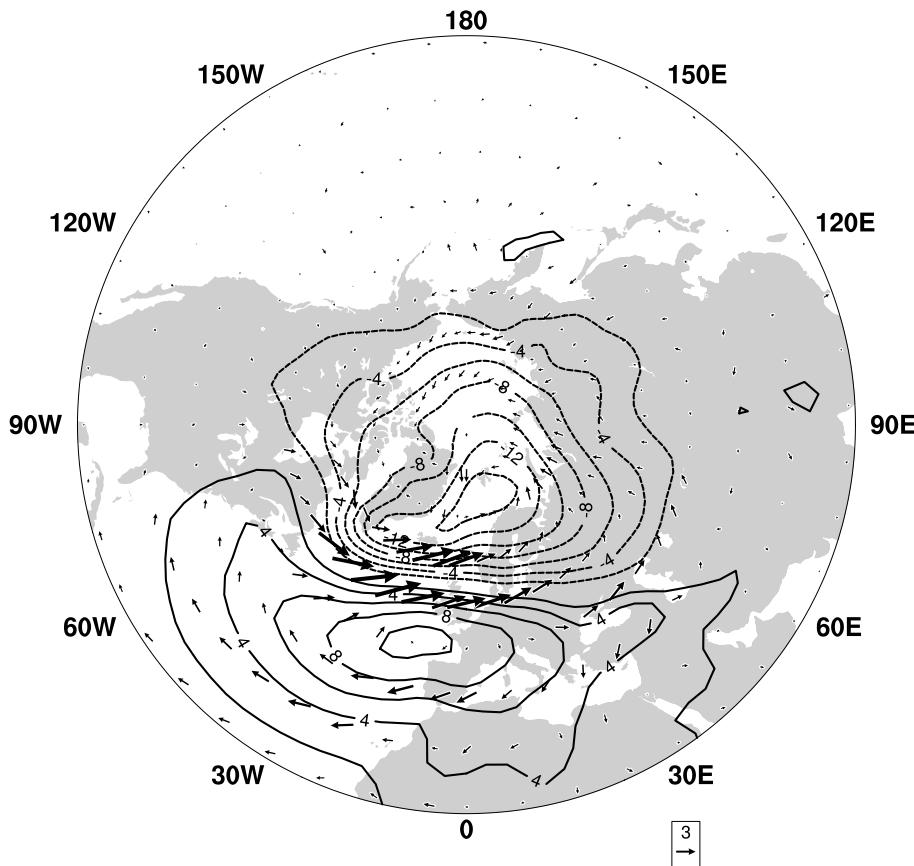

Figure N9 The difference in boreal winter (December–March) mean sea-level pressure and surface vector winds between positive (hi) and negative (lo) index phases of the NAO. The composites are constructed from data when the magnitude of the NAO index exceeds one standard deviation. Nine winters are included in each composite. The contour increment for sea-level pressure is 2 hPa; negative values are indicated by the dashed contours, and the zero contour has been excluded. The scaling vector is 3 m s^{-1} .

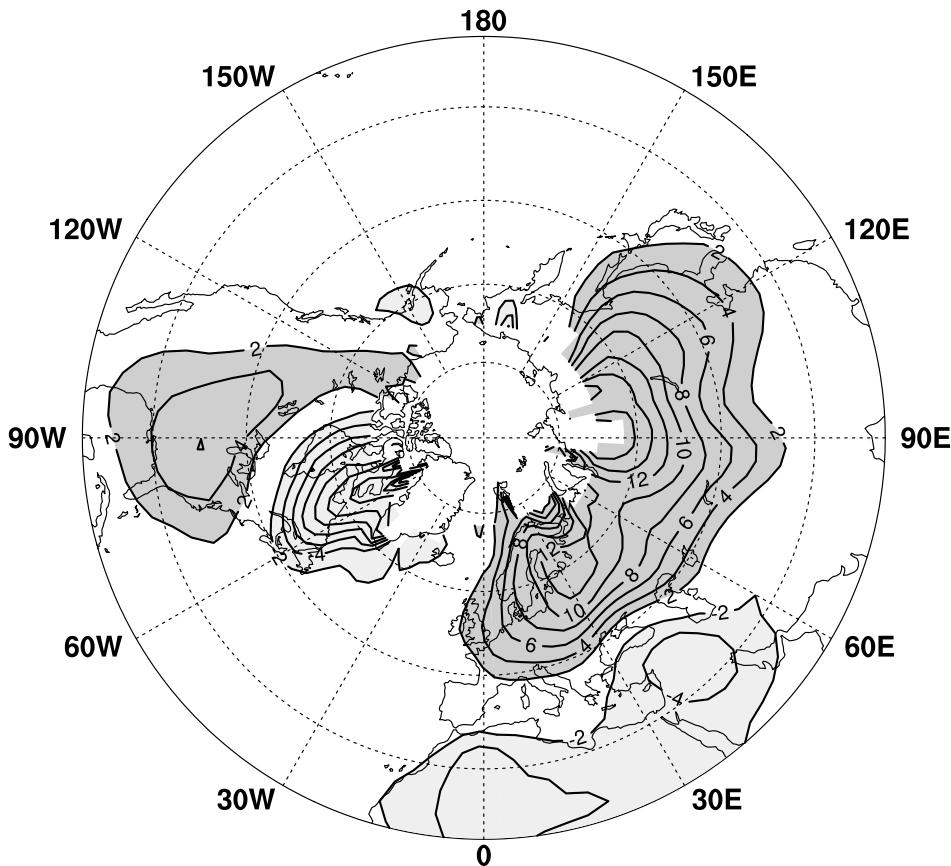

Figure N10 Changes in mean winter (December–March) land surface and sea surface temperatures ($\times 10^{-1}\text{°C}$) corresponding to a unit deviation of the NAO index over 1900–2003. The contour increment is 0.2°C . Temperature changes $>0.2\text{°C}$ are indicated by dark shading, and those $<-0.2\text{°C}$ are indicated by light shading. Regions of insufficient data (e.g. over much of the Arctic) are not contoured, and the zero contour has been excluded.

Changes in the mean flow and storminess associated with swings in the NAO are also reflected in pronounced changes in the transport and convergence of atmospheric moisture (Hurrell et al., 2003). Winters tend to be drier than average over much of Greenland, the Canadian Arctic, much of central and southern Europe, the Mediterranean and parts of the Middle East during positive NAO index winters, whereas more precipitation than normal falls from Iceland through Scandinavia. This pattern, together with upward trend in the NAO index since the late 1960s, is consistent with recent observed changes in precipitation over much of the Atlantic basin. One of the few regions of the world where glaciers have not exhibited a retreat over the past several decades is in Scandinavia, where more than average amounts of precipitation have been typical of many winters since the early 1980s. In contrast, over the Alps, snow depth and duration in recent winters have been among the lowest recorded, and the retreat of Alpine glaciers has been widespread.

In addition to these impacts, significant changes in ocean surface temperature and heat content, ocean currents and their related heat transport, and sea ice cover in the Arctic and sub-Arctic regions are also induced by changes in the NAO. For example, the oceanic response includes changes in the distribution and intensity of winter convective activity in the North Atlantic. The convective renewal of intermediate and deep waters

in the Labrador Sea and the Greenland–Iceland–Norwegian Seas contribute significantly to the production and export of North Atlantic Deep Water and, thus, helps to drive the global thermo-haline circulation. The intensity of winter convection at these sites is characterized not only by large interannual variability, but also interdecadal variations that are synchronized with variations in the NAO (Dickson et al., 1996). Likewise, the strongest interannual variability of Arctic sea ice occurs in the North Atlantic sector and is primarily driven by changes in the NAO. A seesaw in ice extent between the Labrador and Greenland Seas characterizes the ice variations (Deser et al., 2000).

Mechanisms

Considering the significant impact the NAO exerts on the climate (Hurrell et al., 2003), the economy (Visbeck et al., 2002) and ecosystems (Stenseth et al., 2002) of the northern hemisphere, understanding the mechanisms that determine its structure and variability in time is of central importance. It is well known that the basic structure of the NAO results from processes internal to the atmosphere (Hurrell et al., 2003). As such, the month-to-month and even year-to-year changes in the phase and amplitude of the NAO are largely unpredictable. But that forces external to the atmosphere might nudge the NAO

over a particular month or season is important: even a small amount of predictability could be useful, and a better understanding of how the NAO responds to external forcing is crucial to the current debate on climate variability and change.

A number of different mechanisms that could influence the detailed state of the NAO have been proposed. Within the atmosphere itself, changes in the rate and location of tropical rainfall have been shown to influence the atmospheric circulation over the North Atlantic and, in particular, the NAO. Tropical convection is sensitive to the underlying distribution of ocean surface temperature, which exhibits much more persistence than sea surface temperature variability in middle latitudes. This might lead, therefore, to some predictability of the NAO phenomenon.

Interactions with the lower stratosphere are a second possibility. This mechanism is of interest because it might also explain how changes in atmospheric composition influence the NAO. For example, changes in ozone, greenhouse gas concentrations and/or levels of solar output affect the radiative balance of the stratosphere that, in turn, modulates the strength of the winter polar vortex in the lower stratosphere. Given the relatively long time-scales of stratospheric circulation variability (anomalies persist for weeks), dynamic coupling between the stratosphere and the troposphere could yield a useful level of predictive skill for the wintertime NAO.

A third possibility is that the state of the NAO is influenced by variations in heat exchange between the atmosphere and the ocean, sea-ice and/or land systems. A significant amount of numerical experimentation has been done to test the influence of tropical and extratropical sea surface temperature anomalies on the NAO, and these experiments are beginning to lead to more conclusive and coherent results.

O

OCEAN-ATMOSPHERE INTERACTION

The oceans form 70.8% of the atmosphere's lower surface, and are therefore of major significance in structuring both weather and climate over the globe. The actual circulation of the ocean and the interactions between sea-ice and the atmosphere are largely dealt with elsewhere, although feedbacks between the ocean and atmospheric circulation will figure below. The emphasis here is on the ocean as a boundary, permeable to a number of climatically important gases but directly affecting the atmosphere thermodynamically through its sea surface temperature (SST).

Air-sea exchanges

The ocean exchanges heat, moisture, momentum and various gases and particles with the atmosphere. Many of these have an impact on weather and climate and we will return to consideration of the climatically important gas transfers later. However, the predominant exchange of climatic importance is of heat. The mean exchange of heat helps determine the global climate; anomalies in this exchange lead to changes in weather patterns through to longer-term climatic changes.

Heat is exchanged across the air-sea interface predominantly through four physical processes. Solar radiation enters the ocean and is rapidly absorbed below the surface. The ocean radiates back longer wavelength infrared energy; 60–80% of this is returned to the ocean via the greenhouse effect. Turbulent exchange of sensible heat occurs in the planetary boundary layer. This is proportional to the air-sea temperature gradient and the wind speed, with atmospheric instability amplifying the constant of proportionality (the Dalton number). Lastly, heat is (normally) lost to the atmosphere through evaporation and latent heat transfer. This is again proportional to the wind speed, though in a nonlinear way at higher wind speeds, and the specific humidity gradient in the boundary layer.

Typically, the latent heat flux is the largest and most variable heat transfer term, being particularly pronounced above

western boundary currents in winter where, even in a monthly average, latent heat transfer to the atmosphere can be several hundred W m^{-2} . As will be seen below, this has important implications for both mean and anomalous climates, through feedback between storm tracks and upper ocean circulation. A fuller discussion can be found in Bigg (2003).

The ocean and atmosphere also exchange water, with a global mean excess of evaporation over precipitation over the oceans of $36 \times 10^{15} \text{ kg yr}^{-1}$ ($\sim 100 \text{ mm yr}^{-1}$). This provides approximately a third of the precipitation that falls over land. Regionally, however, depending on the balance between dry, windy conditions and moist, cool weather, there may be an oceanic excess of either evaporation or precipitation. In polar regions the oceanic freshwater budget is complicated by the impact of sea-ice and iceberg transport, and subsequent melting. While under normal circumstances these can be neglected for atmospheric studies, we will see later that exceptional, but real, anomalies in iceberg fluxes can lead to extreme climate change.

The ocean and atmosphere also exchange climatically important gases such as carbon dioxide (CO_2), dimethyl sulfide (DMS), hydrogen sulfide (H_2S), nitrous oxide (N_2O), methane (CH_4), carbon monoxide (CO) and methyl iodide (CH_3I). Many of these play a role in the greenhouse effect, and thus influence longer-term climate change, while some (DMS, H_2S and CH_3I) lead to the atmospheric formation of radiatively active particles and cloud condensation nuclei through oxidation. The sea is also an important source of sea salt particles, a major natural seeding source for the coalescence process within clouds, and smaller organic particles.

Monitoring

Sea surface data used in preparing weather forecasting analyses, climate forecasts or merely for climatological studies are obtained in a number of ways. For many years the primary source was merchant ships providing SST through bucket (largely pre-1940) or engine intake measurement, with a small number of fixed-location weather ships taking more extensive measurements. Since the mid-1970s these have been increasingly supplemented by expendable bathythermographs (XBT) for upper ocean temperature profiles, satellite advanced very

high resolution radiometers (AVHRR) for SST, microwave scatterometers for surface winds and waves, and floating and pop-up buoys. Thus over the last 30 years data availability has gone from being heavily biased to shipping routes (and hence the mid-latitude North Atlantic and North Pacific) to global.

There are still problems with more recent datasets. For example cloud cover restricts AVHRR SST temporally and spatially, making polar latitudes very hard to observe. Buoy locations are determined by ocean currents. Scatterometer wind directions are not always uniquely determined. Nevertheless, we now have a much better idea of both mean surface ocean conditions and their temporal variability.

Mean climatic effects of the ocean

The ocean's supply of heat to the atmosphere, and its large heat capacity acting as a thermal moderator to the more variable atmosphere above it, has a significant impact on the geographical pattern of the climate. Figure O1, showing the mean SST for February and August, is a guide to these links.

The basic SST pattern in both seasons and hemispheres is predominantly zonal, as is the atmospheric temperature variation. This is as expected from the basic need for the planet to redistribute heat from the tropics to the poles to maintain thermal equilibrium. However, there are several important exceptions to this zonality. Firstly, in summer (northern hemisphere August and southern hemisphere February), the SST tends to be colder than the nearby land temperature, even where the SST pattern is largely zonal. For example the mean February air temperature in inland subtropical Australia is close to 30°C, yet the adjacent SST is in the low 20s. The opposite is true in winter (northern hemisphere February and southern hemisphere August), when SST tends to be warmer than the nearby land. Thus, Las Vegas in Nevada has a February air temperature just below 10°C while the SST in both the Atlantic and Pacific at a similar latitude is closer to 15°C. The high heat capacity of the ocean, and restriction of heat exchange to its surface only, means that the ocean has a strong moderating effect on climate. Climates of coastal locations are therefore significantly milder than in continental interiors. Note, however, that in regions adjacent to winter or permanent sea-ice the ameliorating effect of the ocean is lost.

Along the western boundaries of midlatitude and subpolar oceans winter temperatures are anomalously warm for their latitude, due to the presence of intense, but narrow, western boundary currents in the upper ocean. These very efficiently transport heat poleward. Indeed, toward the subtropics the ocean provides over half of the total meridional heat transport needed to balance the planetary heat budget (Bryden et al., 1991). These poleward oceanic heat transports are evident in each major ocean basin in Figure O1, but especially in the North Atlantic and North Pacific in winter. The Northeast Atlantic, stretching into the Norwegian Sea, shows a particularly striking signature of warm SST associated with the North Atlantic Drift.

The ocean can provide a net cooling of the atmosphere. Along eastern coasts of the oceans in the midlatitude and subtropics, and to some extent along the equator, cooler than expected SST can be seen in Figure O1. These are caused by upwelling, where equatorward alongshore winds (or easterly along-equator winds) cause water to diverge from the coast (or equator), allowing cooler, subsurface water to upwell. This is most noticeable along the eastern coasts of the Pacific and Atlantic, and in the equatorial Pacific, where the atmosphere above is cooled.

These land-sea thermal contrasts through the seasons have an impact on mean atmospheric pressure fields. Thus, the subtropical high-pressure zones of the North Pacific, South Pacific and South Atlantic are several hPa stronger during the summer than in the winter, due to the relatively cool water at these subtropical latitudes relative to the nearby land. The presence of the warm western boundary currents tends to displace all the subtropical highs to the eastern part of their respective basins. Another direct impact of the SST on atmospheric circulation is that tropical cyclones, or hurricanes, are only formed over off-equatorial waters warmer than about 27°C.

Anomalies in SST are directly linked to both seasonal and inter-annual climate variability so the next four sections will briefly discuss several such climate signals.

Long-range forecasting

For some time it has been known that SST anomalies are related to seasonal-scale climate variability, not just locally but possibly hundreds to thousands of kilometers downstream (Ratcliffe and Murray, 1970). The strongest links between SST and seasonal weather are found in the tropics, and there has been some success in forecasting the onset and strength of El Niño events since the mid-1980s (see next section). However, there is evidence that similar, if weaker, links are present in other parts of the globe. Statistical techniques were first used to exploit these teleconnections and still remain a powerful tool, particularly in tropical regions. More recently, dynamical models of varying complexity up to full-scale coupled ocean-atmosphere-sea ice climate models have been used, increasingly on a routine basis, to forecast both tropical and midlatitude seasonal trends.

Seasonal forecasts have a rather different appearance compared with more familiar daily weather forecasts. As the link between weather and SST is manifested in long-term weather averages, then forecasts are given for conditions averaged over 3-month periods and are often stated in terms of geographical maps of probability. As initial conditions are uncertain, an ensemble of model runs is produced. This allows probabilities to be obtained. Thus, to use an example quoted on the Meteorological Office web-site (<http://www.metoffice.com/research/seasonal/background.html>) for seasonal forecasting over Europe, if 19 of 27 forecasts indicate above normal seasonal temperature over Europe, and eight of the forecasts indicate below-normal temperature, the chance of above-normal temperature is 70%, while the chance of below-normal temperature is 30%.

El Niño

The see-saw in pressure across the tropical Pacific between the Indo-Australian Convergence Zone and the southeastern Pacific, known as the Southern Oscillation (Figure O2), is the largest and most geographically widespread annual scale climatic interaction between the ocean and atmosphere. In the mean, surface pressure is low over the western Pacific and high in the southeast Pacific (the Walker circulation). When these "normal" conditions are accentuated then there is often a La Niña climate anomaly, but when the pressure gradient across the Pacific is reduced there tends to be an El Niño climate anomaly. Some relaxation of east-west pressure gradient occurs annually late in the calendar year, causing warmer than normal water to appear in the equatorial eastern Pacific, as

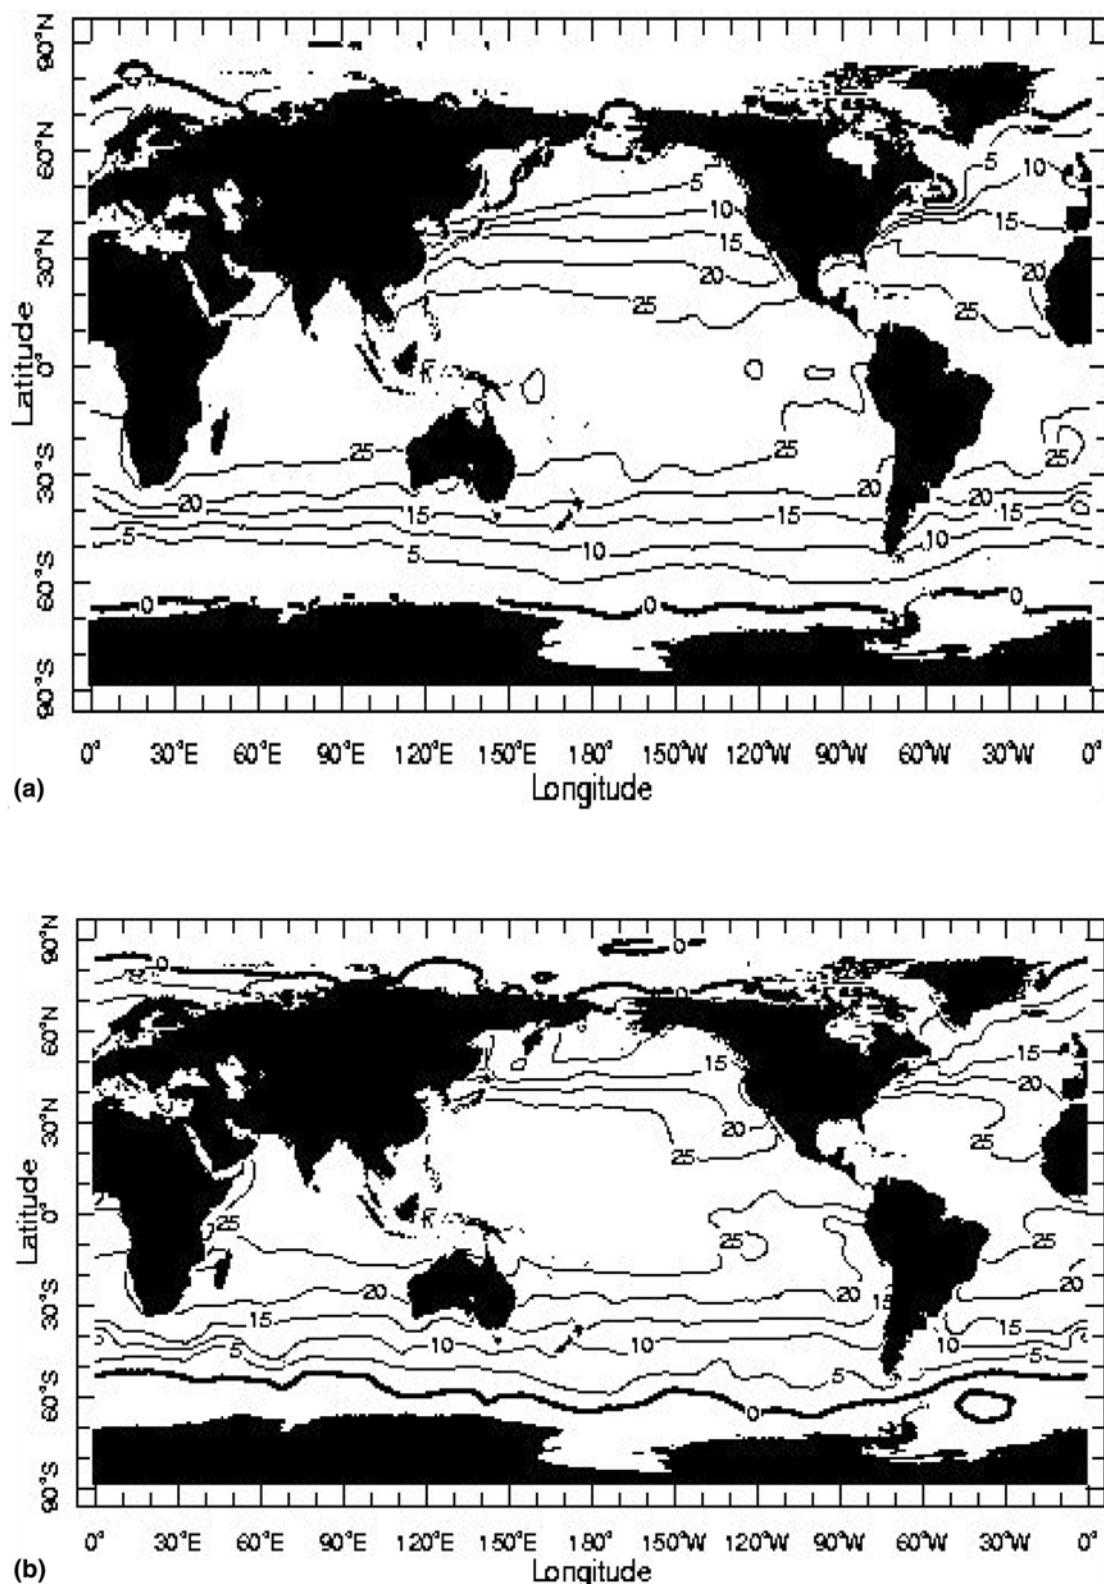

Figure O1 Mean SST for (a) February and (b) August; from the Lamont-Doherty Data Library.

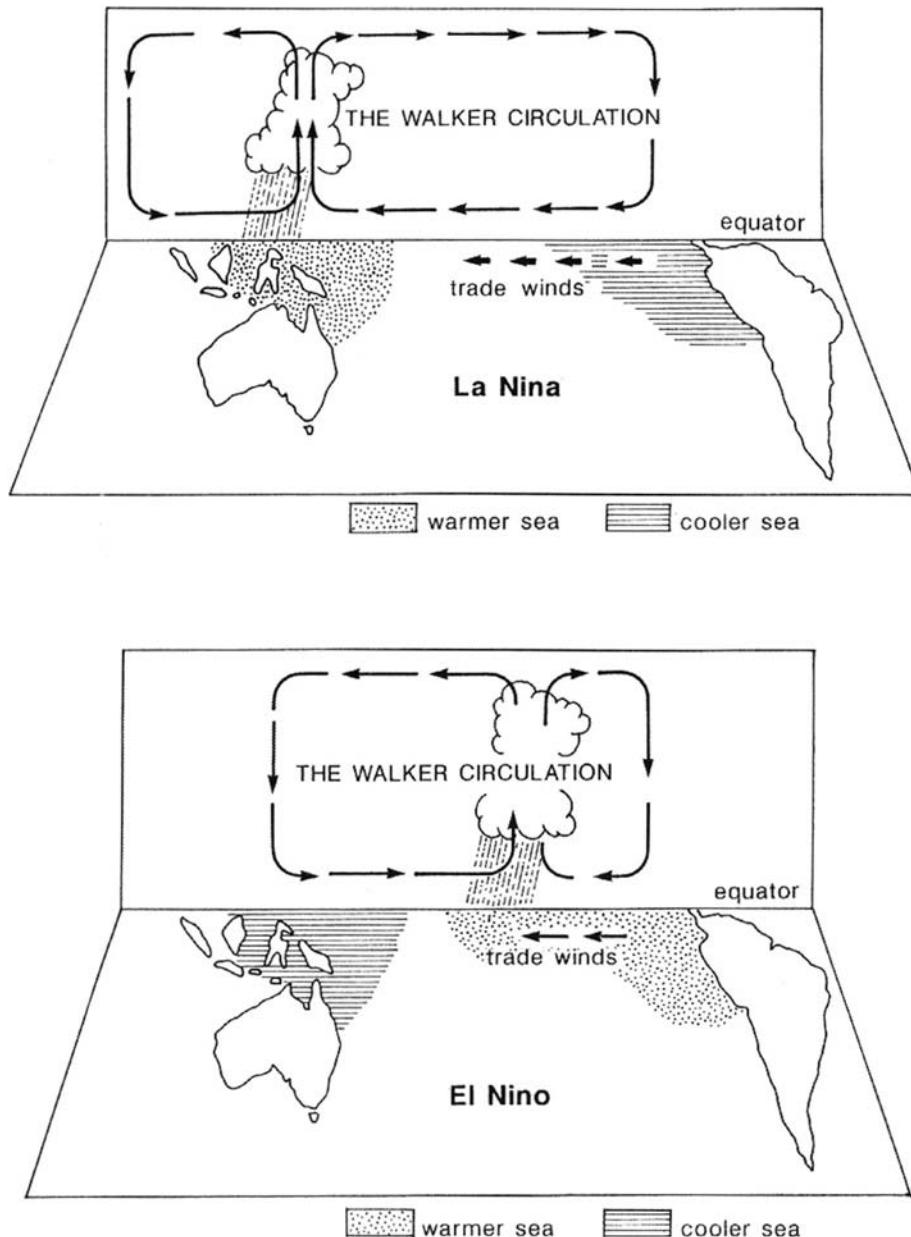

Figure O2 Schematic of the Walker circulation. Adapted from the Australian Bureau of Meteorology online tutorial.

upwelling decreases, and for a warm current to appear along the South American coast where there is usually a cold, northward flow. This current was given the name El Niño (Christ Child) by local fisherman as it usually appeared around Christmas time. Every 3–4 years on average a much warmer and longer-lasting current forms, which is now known to be directly linked, through air-sea interaction, to the sudden relaxation of the east-west pressure gradient along the equator. Such events have therefore become known as El Niño events, with the opposite, cold, events named for a girl child, La Niña (Philander, 1990).

While the existence of the Southern Oscillation has been known of since Sir Gilbert Walker's work in the early decades

of the twentieth century, its connection to El Niño events was not fully realized until Bjerknes' work in 1969. An explanation of the mechanisms underlying such an event had to wait until the mid-1980s (Graham and White, 1988). Even now, the mechanisms leading to variability in the frequency of events are not clear. At some times El Niño events do not occur for a decade (1930s), while at others events can recur annually (early 1940s and early 1990s). Sometimes a La Niña immediately follows an El Niño (1998 following 1997/8), but more often it does not. The character of individual events also varies significantly. Nevertheless, common features do exist and these form the basis of the following discussion.

The trigger for El Niño is a prolonged period of westerly wind anomalies in the strong easterly trade wind belt in the western Pacific. This can come about in a number of ways: a random anomaly, part of the organized convection signal of the eastward passage of the intra-seasonal Madden-Julian Oscillation (Madden, 1986), a linking of the inflow from hurricanes on opposite sides of the equator. Whatever the cause, the westerly anomalies alter the upper ocean, sending a Kelvin wave along the equatorial waveguide. This pulse carries a signal of a relaxing sea level, and thermocline, gradient at speeds of several meters per second towards the eastern Pacific, suppressing upwelling and leading to the upper ocean warming experienced by fisherman off South America. The suppression of upwelling to the east of the original wind anomaly causes the SST to rise, encouraging convection to move eastwards toward it. The westerly wind anomaly propagates eastward with it, initially amplifying and then sustaining the signal in the ocean and atmosphere.

The movement of the Indo-Australian Convergence Zone into the central Pacific has ramifications for the atmospheric circulation well away from the tropical Pacific. Because the Hadley Cell allied with this convergence zone also moves eastward, and an associated Rossby wave is initiated in the atmosphere, a wave train is set off in the upper troposphere, arcing poleward and eastward. This leads to enhancement and southward movement of the Aleutian Low, bringing storms to California, colder and drier conditions over central Canada and wet conditions over the southeast United States. These anomalies often peak in the boreal winter. An extreme signal in the Pacific can lead to further, but weaker, effects downstream over Europe.

Associated with the change in the tropical Walker circulation is disruption to the tropical circulation over the Atlantic, leading to fewer Atlantic hurricanes and drought over west Africa. The Indian Monsoon circulation system can also be affected by a weakening of the summer convection over south Asia, although independent air-sea interaction in the Indian Ocean can limit or eliminate this signal, as was the case in the 1990s (Saji et al., 1999).

Typically, these widespread anomalies last for several months to a year before the oceanic anomaly in the tropical Pacific is eroded by the repeated impact of reflected equatorial long waves from the western Pacific. Once the oceanic heat source sustaining the convection is removed, the convection zone can return to its more normal anchoring in the western Pacific, and the wind field returns to normal. La Niña occurs if this return to normal convection overshoots and the equatorial easterlies become anomalously strong, leading to a strengthening of “normal” atmospheric and oceanic circulation – and air-sea feedback – for a similar time to the preceding El Niño.

The very clear ocean-atmosphere feedback processes set off in El Niño mean that there is the potential for its forecasting to achieve a useful measure of skill. Particularly once the initial signal has begun, climate prediction one or two seasons in advance is possible, and forecasters using a mix of statistical and dynamical methods achieved considerable success in the extreme 1997–1998 event – the so-called climate event of the century (Changnon, 2000) – and also correctly forecast the development of the weaker 2002 event.

The North Atlantic Oscillation

Another region where a pressure see-saw between two semi-permanent pressure centers has considerable climatic impact is

in the North Atlantic, where oscillation in the gradient between the Icelandic Low and the Azores High is known as the North Atlantic Oscillation (NAO; Wallace and Gutzler, 1981). This oscillation operates on a number of different time-scales. It is most pronounced in boreal winter, when the average pressure gradient is at its greatest. Fluctuation in the amplitude of the NAO can also occur from synoptic through seasonal to decadal time-scales. It is sometimes thought to be part of a geographically wider atmospheric pattern called the Arctic Oscillation (Thompson and Wallace, 1998). However, the air-sea interaction involved is clearest in the North Atlantic, so here we will restrict our consideration to the NAO.

The most important effect of changing the pressure gradient between the Icelandic Low and Azores High is in the strength of the westerly winds across the North Atlantic and into western Europe. At times when the pressure difference is enhanced (positive NAO) the westerlies are stronger, leading to stormier but milder conditions in western Europe. In contrast, a reduced pressure gradient (negative NAO) corresponds to weaker atmospheric flow, and so drier, colder conditions over western Europe. Movement in the centers of action is not well captured by the basic pressure difference describing the NAO Index, and can result in significant changes in the regional impact of this climatic signal. There is some evidence that decadal variability in the NAO is related to movement of the key pressure centers.

Stronger winds in positive NAO periods cause more evaporation, and hence more latent heat transfer to the atmosphere from the ocean. This latent heat flux encourages storm formation, and leads to warmer conditions downstream. A negative NAO will reduce latent heat transfer from the ocean, although note that it is easier for continental weather systems to affect the eastern Atlantic in such conditions. There is therefore a strong interaction with the ocean, which contains the potential for a negative feedback: latent heat transfer cools the ocean reducing the heat flux to the atmosphere and discouraging cyclogenesis. The thermal inertia of the ocean means that any such feedback will only operate on seasonal or longer time-scales, and indeed persistent multi-year signals in the SST of the North Atlantic Drift have been observed to propagate eastwards (Sutton and Allen, 1997). The position of the Drift, and hence the source of the latent heat transfer into the atmosphere, is also coupled to the winds, allowing feedback between ocean and atmosphere.

Many environmental parameters have been found to correlate well with the NAO, because of the strong climatic impact in its variation. The change in western European climate between the cold 1960s and the warm 1990s can be seen to be strongly linked to a persistent long-term change from negative to positive NAO over this time. Whether this change was a consequence of global warming or a natural fluctuation coordinating with this signal is not yet known (Stocker et al., 2001).

Pacific Decadal Oscillation

The Pacific Decadal Oscillation (PDO) is a pattern of Pacific climate variability with an El Niño-like spatial fingerprint, but a very different time-scale. Steven Hare described the climate signal in 1996 while researching connections between Alaskan salmon and Pacific climate (Mantua et al., 1997). The PDO differs from phases of the Southern Oscillation in two main ways. The time-scale is much longer: twentieth-century PDO “events” persisted for several decades, while typical El Niño

events last for around a year or less. Spatially, the PDO events are strongest in the North Pacific/North American sector, while secondary signatures exist in the tropics – the opposite is true for El Niño/La Niña events.

There appear to have been only two full PDO cycles in the past century: “cool” PDO regimes prevailed from 1890 to 1924 and again from 1947 to 1976, while “warm” PDO regimes dominated from 1925 to 1946 and from 1977 through (at least) the mid-1990s. The terms “cool” and “warm” refer to the tropical SST signature, while the North Pacific SST tends to be opposite to this. Major changes in northeast Pacific marine ecosystems have been correlated with phase changes in the PDO: warm eras have seen enhanced coastal ocean biological productivity in Alaska and inhibited productivity off the west coast of the contiguous United States, while cold PDO eras have seen the opposite north–south pattern of marine ecosystem productivity.

The causes of the PDO are not currently known, although the time-scale of the oscillation is suggestively similar to that of an oceanic midlatitude Rossby wave. Some coupled climate simulation models produce PDO-like oscillations. These can be similar to the NAO, involving interaction between advective SST anomalies in the western boundary current (the Kuroshio in this case) and variations in the westerlies and latent heat transfer. However, stochastic forcing cannot yet be discounted, because of the long time-scales of oceanic Rossby wave propagation.

Thermohaline circulation

The thermohaline circulation of the ocean is the oceanic equivalent of the meridional circulation in the atmosphere. Surface waters become sufficiently dense to sink, through cooling (North Atlantic) or sea-ice-induced salinification (Antarctic). These dense, deep waters then return to the surface through

turbulent mixing near rough topography over the whole globe, and also through mixing in the strong zonal current, known as the Antarctic Circumpolar Current (ACC), underlying the westerlies in the Southern Ocean, at around 50°S. Surface flow closes the circuit, through entrainment of part of the ACC into the subtropical gyre of the South Atlantic, and through the generation of northwestward-moving eddies from the Agulhas Current of the Indian Ocean as it retroflects at the southern tip of Africa (Figure O3).

The overturning time-scale of the thermohaline circulation is of the order of 1000 years, so the ocean has memory of atmospheric conditions at the millennial time-scale. However, because the strong poleward movement of warm water in the North Atlantic forms part of the thermohaline circulation disruption of this flow on time-scales of only decades (e.g. through catastrophic freshwater inputs damping the ocean’s ability to convect) gives the potential for abrupt climate change over years to decades. Reducing the supply of warm water to the northern Atlantic through suppressing convection reduces the ability of the ocean to provide large quantities of latent heat to the atmosphere. The downstream impact of this can be a reduction in western European temperature of several degrees. Particularly during glacial periods and deglaciation, such changes in northern Atlantic climate have left signs in the paleoclimate record, most dramatically associated with the release of either icebergs, or flood waters from ice dam breaks, from the North American Laurentide ice sheet. The iceberg releases are known as Heinrich events, after the German scientist who, in the 1980s, first identified the ice-raftered debris signal from such events (Heinrich, 1988). Heinrich events are believed to have occurred when the ice sheet over Hudson Bay and central Canada became sufficiently deep that the basal layer became fluid and much of the ice drained into the sea over a few centuries (MacAyeal, 1993). This freshened northern waters,

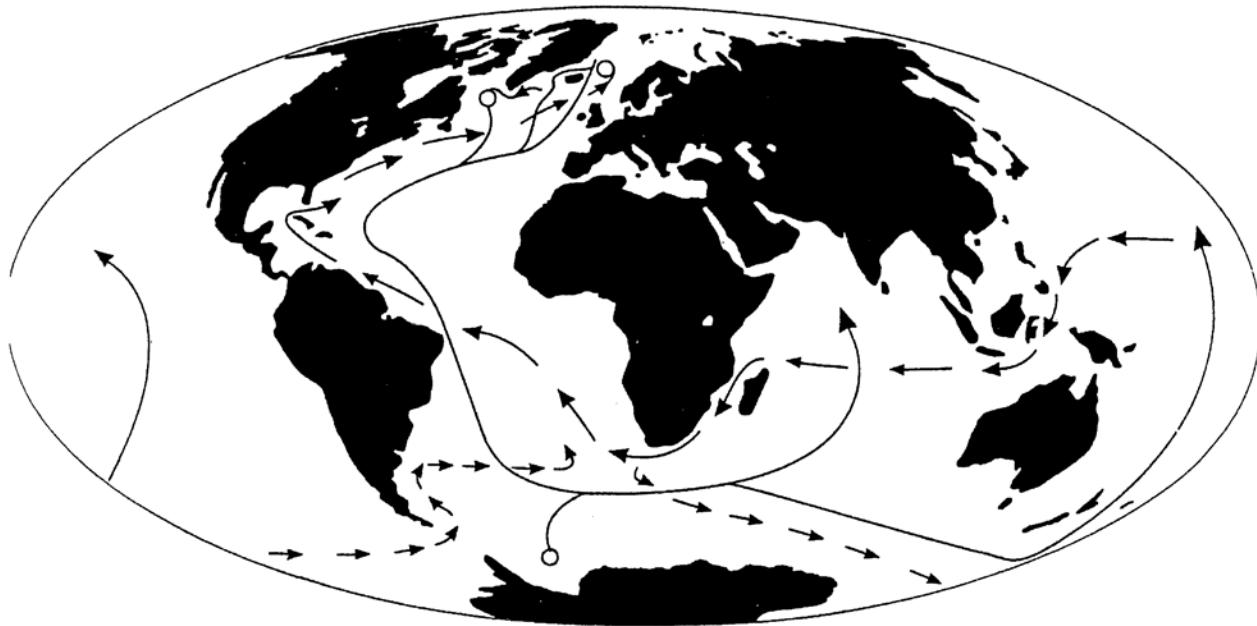

Figure O3 Schematic of the conveyor belt circulation. Circles indicate where deep water is formed; the solid lines show deep-water flow, and the dashed lines show near-surface flow (from Fig. 1.14 of Bigg (2003); reproduced with permission of Cambridge University Press).

stopping convection and plunging the North Atlantic and much of the northern hemisphere into a cold period. The rebounds to warm conditions some centuries later seem to have occurred over a few decades, as convection suddenly switched back on. The most recent such climate oscillation, around 12 000 years ago, is known as the Younger Dryas, although the cause of this is more likely to be related to ice-sheet meltwater release than icebergs. The Heinrich events proper recurred at varying intervals of the order of 10 000 years apart.

Between these extreme climate oscillations another cycle of about 1400 years exists – the Dansgaard–Oeschger Oscillations (Dansgaard et al., 1984) in the records of the Greenland ice cores, or the Bond cycle of ocean floor sediments (Bond et al., 1993). These appear to be less extreme convection transitions, but with similarly temporally abrupt endings and slightly less abrupt beginnings, a climatic signal largely confined to the North Atlantic, and probably involve air–sea interaction at the thermohaline time-scale (Alley, 2001).

Biological feedback

A major change to the way air–sea interaction has been perceived in the last two decades is via the rising profile of potential feedbacks between marine phytoplankton and atmospheric climate. It has been known for many years that the ocean was important in the carbon cycle, and hence in determining the level of atmospheric carbon dioxide, an important greenhouse gas. However, measurements of atmospheric carbon dioxide levels inside ice cores have now shown that as far back as half a million years ago there were tight couplings between global temperature and carbon dioxide concentration. The terrestrial biosphere no doubt contributes to this, but many scientists believe that much of the oscillation between the low levels of atmospheric carbon dioxide in glacial periods and the high levels in interglacials occurs due to feedbacks with the ocean carbon store, and most probably with phytoplankton stocks (Watson et al., 2000). Phytoplankton consume carbon dioxide during photosynthesis, and so atmospheric levels would be reduced if plankton were more abundant. Fertilizing currently iron-poor reaches of the surface ocean in the Southern Ocean and equatorial waters in particular through wind-blown dust is a possible mechanism forcing higher phytoplankton numbers. The ocean is also a source for other greenhouse gases, in particular methane and nitrous oxide, through reducing environments in sediments or low oxygen environments.

An important, but short-lived, gas produced by the ocean is dimethyl sulfide (DMS). This gas is produced by phytoplankton, probably as part of their regulation of cell ionic strength. Amounts vary widely according to species, however. The ocean is a net source of this gas, which has a lifetime in the atmosphere of only a day or so. Its importance lies in the rapid oxidation of DMS to sulfate particles in the atmosphere, a major source of cloud condensation nuclei. Changes in phytoplankton abundance can therefore directly influence cloud coverage and properties, and hence the Earth's radiation budget. The CLAW hypothesis (Charlson et al., 1987) proposes that increased phytoplankton, through elevated DMS levels, leads to increased concentrations of smaller cloud condensation nuclei, which tend to reflect solar radiation more efficiently and so cool the planet. Depending on the effect of cooling on the marine biosphere, which is complex and not fully resolved, this effect might be a positive or negative feedback on global temperature.

OCEAN CIRCULATION¹

Most ocean currents other than tidal currents derive from either the stress of the wind on the water surface or the uneven distribution of mass due to variations in temperature and salinity. In general, the currents in the upper layers of the ocean are attributable to wind stress, whereas those below are part of the thermohaline circulation resulting from the distribution of temperature and salinity, but this distinction is often unclear, and the two are connected by vertical water movements. Just as winds in the atmosphere are rarely steady, so ocean currents are subject to considerable variation. This variation, which is associated particularly with eddy-like features with length scales of the order 100 km, has been the subject of much research in recent years. Here we will be concerned essentially with the time-mean or net circulation on which this variability may be considered to be superimposed.

Wind-induced currents

The wind blowing across a water surface exerts a frictional stress in the direction in which it is blowing, as well as generating waves. There is some forward movement of water particles in wave motion, and the magnitude of the stress that the wind exerts depends on the roughness of the water surface, so the two processes are closely interrelated.

The simplest situation in which to consider the nature of the currents resulting from wind stress is that in which a wind blows at constant velocity over a deep, infinite, and homogeneous ocean, so that the water movement is not impeded by any continental barriers and the coefficient of (eddy) viscosity remains constant with depth. We could reasonably assume that in such a situation the speed of the resulting current would be greatest at the surface and would decrease with increasing depth, and that below some depth at which the current became negligibly small we could ignore friction. Considering the layer above this depth as a whole, and assuming that the wind remains steady for a period long enough to allow a steady current to become established with no acceleration, we can equate the magnitude of the wind stress (τ) with the Coriolis Effect and conclude that the mean current (\bar{u}), and therefore the net transport of water in this layer, is 90° *cum sole* (*cum sole* is sometimes used to mean to the right in the northern hemisphere and to the left in the southern hemisphere) from the wind direction. Thus

$$\tau = D\rho f \bar{u},$$

where D is the depth of the layer so that $D\rho$ is the mass of the layer per unit surface area. Hence

$$\bar{u} = \frac{\tau}{D\rho f}.$$

At any one depth, however, the water is subject to three forces – the stress of the overlying water (or, at the surface, the

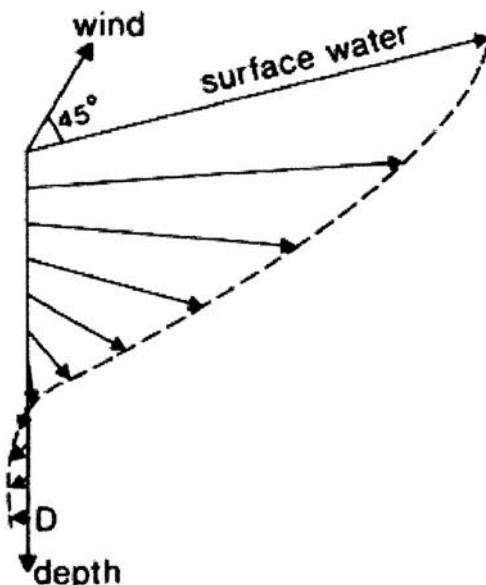

Figure O4 The Ekman spiral, showing variation of current velocity with depth in the Ekman layer.

wind), the stress of the underlying water, and the Coriolis Effect. The effect of this is that the current deviates increasingly *cum sole* with increasing depth. Ekman, who examined this point theoretically, found that the surface current deviates 45° from the wind direction and that the speed of the current decreases exponentially with depth as well as turning further *cum sole* until, at the depth D , it has about 4% of the surface speed and is directed exactly opposite to the surface current. This current structure is known as the *Ekman Spiral* (Figure O4), and the depth D , which varies with the eddy viscosity and the latitude, is called the *depth of frictional influence* and is typically between 50 m and 200 m. The speed of the surface current depends on the same factors as D and on the wind stress, and is usually between 1% and 3% of the wind speed.

Other atmospheric parameters in addition to wind can affect water movement. The sea surface appears to react as an inverted barometer to atmospheric pressure variations. An atmospheric low is thus accompanied by high sea level, and if the winds associated with the low cause water to move toward a coast against which it piles up, particularly high water levels can be experienced. Both midlatitude depressions and tropical cyclones are moving systems; if their speed is appropriate, such high water levels or *storm surges* can travel with them as long waves. This occurs fairly often in the North Sea where a storm surge, accompanying a depression moving rapidly east and with its center passing just to the north of Britain, travels around the coast of Scotland and then follows an anticlockwise path around the edge of the North Sea. Its effects are greatest where the North Sea narrows and shoals in the south, and by the time the storm surge reaches there the northerly winds in the cold sector of the depression may well be causing further water to flow southward in the North Sea.

Surface circulation of the oceans

The Atlantic and Pacific oceans are essentially similar in shape, extending northward from the Southern Ocean and narrowing

¹This article is considerably revised from an original entry in the *Encyclopedia of Climatology* that was based upon Harvey, J.G., 1976. Oceanic circulation. In *Atmosphere and Ocean: our fluid environments*. Sussex: Artemis Press, pp. 119–126.

at their northern ends. The winds between about 10° and 50° latitude are essentially anticyclonic around the subtropical high. This leads to water in the Ekman layer above the depth of frictional influence being transported toward the center of the ocean. The convergence here depresses the main thermocline, but it also leads to the water level sloping downward from the center of the ocean outward, and this gives rise to a gradient current that is anticyclonic, i.e. running in the same direction as the wind (Figure O5).

This *subtropical gyre* is asymmetrical, particularly in the northern oceans, its center being displaced to the western side of the ocean, so that, for example, the Gulf Stream in the North Atlantic and the Kuroshio in the North Pacific are much stronger than any currents on the eastern side of these oceans. The reason for this involves vorticity. If we simplify the situation appreciably by ignoring vertical motion, we can consider the factors that bring about changes in vorticity as the water moves around the subtropical gyre. Throughout the gyre the water is acquiring negative vorticity in the northern hemisphere from the anticyclonic wind stress at the surface. The water on the eastern side is moving equatorward, and its wind-induced negative vorticity may be just sufficient to fit it to the lower positive planetary vorticity at lower latitudes, so that its absolute vorticity is conserved. On the western side, water is moving poleward so that its vorticity becomes negative relative to the Earth and its absolute vorticity becomes increasingly negative. Some braking action is needed to prevent vorticity increasing indefinitely, and this can only be supplied by friction, either at the lateral boundaries or at the sea floor, or by viscosity within the water. This requires much higher velocities on the western side, as friction is proportional to something like the square of the water speed. The result is that the speeds are typically some ten times greater in the warm western boundary current than in the cool eastern boundary current, and the western boundary

current extends to greater depths; but it is less than one-twentieth the width of the ocean and water flows equatorward in most of the remainder, so that the same amounts of water are being transported in both directions. The asymmetry of the subtropical gyres south of the equator is less well marked, and in the South Pacific the cold Peru current on the eastern side is perhaps the dominant feature. The different pattern of distribution of land and sea in the southern hemisphere appears to be responsible for this contrast.

The North Atlantic and North Pacific Ocean currents

The surface currents which most inhabitants of North America are familiar with are those off our East and West coasts. These currents are part of the larger circulation of the North Atlantic and North Pacific. A detailed examination of the currents in the North Atlantic Ocean serves as an illustration of where these currents flow, and their effect on weather and climate. North of the equator in the Atlantic Ocean is a current which moves from east to west. Here the trade winds drag the surface water westward in a slow-moving stream called the North Equatorial Current. The current splits upon reaching South America, with most of the westward-moving water flowing northwest along the coast into the Caribbean Sea and northward into the Atlantic off the North American coast.

Between the island of Cuba and Florida there is a strong current of very warm water flowing out of the Gulf of Mexico and into the Atlantic Ocean. This warm water from the Gulf of Mexico merges with the northward-flowing water from the Caribbean Sea near the West Indies and forms the Gulf Stream. The Gulf Stream, along with the other poleward-flowing currents, transport a tremendous amount of heat from tropical regions toward the poles. While some 60% of the poleward movement of heat is accomplished by the winds of the general circulation, about 40% of the heat is moved by ocean currents. The Gulf Stream is an extremely large current transporting warm water from the tropics, and hence heat, northward off the east coast of the United States. This current is a major factor in weather along the east coast. The current provides a lot of latent heat and water to the atmosphere through evaporation that plays a part in storm activity. Hurricanes often track northward along the Gulf Stream due to the heat that is available to maintain the storms. Because of the size of these storms, even if they remain offshore over the current they can have major impact on coastal areas of the Carolinas. In winter the warm water often provides enough heat for midlatitude lows to form, which then move north along the coast. Some of these lows become well developed nor'easters which inflict major damage to beaches and coastal property. How far northward the warm water flows, and how close to shore the current flows, varies with the season and from year to year.

The Gulf Stream is one of a number of currents that flow along the western side of ocean basins. In the North Pacific Ocean is the Kuroshio Current. It has its origin near the equator, then flows northward toward the islands that make up Japan, and then turns eastward into the Pacific Ocean. These warm currents are not limited to the northern hemisphere; they are found in the Indian Ocean and in the South Atlantic Ocean. These currents flow away from the equator, as do the Gulf Stream and Kuroshio Currents of the northern hemisphere. The Agulhas Current flows southward along the east coast of Africa. All of these currents flow fairly quickly, and move a very large volume of water. They all affect the regional climate.

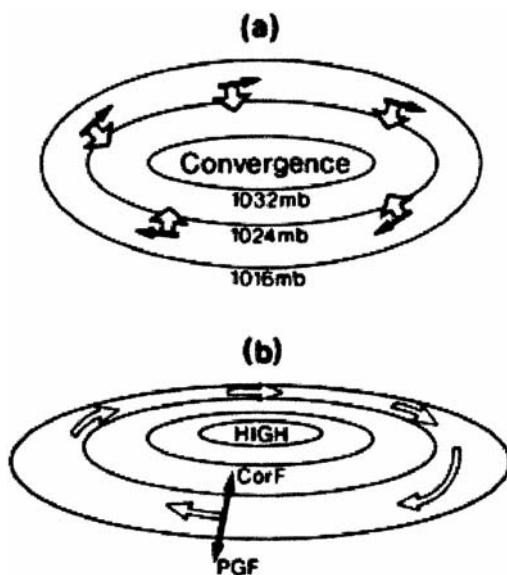

Figure O5 Water movements associated with anticyclonic winds in the northern hemisphere: (a) atmospheric pressure and winds, and associated Ekman transports to the right; (b) resultant topography of the sea surface and associated gradient currents below the depth of frictional influence.

In the general vicinity of New England the westerly winds direct the Gulf Stream away from North America. Much of the Gulf Stream water re-circulates to the west of the mid-Atlantic Ridge. That which crosses the Ridge spreads out as it goes eastward and is known as the North Atlantic Drift. The current remains warm as it flows toward northern Europe, which makes winter conditions there unusually mild for those latitudes. Some of the warm water flows north between Iceland and the British Isles and along the Scandinavian Peninsula (Figure O6).

Part of the North Atlantic Drift splits and flows southward along the west coast of Spain and Portugal as the Canary Current, named for the Canary Islands. The water in this current is relatively cool as it flows south after having crossed the North Atlantic. It is cool only relative to the water temperature in mid-ocean. Many of the characteristics of the Canary Current are seen in its equivalent current off North America, the California Current.

The California Current flows southward roughly parallel to the west coast of North America. Since the water making up this current comes from the North Pacific it is quite cool. All along the west coast of the United States the near-shore water is quite cool. As the current flows south from Washington to California it is to be expected the water would warm as it receives more solar radiation. However, upwelling cold water keeps the surface water rather cold all the way south past the Mexican border. This upwelling provides a cold surface over which the onshore winds cross before reaching land. The cold surface tends to stabilize the onshore moving air, increasing the aridity along some coasts. This is particularly the case along southern California and Baja California. This cool current and upwelling keeps summer water temperatures off the California beaches fairly cool, and much cooler than the water at the same latitudes off the east coast. Temperatures in the California current are typically below 20°C as surfers and bathers are only too aware.

Another region which is exceptionally dry as a result of cool stabilizing water offshore is along the coast of Chile. Here precipitation seldom falls except during times of El Niño. Details of this well-known ocean current, and the Southern Oscillation with which it is associated, are discussed in various items in this volume.

Currents of low and high latitudes

In the trade wind zone, water is transported across the oceans to the western side, and thus there is a slope of the sea surface from west to east. Along the intertropical convergence zone, where winds are light, water is able to flow back downhill to the east, and as it is so near to the equator Coriolis has little effect on it. This current is known in each ocean as the *Equatorial Counter Current*. At the equator itself, where the Coriolis Effect changes direction, there is divergence at the water surface. This brings the thermocline nearer to the surface and also promotes vertical mixing in it, which leads to the water above the thermocline being *denser* at the equator than on either side, but that below the thermocline being *less dense* at the equator than on either side. This causes the pressure gradients at the depth of the thermocline (about 100 m) to slope away from the equator to either side, which in turn causes geostrophic currents toward the east, both immediately north and south of the equator. Further, on either side of the equator, the directions of the wind-induced currents at a depth of 100 m will be nearly opposite those of the surface currents and, although very weak, they will lead to convergence at the equator and will contribute to the flow there with an easterly component.

At latitudes greater than 50° there is a marked contrast between the northern and southern hemispheres. In the North Atlantic and North Pacific, water movement is obstructed by continental barriers, but in the southern hemisphere it is able to travel right around the globe in the Antarctic Circumpolar

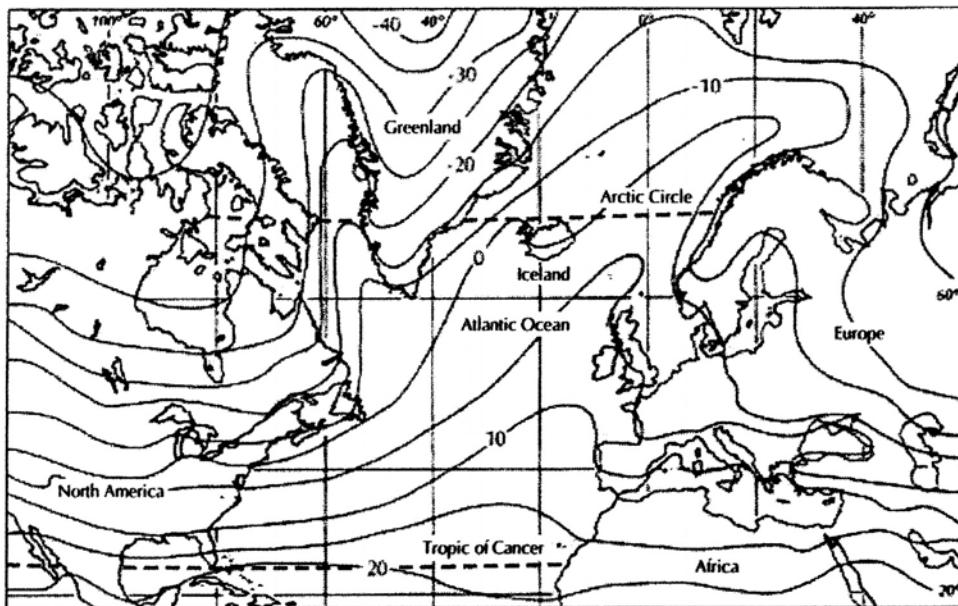

Figure O6 Average January air temperatures across the North Atlantic and neighboring lands. Note the comparative position of the freezing isotherm over North America and northern Europe.

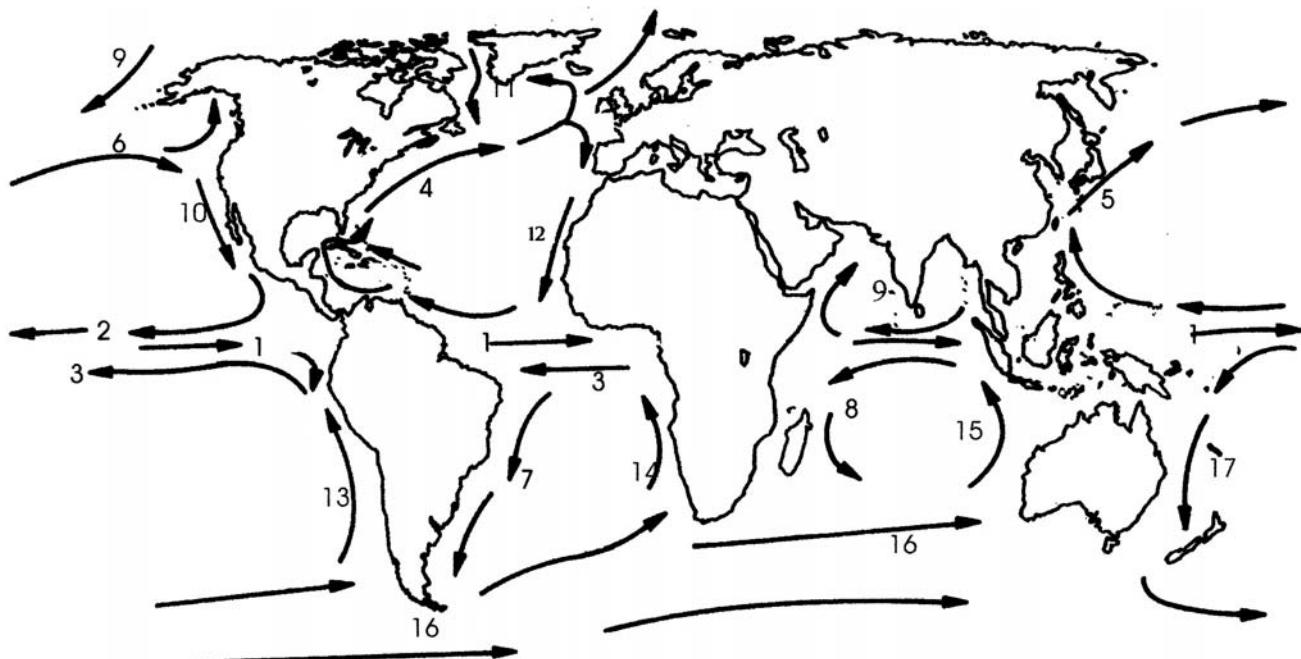

Figure O7 Generalized map of world surface ocean currents (see Table O1 for details).

Current. Over the Southern Ocean the winds are essentially westerly, giving net water transport away from the Antarctic continent. This causes the sea surface to slope upward toward the equator, and the associated gradient currents run toward the east, again in the same direction as the wind is blowing. There is, however, a very important convergence zone surrounding Antarctica, lying generally somewhere between 50°S and 60°S and known as the *Antarctic Convergence*. There is a marked increase in sea surface temperature as one proceeds northward across this convergence, and it is here that water sinks to form *Antarctic Intermediate Water*. Its location has been related to the zone of strongest winds over the Southern Ocean, but its position is too constant for it to be attributable entirely to the wind field, and there are various theories relating it to the circulation of subsurface water.

In the North Pacific there is a *subpolar gyre* comprising the Alaska and Oyashio currents that is comparable to the subtropical gyre to the south of it, but in the opposite sense associated with the cyclonic wind stress in latitudes 50–70°. In the North Atlantic the equivalent subpolar gyre is interrupted by Greenland and exists in two parts, one on either side of Greenland. The East Greenland Current carries pack ice and icebergs southward from the glaciers that reach the east coast of Greenland. Off Cape Farewell this current converges with the warm Irminger Current, and most of the ice soon melts, though some may persist in the cool inshore part of the northerly-flowing West Greenland Current. To this is added a considerable input of icebergs from glaciers that reach the West Greenland coast, particularly in North-East Bay and Disko Bay. These continue in the subpolar gyre of the Labrador Sea and Baffin Bay, and in due course travel southward in the Labrador Current to reach the Grand Banks off Newfoundland. The greatest numbers are encountered here in spring and early summer, having been released

perhaps two years earlier from a fjord in the spring thaw and then having spent their last winter frozen in the ice between Baffin Land and Labrador. Off Newfoundland the larger icebergs will ground and gradually break up and melt in this region of convergence between the warm Gulf Stream and the cold Labrador Current. The Indian Ocean extends less far to the north than the Atlantic and Pacific oceans, and is subject to the major seasonal wind reversal of the monsoons.

Figure O7 provides a simplified view of world surface ocean currents.

Upwelling

Zones of convergence and divergence in the flow of the upper layers of the ocean have already been noted. Divergence occurs particularly where the wind-induced transport is offshore, and it requires upwelling from below. This brings water rich in nutrients to the photic zone, and hence areas of upwelling are characterized by considerable biological productivity. As previously noted, the main regions to which this applies are the cool

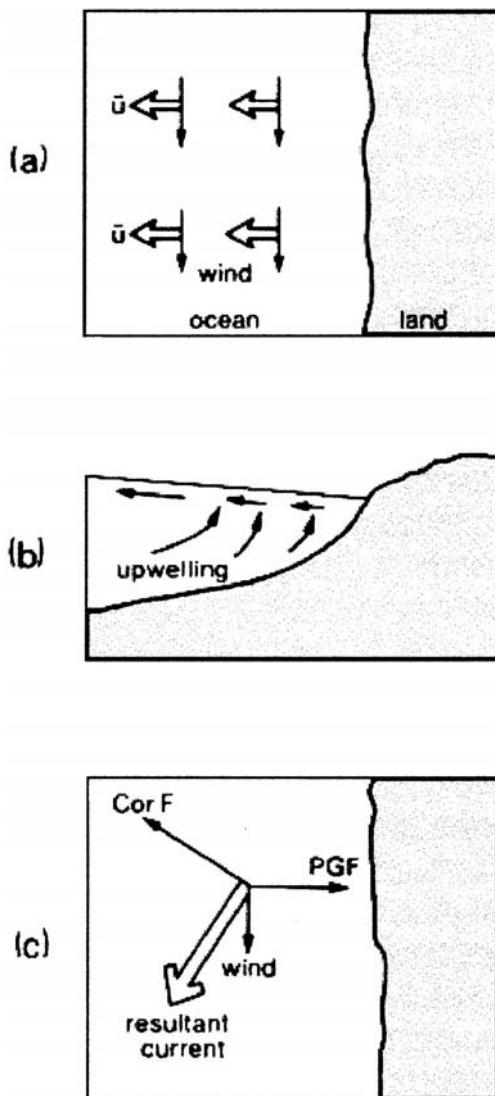

Figure O8 Upwelling in eastern boundary currents in the northern hemisphere: (a) plan view showing transport resulting from the wind stress; (b) profile showing associated vertical water movements and sloping sea surface; (c) possible balance of forces and resultant current.

eastern boundary currents of the subtropical gyre (Figure O8). The anomalously low temperatures of these currents are depressed further by the upwelling of cool water, thus advection fogs are often encountered in such regions. The vertical water movements associated with the convergences and divergences so far discussed are chiefly limited to the water above and within the main thermocline.

Thermohaline circulation

Figure O9 provides the elements of flow at various ocean levels. Figure O9(b) is a schematic model showing how surface flow from equatorial regions is countered by sinking in the polar realm. Between the spreading deep water and the surface flow a thermocline occurs. This is a layer in which a vertical

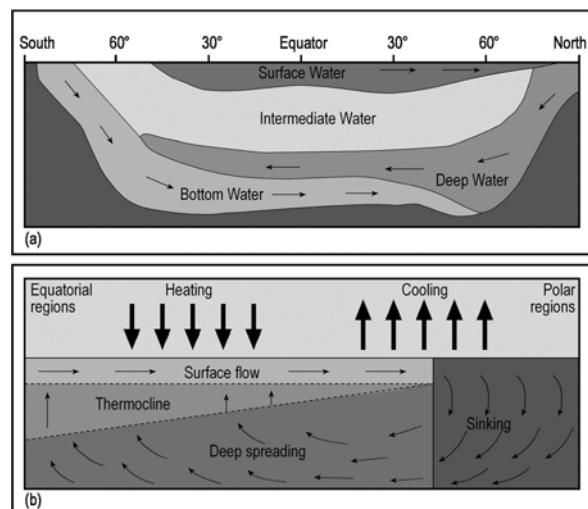

Figure O9 (a) A cross-section of the Atlantic Ocean showing the variations in water with depth. (b) A schematic model showing the relationship between surface flow, sinking, and deep spreading of ocean waters between low and high latitudes.

temperature gradient, one that is appreciably greater than the gradients above or below, occurs. Figure O9(a) provides a diagrammatic interpretation of this as applied to the Atlantic Ocean from north to south.

The surface waters become sufficiently dense to sink, through cooling (North Atlantic) or sea-ice induced salinification (Antarctic). Bigg (2003) notes that these dense, deep waters then return to the surface through turbulent mixing near rough topography over the whole globe, and also through mixing in the strong zonal current, known as the Antarctic Circumpolar Current (ACC), underlying the westerlies in the Southern Ocean, at around 50°S. Surface flow closes the circuit, through entrainment of part of the ACC into the subtropical gyre of the South Atlantic, and through the generation of north-westward-moving eddies from the Agulhas Current of the Indian Ocean as it retroflects at the southern tip of Africa. As shown in Figure O10, this is often referred to as the great ocean conveyor belt.

Paleoclimatologists are particularly interested in the overturning time-scale of the thermohaline circulation. It is of the order of 1000 years, so the ocean has memory of atmospheric conditions at the millennial time-scale. However, because the strong poleward movement of warm water in the North Atlantic forms part of the thermohaline circulation disruption of this flow on time-scales of only decades gives the potential for abrupt climate change over years to decades. Reducing the supply of warm water to the northern Atlantic through suppressing convection reduces the ability of the ocean to provide large quantities of latent heat to the atmosphere. The downstream impact of this can be a reduction in western European temperature of several degrees. In his account of ocean-atmosphere interactions in this volume, Bigg provides further analysis of the effects of such an impact. Much additional information about deep-water circulation and climatic change is also to be found in the *Encyclopedia of Paleoclimatology and Ancient Environments*.

OROGRAPHIC PRECIPITATION

Orographic precipitation is caused or enhanced by one or more of the effects of mountains on the atmosphere. These effects include the upward or lateral motions of air directly caused by mountains acting as a barrier, as well as the thermal effects of the mountains which cause elevated heat or cold sources. In addition, mountains influence the atmospheric circulation and precipitation processes indirectly on a range of scales from the production of lee waves downstream from isolated peaks to the development of cyclones downstream from major mountain ranges.

Stratiform precipitation

Mountains can generate both stratiform precipitation, which takes place in a statically stable atmosphere, and convective precipitation, which results from the release of static instability. The most obvious effect of mountains is that they can cause the

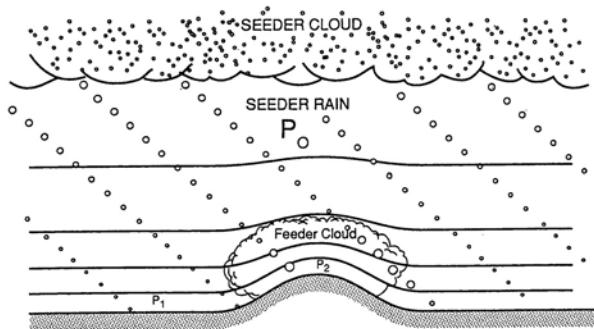

Figure O11 Conceptual model illustrating orographic enhancement of rain by the seeder–feeder mechanism. The size of a droplet falling from the cloud indicates the precipitation intensity at that point. Here P_0 indicates the intensity of the seeder precipitation entering the top of the feeder cloud, P_1 is the intensity of the rain at the surface upwind of the hill and P_2 is the intensity of the rain at the surface in the orographic maximum near the top of the hill (from Banta, 1990).

air encountering them to rise. Rising air cools adiabatically and if it is sufficiently humid condensation and perhaps precipitation can occur. It is widely recognized that the slope on the upwind side of the prevailing wind (the windward side), is more likely to have precipitation than the leeward side. Precipitation formed by this mechanism is widely referred to as upslope precipitation. In contrast, some of the world's deserts are on the leeward side of mountain ranges.

Upslope precipitation may be enhanced by the seeder–feeder mechanism. A low-level stratus cloud (feeder cloud) forms near the top of a mountain. Its temperature is below freezing but warm enough so that it lacks ice nuclei. Ice crystals fall from a higher (and colder) seeder cloud into the feeder cloud. These ice crystals grow at the expense of the water droplets in the feeder cloud by the Bergeron process. The large ice crystals then precipitate out of the feeder cloud to the Earth's surface (Figure O11). This process increases the precipitation efficiency of the feeder cloud because the moisture from small water droplets, which otherwise would not have reached the Earth's surface, evaporates and is deposited on the ice crystals. People have been inspired to encourage this process artificially by seeding the feeder cloud with excellent ice nuclei such as silver iodide. Under the appropriate conditions enhanced precipitation may result.

Upslope precipitation can be displaced upwind of the mountain by blocking. Air which is colder than its environment resists vertical displacement. As it is pushed against the mountain, a high-pressure area is created. Flow approaching the barrier encounters this high-pressure area and decelerates. Convergence and rising motion result, possibly producing precipitation. Convergence can also be generated by a mountain valley which grows narrower in the direction toward which the wind is blowing (channeling) or by air currents that are deflected around the mountain coming together on the mountain's lee side (lee side convergence) (Figure O12). Orographically generated waves can also modify upslope flow and produce areas of enhanced upward motion. Thus, there is no general rule about where upslope flow will produce the maximum precipitation amount along the slope. This place depends on the wind, stability, and local topography as well as the prevalence of blocking and mountain waves.

Convective precipitation

Mountains can generate precipitation through the release of static instability by providing a lifting mechanism for air parcels as well as by orographic processes that destabilize the air column. Precipitation can be generated by three categories of processes: orographic lifting, thermal effects and obstacle effects. Some examples of these processes are illustrated in Figure O12. Orographic lifting can bring air to the level of free convection (i.e. the level at which it becomes positively buoyant). If the atmosphere has a sufficiently thick layer above this level which is statically unstable, precipitation may result. Lifting of an air column will make it more statically unstable. An atmospheric layer which is potentially unstable is one which will become statically unstable if it is lifted. The upward motion generated by mountains may release this potential instability.

The thermal effects of mountains occur because orographic features can serve as elevated heat or cold sources. During the day the slope is heated by the sun. It warms the air next to it which then becomes warmer than the atmosphere at the same level away from the mountain over lower land. Thus, there is low pressure next to the mountain toward which the air moves – producing upslope flow. This heating can be modified by surface conditions. Bare rock will transfer more sensible heat to the atmosphere than snow cover. At night the mountain surface cools, which causes the air above it to cool and results in air flows down the slopes. Air moving across the mountain top during the day is heated by the mountain. This heating helps to destabilize the air column. In addition, convergence may be produced at the ridge crest as air flows up the slope from opposite directions. The combination of the heating and the heating-induced convergence can generate thunderstorms. At night, downslope winds from mountains on opposite sides of a valley can converge in the valley and encourage the generation of thunderstorms as well.

Mountain ranges and high-plateaus can have larger-scale thermal effects on precipitation. During the summer, especially during the day, large areas of high elevation act as an elevated heat source. The air over them is warmer than the air at the same height in the surrounding lowlands. Thus, low-pressure forms near the surface over high-elevation areas. Convergence into this low-pressure area can encourage the formation of thunderstorms. Since heating is stronger during the day, the location of the lowest pressure varies diurnally. The changes in this location can affect the time of day that is most favorable for precipitation to form for a particular place in or near a mountainous region.

Mountains also act as obstacles to air flow, and in so doing can encourage the development of convective precipitation. Channeling and lee side convergence, that favor stratiform precipitation, may also favor convective precipitation if the vertical profile of moisture and temperature are favorable. These processes can cause moisture convergence as well, and static stability is quite sensitive to atmospheric humidity.

Under stable static stability conditions, mountains may generate buoyancy waves – commonly known as gravity waves. These waves propagate downstream (and sometimes upstream as well) of the mountain. The parts of the wave which contain upward-moving air may aid in the development of convective storms, especially if they interact with other mountain-generated circulations such as the diurnal mountain-valley winds.

Orographic variations can contribute to the development of convective storms in their surrounding areas as well as in the

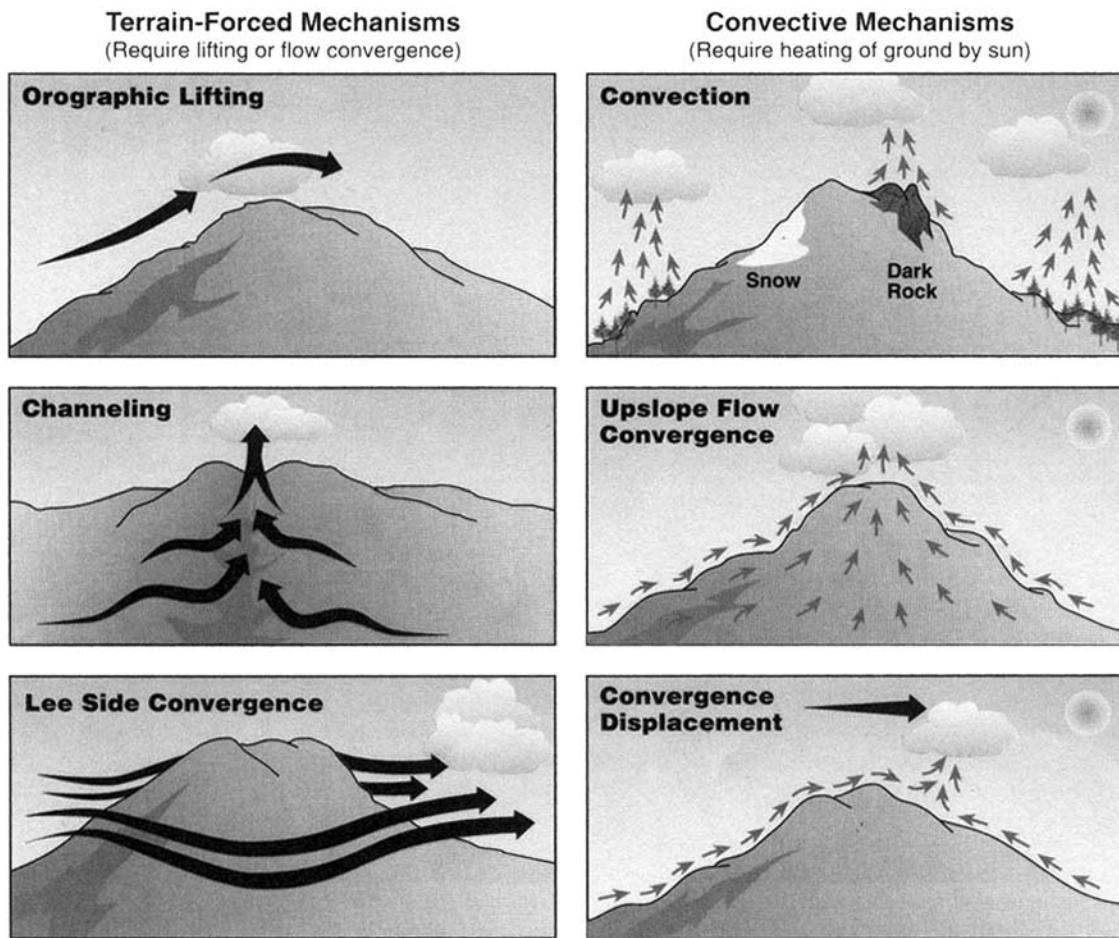

Figure O12 Terrain-related mechanisms that can produce lifting motions and that may trigger thunderstorms (from Whitman, 2000).

mountainous area itself. As they interact with the large-scale wind field, mountains may generate downstream eddies in the flow under some conditions. An example of such an eddy is the so-called "Denver cyclone". Such a cyclonic circulation can have areas of convergence and vorticity which encourage the development of convective storms. Outflow from thunderstorms generated within the mountains may initiate convective storms in the surrounding lowlands.

Another obstacle effect which encourages convective precipitation is mountain blocking of cold advection. In this situation cold advection is occurring to a height which reaches above the top of the mountain. The mountain blocks and retards the cold advection at its base. Above the peak, however, the cold advection proceeds unhindered. The increase in the rate of cold advection with height above the mountain's base destabilizes the layer – perhaps enough to make it suitable for the development of convective storms. This process does not occur often; most cold airmasses are shallow, not even as high as some mountain ranges. In addition, temperature advection in the atmosphere tends to be stronger near the Earth's surface because of stronger temperature gradients there. Thus, this process occurs only when the cold airmass is unusually deep and the winds above the surface are unusually strong.

The large number of processes that can contribute to the initiation of thunderstorms over mountainous areas would imply that in many cases two or more of these processes are involved in storm generation. Many of these processes depend on a particular topographic feature or a process that occurs during one part of the day. Thus, one would expect that some places in mountainous regions are more likely to generate thunderstorms than others. Indeed such places have been observed but they vary, even within one day, depending on the winds and atmospheric static stability. It has also been observed that most places in and around mountainous regions are more likely to receive convective precipitation at some times of day than at others. Furthermore, the time of day which is most favorable can change drastically over a horizontal distance of a few tens of kilometers.

Influence on extratropical cyclones

Extratropical cyclones can generate upslope flow which is enhanced by baroclinicity and may produce considerable precipitation amounts. Mountains also exert influence on the extratropical cyclones themselves. Since these weather systems often produce precipitation, this is an indirect orographic influence on precipitation. An eastward-moving extratropical

cyclone approaching a north–south barrier will often not actually cross the barrier but move northward. A secondary cyclone then develops to its southeast on the lee side of the mountain range. This process is known as lee cyclogenesis and it is why the lee sides of mountain ranges are often known as places where cyclogenesis is common.

OSCILLATIONS

Any phenomenon that tends to vary above or below a mean value in some sort of periodic way is properly designated as an *oscillation*. It may be recognized eventually as a predictable cycle, but this term should not be used unless the period has a recognizable regularity; thus the sunspot cycle has a variable amplitude and period (8–13 years from peak to peak) but after several centuries it is a predictable event, even though the parameters are not simple. An oscillation is sometimes used for the swing from one extreme to the other, that is a half-cycle.

Several types of oscillation are recognized: (a) *damped oscillation*, one with constantly decreasing amplitude; (b) *neutral, persistent or undamped oscillation*, maintaining constant amplitude; (c) *unstable oscillation*, growing in amplitude and then breaking down; (d) *stable oscillation*, generic class including (a) and (b); (e) *forced oscillation*, one set up periodically by an external force; (f) *free oscillation*, a motion established externally but which then receives no further external energy.

The major oscillations of the planetary atmospheric pressure fields were proposed by Sir Gilbert Walker, who first described and named the seesaw pressure readings of the southern oceans as the Southern Oscillation. Walker's work went relatively unnoticed until recent decades. In a 1966 paper Bjerknes recognized the contributions of Walker and identified the Walker Circulation.

Increased research on teleconnections has identified other oscillations. A brief description of the main oscillations is given here; more detailed information may be derived from cross-referenced items.

The *Southern Oscillation* (SO) is a pressure anomaly over the Indian and South Pacific Oceans. It has a slightly variable period averaging 2.33 years and is often analyzed as part of an ENSO (El Niño-SO) event. A large amount of literature is

available for this oscillation with a good overview, from both the scientific and social aspects, provided by Glantz (2001).

The *North Atlantic Oscillation* (NAO) concerns the stability of the Icelandic low-pressure cell and the Azores–Bermuda high-pressure cell. The NAO has a marked influence upon the climates of Western Europe.

The *North Pacific Oscillation* (NPO) is also known as the Pacific Decadal Oscillation (PDO). It is a long-lived phenomenon and is defined by surface ocean temperatures in the northeast and tropical Pacific Ocean. The NPO has a long-term influence on the climate of North America.

The *Madden–Julian Oscillation* (MJO) is characterized by an eastward progression of tropical rainfall. Anomalous rainfall patterns, which may be enhanced or suppressed, are first identified over the western Indian Ocean and remain viable across the warm waters of the western and central Pacific Ocean.

The *Pacific North American Oscillation* (PNA) is an alternating pattern between pressures in the central Pacific Ocean and centers of action over western Canada and the southeastern United States. It is expressed as an index that is both ocean- and land-based.

The *Arctic Oscillation* (AO) is an oscillation in which atmospheric pressure, at polar and midlatitude locations, fluctuates between defined positive and negative phases. It is computed as an index by comparing pressure in the polar region with pressure at 45°N.

The *Antarctic Oscillation* (AAO) is represented by an oscillation in values of mid- and high-latitude surface pressure systems in the southern hemisphere. It is quantified by the Antarctic Oscillation Index (AAOI). This is the monthly zonal mean sea level pressure at 45°S in relation to the same variable calculated for 65°S.

The *Quasibiennial Oscillation* (QBO) is a low-latitude oscillation that is longer than the dominant annual cycle and whose identification rests with sophisticated computer modeling. Associated with fluctuations of the ITCZ, it is a periodic reversal of winds in the lower stratosphere at elevations between 20 and 30 km.

Most oscillations are involved with the strength and location of the major planetary highs and lows (*centers of action*) and sea surface temperatures, and are derived statistically from long-range pressure observation series. For some, and to a lesser extent, rainfall and temperature series can be employed. Much information about the calculation and use of the oscillations may be derived from NOAA, Climate Prediction Center (<http://www.ncep.gov/>).

OZONE

Electrical discharges in air produce a distinctive smell, once thought to be that of electricity itself. This was reported in 1785 by Van Marum, who observed that oxygen gas in which electricity had sparked would then tarnish mercury. In 1840 Schöbein noted the smell again in oxygen from electrolysis of acidulated water and concluded it was a gas, which he named from the Greek *ozon*, “smelling”. Five years later, de la Rive formed ozone from pure oxygen gas (O_2), proving de Marignac’s idea that ozone was an allotrope, or alternate form,

of oxygen, but it was not until 1865 that Soret found, from volumetric analysis, the correct formula of O_3 .

Ozone is present in natural air, as first shown by Houzeau in 1858. Schöbein’s paper strips saturated with starch-iodide solution, which turn blue in the presence of ozone, provided an inexpensive test, and paper ozonometry became popular in nineteenth-century Europe. Concentrations were higher in coastal areas and bright sunshine, and depleted in smoky rooms, mines, and industrial areas, so ozone was associated with clean air and good health. As a powerful oxidant it deodorizes air, and it is also a potent disinfectant. Used instead of chlorine in many water-treatment plants, it leaves only oxygen as a residue, and from the early twentieth century ozone found use for some medical treatments. The idea that ozone is good for health is heard to this day, but proof was always elusive. Like many supposed tonics its effects are damaging in some circumstances or at higher concentration, and the truth is both more complicated and more interesting.

Ozone condenses below -112°C to a (highly explosive) deep ink-blue liquid, and a 10-cm cell of pure gas is also visibly blue due to absorption of red light. Ozone even more strongly absorbs ultraviolet (UV) light, especially at wavelengths between 230 and 290 nm for which even 2–3 mm of the gas is opaque. This discovery by Hartley in 1881 enabled him to account for a sharp cut-off below 300 nm in the spectrum of sunlight, as observed by Cornu. The natural ozone concentrations of 20–50 ppb (molecules per 10^9 air molecules) at ground level could not account for the amount of absorption, so Hartley concluded that much greater ozone concentrations must occur at higher altitude. Improved spectroscopy, first by photographic techniques and subsequently by photoelectric techniques, provided dramatic confirmation in the 1920s. The clearest evidence, and approximate profiles of ozone concentration, came with the 1929 discovery by Götz of the Umkehr effect; relative absorption at two ultraviolet wavelengths reverses as light from the rising or setting sun takes different paths through layers of the atmosphere. In 1934 Götz located the maximum ozone density at 22 km altitude, and in the same year the first balloon soundings gave similar results. Exact profiles of ozone and temperature change measurably by the hour, but they all look similar for given latitude and season.

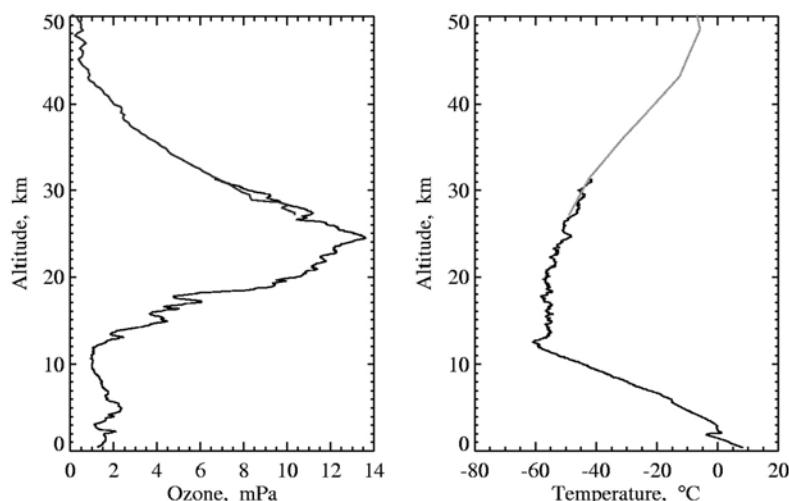

Figure O13 Profiles of ozone concentration (partial pressure) and temperature at 45°S, January 2004, measured by electrochemical sonde and lidar. The ozone layer from ~ 12 to 50 km altitude defines the stratosphere and maintains the temperature profile.

In 1926 Dobson built the first of the ozone spectrophotometers that bear his name. Individually numbered, and now regularly intercalibrated, over 90 of these instruments provide routine measurements of column ozone around the globe. Their stability and precision has played a pivotal role monitoring atmospheric change and in comparison with later instruments, including the satellite-borne systems which now give true global coverage. Dobson's name also persists in the unit of measurement for column density of ozone and other trace gases, the Dobson Unit (DU) or milli-atmosphere-centimeter.

A typical ozone column of 300 DU is equivalent to a layer of pure gas at standard temperature and pressure (STP) just 3 mm thick. As thin as this seems, it is sufficient to block over 95% of the solar UV that causes eye, skin, cell and DNA damage in living things, and photochemical breakdown in many materials. Life on Earth has evolved to depend on ozone for protection from damaging UV radiation, and it is threatened by reduction in the ozone layer.

Relative uniformity and stability of ozone column amounts was an early surprise from the network of ozone spectrometers. Photochemical production was expected to enhance ozone by day, and produce greater column amounts at the equator and in summer. Instead there is little diurnal change, there is more ozone over high latitudes than above the tropics, and the seasonal pattern is complex and differs between hemispheres. As found by Dobson, global ozone distribution depends mostly on atmospheric circulation, in which long-lived ozone produced 30 km above the tropics is carried toward the poles, and at all latitudes is mixed only slowly downward.

The Chapman equations

In 1930 Chapman provided a mechanism for the formation and stability of the ozone layer. At altitudes above about 20 km, UV radiation of wavelength $\lambda < 243$ nm causes photodissociation of oxygen molecules

Ozone is formed when the atomic oxygen, O, combines with O₂. The newly formed bond is unstable unless a third body carries away excess energy, so the process is written

The additional body, M, is a molecule of atmospheric nitrogen, N₂, or oxygen. In its turn, ozone absorbs UV at longer wavelengths to photodissociate

Although (3) appears to destroy ozone, the atomic oxygen can again participate in (2), so together these reactions just partition "odd oxygen", the total of O and O₃. Destruction of ozone is by reaction between the odd oxygen species

At its peak, ozone mixing ratio is about 8 ppm, or less than one ozone molecule to every 100 000 oxygen molecules, so (4) predicts only slow removal of ozone by chemistry.

The Chapman model explained the vertical profile of ozone in the middle atmosphere, and its persistence; it also explains much of the dynamics. In the lower atmosphere, temperature decreases with height, allowing warm or moist air to remain buoyant over large vertical motions and enabling the normal weather processes of cloud formation and precipitation. This

region of convective motion is the "troposphere" (Greek *tropos* = turning), extending to the "tropopause" at about 17 km altitude above the tropics and about 10 km over the poles.

At higher altitude, absorption of solar UV by O₂ and O₃ in reactions (1) and (3), and some absorption by ozone of infrared radiation from below, heats the atmosphere so that temperature increases with altitude, suppressing convection." heats the atmosphere so that temperature increases with altitude, suppressing convection. Air movement is confined within layers, giving the name "stratosphere" to the region up to about 50 km altitude. Though it contains less than 10% of the total atmospheric mass, the stratosphere includes more than 90% of the ozone, whence its alternate name, the "ozone layer". There is very little mixing across the tropopause, or vertically within the stratosphere, so that air rising over the tropics carries ozone slowly outward to the poles. As a tracer of stratospheric motion, ozone measurements were used to improve weather prediction, and a global network of ozone stations was proposed for the International Geophysical Year in 1958. The World Meteorological Organization (WMO) assumed responsibility for standard procedures and the Global Ozone Observing System (GO3OS) was established.

The dispersal of radioactive debris from nuclear weapons tests in the 1960s gave a more detailed picture of stratospheric circulation, and with more accurate values for chemical reaction rates it became clear that the Chapman model underestimated ozone loss. Reaction (4) is supplemented with several catalytic cycles of the form

The first-proposed catalyst X was the hydroxyl radical, OH, produced from water vapor. In 1970 Crutzen and Johnston discovered that oxides of nitrogen, with X = NO in (5), played a much greater role. At that time fleets of supersonic aircraft flying in the lower stratosphere were seen as the future of commercial aviation, and jet engines generate large amounts of "active nitrogen", or NO_x (NO and NO₂). Consequent damage of the ozone layer could increase the incidence of skin cancers and other health risks of UV light. In an era of increasing concern about anthropogenic pollution of terrestrial and aquatic environments, the stratosphere was now also seen to be at risk, and soon a much larger threat appeared.

Chlorofluorocarbons

Chlorofluorocarbons (CFCs) had been discovered in 1928 to solve the many problems in refrigeration with toxic and corrosive gases such as ammonia. With very good thermodynamic characteristics and nil toxicity, CFCs seemed the perfect choice, and their usage steadily increased. Through the 1950s they found use in air-conditioning, as propellants and foaming agents, and as solvents. Their chemical inertness made release to the environment seem harmless.

With the 1961 invention by Lovelock of the electron-capture detector, air samples from the remotest places on Earth were found to contain measurable, and steadily increasing, amounts of CFCs. Breakdown of CFCs in the troposphere is negligible, and they are well mixed through a hemisphere within months of release. Complete mixing between hemispheres takes 1–2 years, and transport into much of the stratosphere takes 2–5 years. It is only high in the stratosphere, exposed to solar radiation at shorter UV wavelengths, that CFCs breakdown occurs,

releasing atomic chlorine. This life history of CFCs was determined in 1974 by Molina and Rowland, and they further showed that Cl atoms are very effective as the catalyst X in (5). Chlorine compounds are common in the troposphere, both from sea salt and volcanic HCl, but their high solubility in cloud water effectively traps them below the tropopause. Molina and Rowland established that stratospheric chlorine was almost entirely from manufactured CFCs. Over a century it could reduce the ozone layer by 5%.

The finding was widely publicized, and some consumer resistance to CFCs followed. A ban on CFCs in spray cans and other inessential uses was promoted, and it was enacted by the United States, Canada, Norway and Sweden in 1978. National and international agencies undertook reviews of the science and state of global ozone. In collaboration with WMO's newly constituted Global Ozone Research and Monitoring Project, the United Nations Environment Program (UNEP) established a Plan of Action on the Ozone Layer in 1977. Every 3–4 years from 1982 its reports would summarize the global consensus on ozone depletion science, environmental impacts, and technical advances. In March 1985, after 4 years of negotiation, the Vienna Convention for the Protection of the Ozone Layer was adopted by 21 nations. Though unspecific, and committing nations to do little more than encourage research, cooperate and exchange information, it was a milestone. Nations agreed in principle to tackle a global environmental problem before its effects were felt, or even scientifically proven. They did not have to wait long for that.

Antarctica

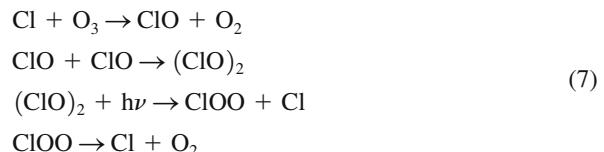

Unusually low (~200 DU) total ozone at Syowa, Antarctica, in October 1982, was reported at the Ozone Commission Symposium in 1984, but its significance was not recognized. In 1985 Farman, Gardiner and Shanklin discovered the “ozone hole” over Antarctica from Dobson spectrophotometer data. Reanalyzed satellite data from the late 1970s onward showed its extent; ozone across the continent was massively depleted every spring as sunlight returned to air trapped in the winter polar darkness.

Such a large effect had not been foreseen, but the previous concerns had primed the research community for a quick response with ground-based, *in-situ*, and satellite-borne measurements, and detailed models of stratospheric chemistry, radiation and dynamics. The mechanism of the Antarctic ozone hole was elucidated by Solomon et al. in 1986. At lower latitudes, catalytic destruction of ozone by chlorine is limited by NO, which reduces the chlorine monoxide (ClO) needed to complete the sequence. Much of the reactive chlorine is in the form of HCl or ClONO₂, reservoir species which do not themselves contribute to ozone destruction. In polar winter, temperatures below −78°C lead to the formation of clouds in the stratosphere, which is otherwise too dry to form clouds. Polar stratospheric cloud (PSC) particles occur as both solid and liquid, in various mixtures of nitric and sulfuric acids and water according to temperature and formation sequence. Surface reactions on PSCs catalyze the reaction

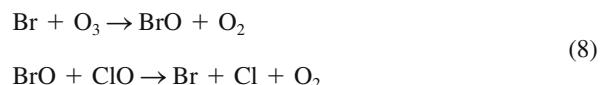

where the (s) denotes attachment to the surface. While temperatures remain cold enough, the PSC particles fall out of the stratosphere on a time-scale of weeks to months, removing water and active nitrogen but leaving chlorine gas. As sunlight

returns in the spring it is rapidly photolysed, initiating the sequence:

The first reaction is the same as in (5) for X = Cl, but it now works with the products of both the third and fourth reactions in (7). The net effect is very rapid destruction of ozone, and in the 13–20 km altitude range ozone is completely destroyed over the entire Antarctic continent. Stratospheric circulation again plays a very large part, as the extreme cold of the Antarctic stratosphere maintains a strong polar vortex isolated from mid latitude air. Bromine acts in a similar manner to, and also in concert with, the much more abundant chlorine, especially through the reactions:

As the Antarctic ozone hole steadily worsened through the 1980s and early 1990s, a massive international research effort sought to fully understand the phenomenon, monitor and model its effects, and determine its influence on global stratospheric ozone. Of particular concern was whether there would also be an ozone hole over the Arctic, which would affect a substantial proportion of the world's population, especially in the wealthy industrialized countries. With warmer temperatures and more variable winds, the Arctic vortex is much less stable than its Antarctic counterpart, and it is not confined to the winter polar night. Nonetheless ozone depletion over the Arctic was observed from about this time, and it continued to worsen even after the Antarctic ozone hole stabilized in its annual extent (Figure O14). There would indeed have been a substantial threat to northern hemisphere peoples but for the action

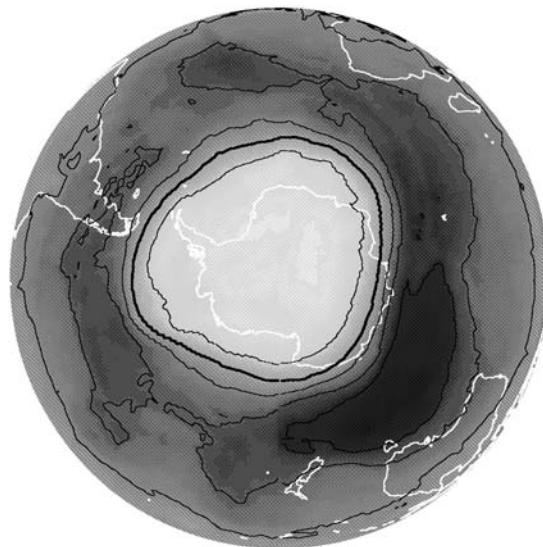

Figure O14 Southern hemisphere ozone from NASA satellite on 24 September 2003. Contours are at 60 DU intervals, with a thicker contour at 220 DU to mark the boundary of the Antarctic ozone hole. In surface area this was the second largest hole on record.

prompted by the earlier Antarctic phenomenon.

Protocols

The severity of Antarctic ozone depletion greatly hastened ratification of the Vienna Convention, and its implementation, so that in 1987 the landmark Montreal Protocol on Substances that Deplete the Ozone Layer was concluded by UNEP. It was much tougher than had been thought possible only a few months before.

The Protocol allows for special circumstances, especially developing countries with low consumption rates, but it sets the elimination of ozone-depleting substances as its final objective. When the Montreal Protocol came into force, on time, on 1 January 1989, 29 countries and the EEC, representing approximately 82% of world consumption, had ratified it. Since then several other countries have joined.

The Protocol was only a first step, but it was intentionally flexible, to be tightened or modified as the scientific evidence developed. Indeed it stipulates regular assessment of all relevant scientific, technological, environmental and economic research to guide its revision and implementation. Through international effort, understanding of stratospheric ozone chemistry and its consequences advanced rapidly, and it showed that very much tighter and greater controls would be needed. Governments and industry moved with surprising speed and determination to meet this challenge.

By 1988 a decrease of ozone concentrations by ~10% per decade in the mid-latitude lower stratosphere was documented, and airborne Antarctic research proved conclusively that active chlorine and bromine byproducts of human activities are the cause of the springtime Antarctic ozone hole. The 1990 London Amendment strengthened the Montreal Protocol by phasing out all CFC production and consumption by 2000. The 1991 WMO/UNEP Ozone Assessment confirmed ozone decline not only in winter and spring but all year round, and everywhere except over the tropics; and very large concentrations of ClO measured in the Arctic increased concern for potentially stronger ozone decline. The 1992 Copenhagen Amendment sought to phase out CFCs by the end of 1995, and added controls on other compounds. Further amendments were agreed in Montreal (1997) and Beijing (1999).

In June 1991 Mount Pinatubo in the Philippines erupted massively, injecting around 20 million tonnes of sulfur dioxide directly into the stratosphere, where it oxidized to sulfate aerosol and spread over the globe. This aerosol cloud caused the greatest single disturbance to Earth's radiative balance in a century, and catalyzed ozone destruction by halogens in a manner similar to PSCs. Satellite measurements show that, in 1992–1993, global total ozone reached a minimum, not surpassed since, when it dipped to 5% below the 1964–1980 average.

Though it was the immediate cause of the ozone minimum, the volcanically derived aerosol had a large impact only because of human influence on the chemical state of the stratosphere. There is some similarity in the story of stratospheric bromine. The Montreal Protocol included, from its inception, brominated CFCs called halons that were used in fire extinguishers and suppressants. With atmospheric longevity of several decades, halons were known to be a major source of stratospheric bromine. By 1994 bromine was found to be 50 times as destructive of ozone as chlorine per atom, largely because its deactivation to reservoir species was very slow. At the same time methyl bromide, manufactured for use as a fumi-

gant, was found to live long enough to reach the stratosphere and contribute to ozone destruction, so its production and use was restricted. Methyl bromide is produced naturally in the ocean, which is the largest source but also a sink for the gas. It was also found to be a product of biomass burning, a regular seasonal activity, especially in the tropics, over centuries. Once again, the rapid change in atmospheric chemistry in recent times had created such instability that even natural processes could trigger damage.

Between 1992 and 1994 the Antarctic ozone hole spread over more than 24 million square kilometers during spring, and column amounts less than 100 DU were recorded. Whether measured by total area, ozone minimum, or amount of "missing" ozone, the Antarctic ozone hole was at its worst from the 1990s into the early 2000s. Arctic ozone destruction became routine through this period, but with much greater variability as noted earlier.

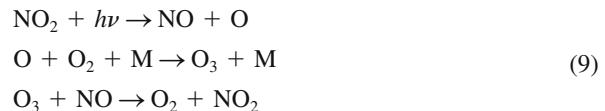

Computational models of stratospheric chemistry and dynamics predict slow recovery of polar and global ozone through the first century of the new millennium, but at the time of writing it is too early to detect such recovery. Controls on manufacture and use of ozone-depleting substances seem to be working: total tropospheric concentrations of halogenated compounds, weighted by their ozone depletion potential (ODP), have fallen gradually since the peak in 1992–1994. The peak in stratospheric loading of halogens was delayed by mixing times to the end of the millennium, with reductions expected to be detectable by the end of the first decade.

The early beneficial image of ozone was well supported by understanding of its role in the stratosphere, which protects the surface environment from damaging, especially carcinogenic, UV radiation. At the same time, the image of tropospheric ozone took a different turn.

Urban Smog

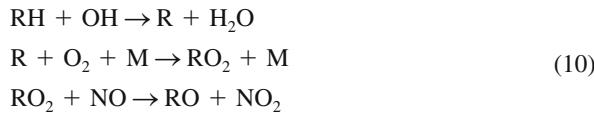

From the late nineteenth into the mid twentieth century northern cities such as London suffered serious smog, as fog on damp winter nights became laden with smoke containing soot and sulfur dioxide from burning coal, oil, and wood. Such smog causes severe irritation of the respiratory system; it is very debilitating and can be fatal. As automobile usage increased through the mid-twentieth century, air pollution in Los Angeles, and later other cities, also caused respiratory problems and stinging eyes. It was again described as smog, but this is misleading. It is worst in sunlit conditions, with low humidity, and there was another important difference.

In traditional smog, ozone is depleted by reaction with airborne particles. By contrast Haagen-Smit showed in the early 1950s that high ozone concentrations are a feature of Los Angeles smog, which results from photochemistry in a mixture of NO_x and hydrocarbons. The basis of this process is:

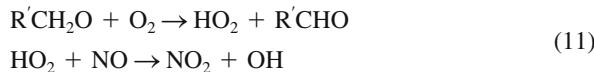

This reaction series is rapid in sunny conditions, where the lifetime of the NO₂ molecule is just a few minutes, but alone it does not raise ozone concentration because of destruction in the third reaction, necessary to reform NO₂ and sustain the cycle. With hydrocarbons present, NO is converted to NO₂ without

removal of ozone. Using R to represent a carbon chain (alkyl group), the main reactions can be summarized as:

and, rewriting R as R'CH₂:

Carbon monoxide also contributes, through the reactions:

With alkyl peroxy (RO₂) and hydroperoxy (HO₂) radicals converting NO to NO₂, as in (10) and (11), ozone produced in (9) can increase to high concentrations in photochemical smog, and it is the cause of eye and bronchial irritation as well as plant and material damage. Contrary to its past status as a sign of clean air, ozone is recognized now as an unwelcome product of industrialized society. Its concentration is an index of air pollution, and regulations in many countries seek to reduce it by controlling emissions of the NO_x and hydrocarbon precursors. The main sources of both in the developed world are combustion of fossil fuels – oil, coal, and gas – in a tradeoff with combustion temperature. Inefficient burning results in more hydrocarbon and CO emissions, while high temperatures and efficient burning produce more NO_x. There is some irony that the same jet aircraft which threaten life-supporting ozone by flying in the lower stratosphere can increase the production of ozone near the ground where it is a health hazard. Motor vehicles, however, are a much greater source of the precursors.

Understanding of these reactions in polluted environments prompted Crutzen in 1973 to another insight in global ozone chemistry. As carbon monoxide, methane, and other hydrocarbons are dispersed across the globe, reactions (9)–(12) produce ozone in the background atmosphere. Tropospheric ozone had been thought to come from exchange across the tropopause, but production *in situ* is of comparable magnitude. The industrial sources of NO_x and hydrocarbons are supplemented by rural burning of biomass, especially widespread in the tropical dry season, and so it also contributes substantially to tropospheric ozone production.

Future impacts

Again and again, the story of ozone has demonstrated the long reach of human influence on the chemistry of Earth's atmosphere. It has also shown that such influence can be controlled, through concerted international effort directed by detailed scientific study. For their part in understanding the formation and decomposition of atmospheric ozone, Paul Crutzen, Mario Molina and Sherwood Rowland were awarded the 1995 Nobel Prize in Chemistry.

Even with success in atmospheric ozone chemistry, major questions remain. Destruction of ozone has caused an increase in solar UV radiation reaching Earth's surface, where it damages living tissue. The incidence of ocular cataract and skin cancer has increased worldwide, though more as a consequence of migration and lifestyle changes than ozone depletion. Damaging

as it is, UV has long been known to be essential for life through production of vitamin D, deficiency of which causes rickets and even, ironically, increased cancer risk. Human skin color has evolved over millennia from humanity's African origins so that natural pallor increases strongly with distance from the equator. Such evolution cannot keep pace with recent rapid migration, and concomitant changes to more indoor or outdoor lifestyles, so that many people are exposed to too much UV at certain times even as others may receive too little. Ozone change may compound this problem, but it has also fostered research to understand UV variation and especially its biochemical effects.

Climate change through enhanced greenhouse gas concentrations is now the main focus of worldwide concern about the effects of atmospheric chemistry on transmission of solar radiation. Here too the science of ozone depletion has made a large contribution. Many participants in ozone chemistry are greenhouse gases, including CFCs and HFCs, hydrocarbons, water vapor, and ozone itself. Accurate models of stratospheric chemistry, dynamics and radiation are a valuable adjunct to their much more complex counterparts in the troposphere. Very significantly, the success in addressing and solving human-induced ozone destruction serves as a model for the United Nations Framework Convention on Climate Change and its implementation through the Kyoto Protocol.

P

PACIFIC (HAWAIIAN) HIGH

The (North) Pacific (Hawaiian) High is a semipermanent cell of high pressure centered in the eastern Pacific from 35 to 45°N. It is one of the principal “centers of action” in the northern hemisphere, expanding in summer and contracting in winter.

As shown in Figure P1, the Pacific High has a July mean sea-level pressure of 1026 mb (30.3 in), analogous in pressure and dimensions to the Azores High, its Atlantic counterpart. The subtropical highs are one of the key elements of the Earth’s surface pressure. Their origin is not wholly understood, but it is believed that dynamic rather than direct thermal causes are foremost (Trewartha and Horne, 1980).

The Pacific waters are relatively cooler than the continents in the summer, thereby permitting the expansion of the Pacific High

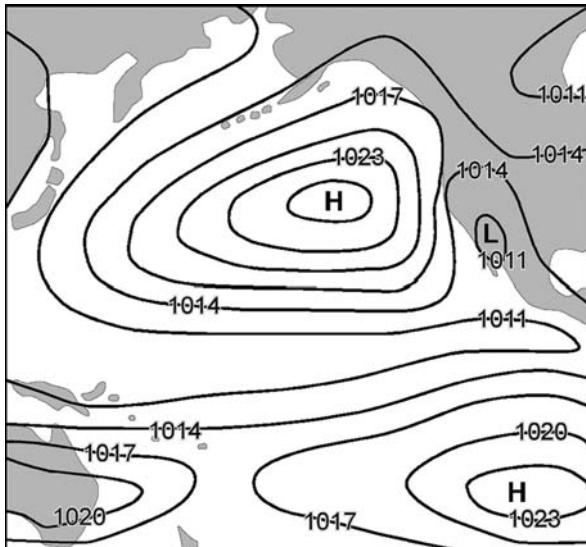

Figure P1 Average sea-level pressure in July.

and saving the subtropical high-pressure belt from elimination by continental heating. It is extensive enough in the summer to spread its influence into the middle latitudes. Air tends to subside on the eastern sides of subtropical highs, heating adiabatically and leading to warm, dry weather conditions. As the Pacific High expands along the Pacific coast of North America it causes a marked reduction in rainfall. Thus, the lengthy summer drought of Mediterranean-type climates (southern California) is attributed to the effect of the expanding subtropical high.

The subtropical belt of high pressure is rather irregular at sea level, but becomes fairly uniform at higher elevations. The axis of the belt tilts southward as the warm air is to the south. At

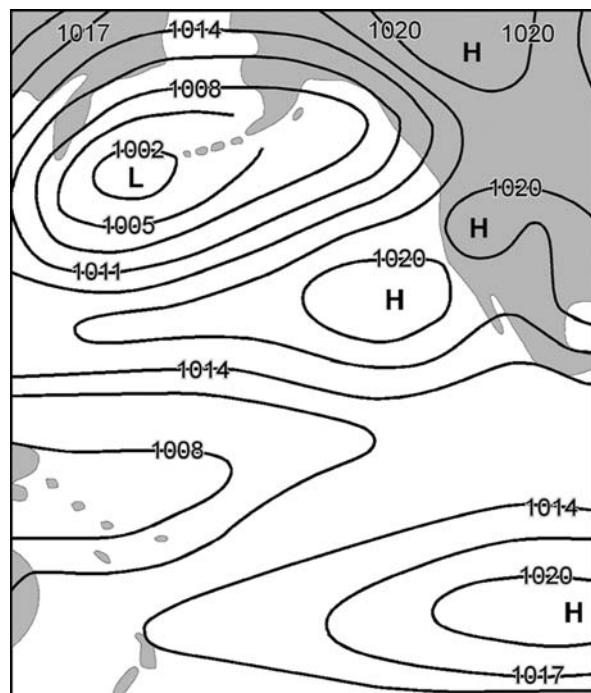

Figure P2 Average sea-level pressure in January.

3000 m (10 000 ft) the belt is located 10–15°S of its sea-level position (Petterssen, 1969).

During the winter the relative warmth of the Pacific Ocean in subtropical latitudes is insufficient to eliminate completely the dynamic subtropical belt of high pressure. Thus, the Pacific High contracts to become a weaker, smaller, but still noticeable anticyclonic cell (Willett and Sanders, 1959). As shown in Figure P2, the January mean sea-level pressure is 1020 mb (30.12 in), compared to the July mean of 1026 mb (30.3 in). Also, the Pacific High shifts equatorward during the winter, centering around 30°N.

In their study of the Pacific “centers of action”, Christoforou and Hameed (1997) found that the location of the Pacific High was highly correlated with mean annual sunspot numbers. When solar activity is at a minimum during its 11-year cycle, the Pacific High migrates southward.

PACIFIC NORTH AMERICAN OSCILLATION (PNA)

The Pacific North American oscillation (PNA) is an alternating pattern between pressures in the central Pacific Ocean and

centers of action over western Canada and the southeastern United States. The PNA is associated with a Rossby wave pattern and refers to the relative amplitudes of the ridge over western North America and the troughs over the central North Pacific and southeastern United States. Such a pattern tends to be most pronounced in the winter months.

There are two phases of this teleconnection. A positive phase occurs when deeper than normal troughs occur over the eastern United States and the region of the Aleutians. A negative phase (sometimes called the reverse Pacific North American pattern) is characterized when the troughs are filled and a ridge over the Rockies is lowered. The positive phase is associated with meridional upper air flow and the negative by zonal upper air flow.

According to Wallace and Gutzler (1981) the PNA is a “quadrupolar” pattern of pressure height anomalies. Anomalies with a similar signs are located south of the Aleutian Islands and the southeastern United States and those with opposite signs (to the Aleutian center) are in the vicinity of Hawaii and the intermountain region of Canada.

To identify PNA patterns the Climate Prediction Center (CPC) of NOAA uses empirical orthogonal functions (EOF) applied to the 500-hPa height anomalies in the northern hemisphere. Daily and monthly PNA values are constructed and used in climate prediction. Figure P3 provides an example of the plotted data that the CPC provide.

In a two-part study of the role of the PNA in the climate of the United States Leathers et al. (1991) found a number of meaningful relationships. They demonstrated that regional temperatures and precipitation are highly correlated to a derived PNA index across the United States, especially in winter. Correlations for precipitation were less extensive than those of temperature, but clear relationships were obtained. Studies have also found that the PNA index is strongly linked to moisture variability in an area extending from southeast Missouri to Ohio, with a very strong correlation in southern Indiana. It has been observed that cyclones in the Great Lakes region of North America originate more from the northwest in those months when PNA-positive occurs, while cyclones from the west and southwest occur more often with a PNA-negative index. From these studies, and others like them, it is clearly evident that the PNA plays a significant role in the climates of North America.

PALEOCLIMATOLOGY

Climate has changed through geological time, and paleoclimatology is the study of such changes (Frakes, 1978; Ruddiman, 2001). The changes have taken place at a variety of scales, and range from minor fluctuations within the instrumental record (with durations of the order of a decade or decades) to major geological periods (with durations of many millions of years). The shorter-term changes include events such as the period of warming that took place in the first decades of the twentieth century. The changes with durations of hundreds of years were characteristic of the Holocene and include various phases of glacial advance and retreat such as the Little Ice Age between 1500 and 1850. The fluctuations within the Pleistocene Ice Age (Bowen, 1978), consisting of major glacials and interglacials, lasted for 10 000–100 000 years, whereas the Pleistocene itself, termed *a minor geological variation*, consisted of a group of glacial and interglacial events that lasted in total

approximately 2 million years. Such major phases of ice age activity appear to have been separated by about 250 million years. Figure P4 shows the nature of these different orders of change.

At the beginning of the nineteenth century it was still widely believed that the world was created in 4004 BC, and that its surface had been molded by catastrophic events such as the biblical Noah's flood. Given such a short time span for Earth history, and given the invocation of the flood to explain changes in the sedimentary record, it is not surprising that at that time there were few grounds for believing that the Earth's climate had undergone major changes through an extended time period (Goudie, 1992). However, as geologists examined the sedimentary and paleontological record, the evidence for the Earth having a more lengthy history became apparent, and the idea that climate and other aspects of the environment had fluctuated during this enlarged span of time resulted initially from the discovery that Norwegian and Alpine glaciers had formerly extended farther than the bounds of their current limits. After the 1820s the concept of the Ice Age became accepted by more and more geologists, notably by Louis Agassiz. By the 1860s it was evident that the Pleistocene ice age had consisted of multiple glaciations, and Penck and Brückner introduced their highly influential fourfold model of the Güz, Mindel, Riss, and Würm glacials from work in Bavaria. Early studies of continental drift involved an appreciation of how climates in particular areas might have changed over longer time-scales, thereby explaining the presence of Dwyka glacial deposits in central Africa in the Permo-Carboniferous (see, for example, Wegener, 1967). Major developments in paleoclimatological studies occurred after World War II when isotopic methods for paleo-temperature assessment became available, dating techniques such as radiocarbon and paleomagnetism enabled sequences to

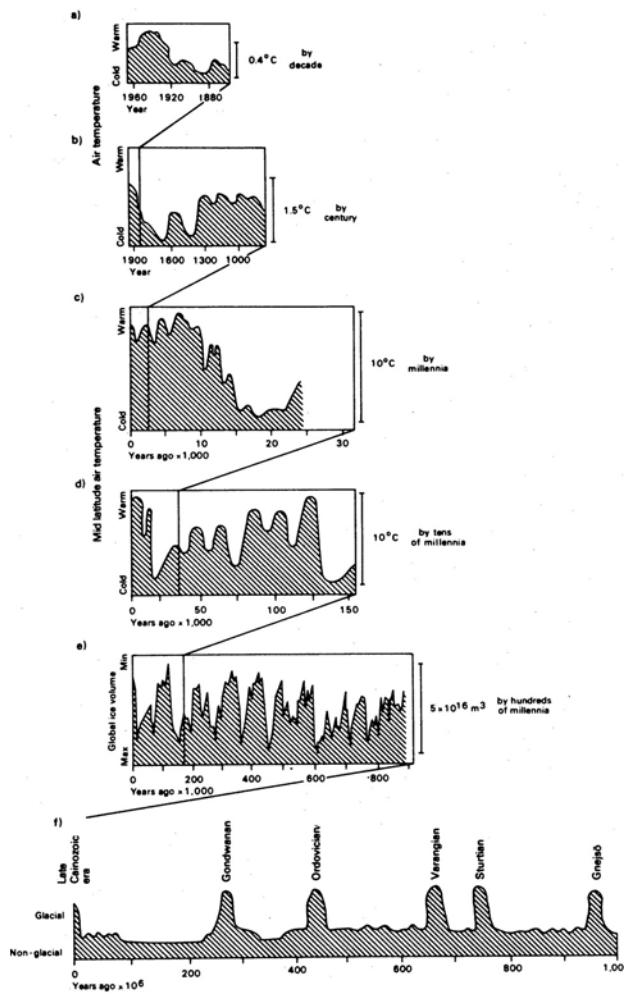

Figure P4 Different scales of climatic change. (a) Changes in the 5-year average surface temperature over the region 0–80°N; (b) winter severity index for eastern Europe; (c) generalized northern hemisphere air-temperature trends, based on fluctuations in alpine glaciers, changes in tree-lines, marginal fluctuations in continental glaciers, and shifts in vegetation patterns revealed in pollen spectra; (d) generalized northern hemisphere air/temperature trends, based on midlatitude sea-surface temperature, pollen records, and worldwide sea-level records; (e) fluctuations in global ice-volume recorded by changes in isotopic composition of fossil plankton in a deep-sea core; (f) spacing of ice ages in geological time.

be established more firmly, and improved techniques involving piston corers enabled lengthy, relatively undisturbed sedimentary sequences to be recovered from the ocean floors (Turekian, 1971; Bradley, 1999).

Techniques of paleoclimatological analysis

The various lines of evidence used to infer past climates are listed in Table P1. The most reliable information comes from instrumental observations made since the late seventeenth century. Climatic information from preinstrumental times is provided by various historical sources, for many types of

Table P1 Sources of information on climatic change

Instrumental records since the late seventeenth century
Historical sources, especially since AD 1000
Faunal and floral information
Terrestrial plants (e.g. palms, mangroves, etc.) in fossil form
Large reptiles, probably indicating warmth
Corals, indicating warmth
Giant shelled mollusca, indicating warmth
Coal, indicating humidity
Peat remains, indicating vegetation types
Pollen analysis of sediments, indicating vegetation types
Temperature-sensitive Foraminifera in deep-sea cores, etc.
Coleoptera
Tree rings, indicating warmth and moisture
Sedimentological and stratigraphic information
Ironstones and bauxites, indicating tropical moisture
Reed beds, indicating tropical moisture and aridity
Evaporites, indicating hot (?) and dry conditions
Eolian sandstones, indicating desert conditions
Limestones, thick, pure sequences indicating warm seas
Phosphates, e.g. collophane, indicating arid coast upwelling
Tillites, lithified glacial material, indicating cold conditions
Iceberg rafted debris in deep-sea cores, indicating cold conditions
Eolian dust on land (loess) and in ocean cores, indicating aridity
Oxygen isotope composition of fossils, indicating temperature
Chemical composition of lake cores, indicating precipitation levels
Oxygen isotopic and chemical composition of deep ice cores, indicating temperature
Fossil soils, e.g. calcrete crusts, indicating semiaridity
Geomorphological information
Pingos, palsens, ice wedge polygons, etc., indicating permafrost
Cirques, indicating snow line positions
Closed lake basin shorelines, indicating precipitation
Fossil dunes, indicating aridity and wind direction
Tufa mounds, indicating higher groundwater
Caves, alternations of solution, indicating moisture, and precipitation, indicating aridity
Angular scree, indicating frost action
Misfit valley meanders, indicating higher stream discharge levels
Eolian fluted bedrock and shaped deflation basins, indicating aridity, deflation, and wind direction

material have survived: accounts of severe climatic events, information about recurring phenomena such as crop yields and harvest dates, and statements concerning weather-related events such as the dates of freezing of lakes and rivers. However, historical accounts, though useful (see, for example, Lamb, 1982), are subjective and generally qualitative.

Over longer time spans more indirect evidence for climatic change has to be employed (Lowe and Walker, 1997). Any variable that responds in an identifiable manner to climatic change and that can be dated can be used. Such data vary greatly in terms of the facet of climate that they indicate, their sensitivity, their speed of response and the reliability with which they can be dated. In Table P1 these methods are divided into certain main classes: the faunal and floral, the sedimentological, and the geomorphological.

Of all these different techniques, the ones that must be singled out for special attention because of their importance are those associated with the use of deep-sea cores (Kukla, 1977). Although the ocean floors are by no means completely stable (burrowing organisms, solution, and currents create problems), they offer a more continuous and lengthy stratigraphic record than most terrestrial sections, so that cores of sediment taken from them can be used and interpreted in a variety of ways.

They can be dated by radiometric means, paleomagnetic epochs, whether normal or reversed, can be examined, and the lithological characteristics of the sediments within the cores can be determined with a view to finding out about changes in terrigenous sediment sources (Table P2). One of the most productive ways of examining the cores has been the study of changes in the frequency of particular “sensitive species” of Foraminifera that are thought to reflect changes in the temperature of ocean waters (e.g. *Globorotalia menardii*). Another way in which the Foraminifera can be used is by the measurement of the O¹⁸/O¹⁶ ratios in their calcitic tests, for this ratio reflects the temperature of the water in which the beasts lived and also the volume of water stored up in the ice caps. During glacial episodes immense ice sheets of isotopically light ice (i.e. depleted in O¹⁸) accumulated in North America and over Scandinavia. When this occurred, the oceans diminished in volume, became slightly more saline, and isotopically more positive (i.e. enriched in O¹⁸). This enrichment is recorded in the isotopic composition of the Foraminifera. The changing composition thus provides a record of glacials and interglacials. In addition, deep-sea cores may contain varying proportions of aeolian debris, fluvial sediments, and iceberg rafted debris that indicate varying inputs of material from terrestrial sources.

Early climate history of the Earth

Little is known about the very early climatic history of the Earth, for rocks deposited before about 2800 million years ago are generally so metamorphosed that it is extremely difficult to extract climatic information from them. Indeed, the only way of deducing the climatic history from the formation of the Earth (4500 million years ago) until 2800 million years ago is by numerical modeling, with certain assumptions made about the gaseous content of the atmosphere. If the carbon dioxide and

ammonia contents of the early atmosphere were considerably elevated over present levels, then it is likely that Earth surface temperatures would also have been elevated because of a marked greenhouse effect.

In the early Proterozoic (around 2700–1800 million years ago) evidence from Canada suggests that the first known glaciation occurred. It was probably a complex event with recurring glacial events rather than a continuous glaciation, and it was followed by a relatively warm phase that persisted to around 950 million years ago. During the late Precambrian at least three major glacial episodes occurred, each lasting about 100 million years and centering on about 615 million, 770 million, and 940 million years ago.

Toward the end of the Proterozoic, the record of climate improves because the sedimentary record is better preserved and animals with shells that could be preserved as fossils had spread through the oceans. In general climatic conditions between 570 million and 225 million years ago were relatively warm, though in the Sahara there is evidence of a brief glacial event in the late Ordovician around 430 million years ago. The Permocarboniferous was characterized by a long glaciation from 330 to 250 million years ago, and ice caps were extensive on the supercontinent of Pangaea.

During the succeeding Mesozoic era the evidence of deep-sea cores becomes of greater utility. Temperatures ranged from 10–20°C at the poles to 25–30°C at the equator. There were, however, fluctuations in temperatures, with slight cooling taking place at the start of the Jurassic and with marked high-latitude warming taking place during the first half of the Cretaceous. Global cooling took place toward the end of the Cretaceous, however, and a long-term cooling trend commenced at the start of the Eocene epoch some 55 million years ago. The Cenozoic suffered various marked short-term cooling episodes: at the mid-Palaeocene (ca. 60 million years ago), in the Middle Eocene (ca. 45 million years ago); at the Eocene–Oligocene boundary (ca. 38 million years ago); and in the Middle Oligocene (ca. 28 million years ago). There is some evidence that the Antarctic glaciers may have come into existence in the Eocene and that about 10–15 million years ago mountain glaciers came into existence in the northern hemisphere.

There is also evidence for climatic deterioration from floral remains, and the general decline in temperatures during the Tertiary is shown in Table P3. In the early Tertiary the North Atlantic region was characterized by a widespread, tropical rainforest vegetation. For example, in the London–Hampshire basin of southern England there was the Malaysian *Nypa* palm and *Avicennia* (mangrove) swamp. In the pre-Miocene Bovey Tracey beds in western England are the remains of many tropical plants including *Osmunda*, *Calamus*, *Ficus*, *Symplocos*, and *Lauras*. However, by Pliocene times the tropical vegetation of the North Atlantic Region was being replaced by a largely deciduous, warm temperate flora including *Sciadopitys*, *Tsuga*, *Sequoia*, *Taxodium*, and *Carya*. The last appearance of palms north of the European Alps is in the late Miocene flora at Lake Constance.

The Tertiary may also have been a time of increasing aridity. Studies of aeolian material in deep-sea cores from the Pacific Ocean (Leinen and Heath, 1981) have demonstrated that there were low rates of dust deposition 50–25 million years ago. This, Leinen and Heath believe, reflects both the temperate, humid environment that was seemingly characteristic of the early Tertiary and the lack of vigorous atmospheric circulation at that time. From 25 million to 7 million years ago the rate of

Table P2 Information to be gained from deep-sea cores

Indicator	Environmental information
O ¹⁸ /O ¹⁶ ratios	Temperature, ice volume
Coarse debris	Iceberg rafting
Eolian dust	Aridity
Sensitive species Foraminifera	Temperature
Total species Foraminifera	Temperature
Clay minerals	Weathering regimes on land
Fluvial sediments	River inputs
Coccolith carbonates	Temperature
Aeolian sand turbidites	Aridity

aeolian accumulation on the ocean floor increased, but it became greatly accelerated from 7 million to 3 million years ago. However, it was around 2.5 million years ago, at the end of the Tertiary, that the most dramatic increase in aeolian sedimentation occurred. This accompanied the onset of northern hemisphere glaciation.

The causes of the Cenozoic climate decline, illustrated in Figure P5, are still not fully understood, but the trend seems to be associated with the breakup of the ancient supercontinent *Pangaea* into the individual continents we know today. About 50 million years ago Antarctica separated from Australia and gradually shifted southward into its present position, centered over the South Pole. At the same time the continents of Eurasia and North America moved toward the North Pole. As more and more land became concentrated in high latitudes, ice caps could

develop, surface reflectivity could increase, and, as a consequence, climate probably cooled all over the world. In addition, as the southern continents drifted away from Gondwanaland, India collided with Eurasia to produce the Tibetan Plateau, a feature so large and high that it changed the whole circulation of the northern hemisphere and drew cold Arctic air into Europe and Canada. Moreover, the closure of the straits of Panama in the Pliocene caused the ocean circulation to become less zonal and more meridional, thereby modifying the crucial thermohaline circulation.

Pleistocene and Holocene

The climatic deterioration of the later Tertiary eventually led to the glacial events of the Pleistocene. The classic model for the

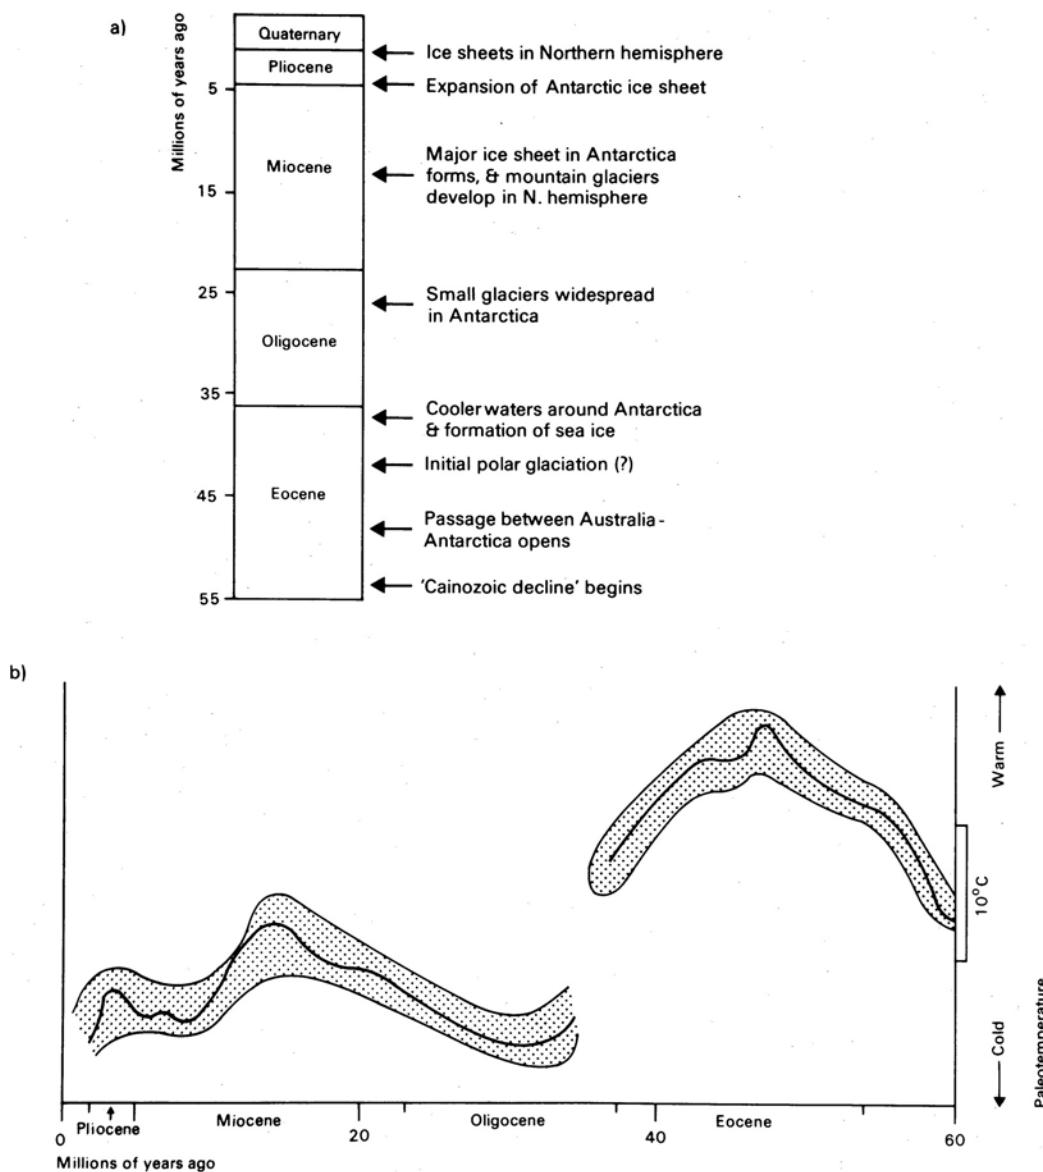

Figure P5 Cenozoic climatic decline. Generalized outline of significant events: temperature changes calculated from oxygen isotope values of shells in the North Sea (source: Goudie, 1983).

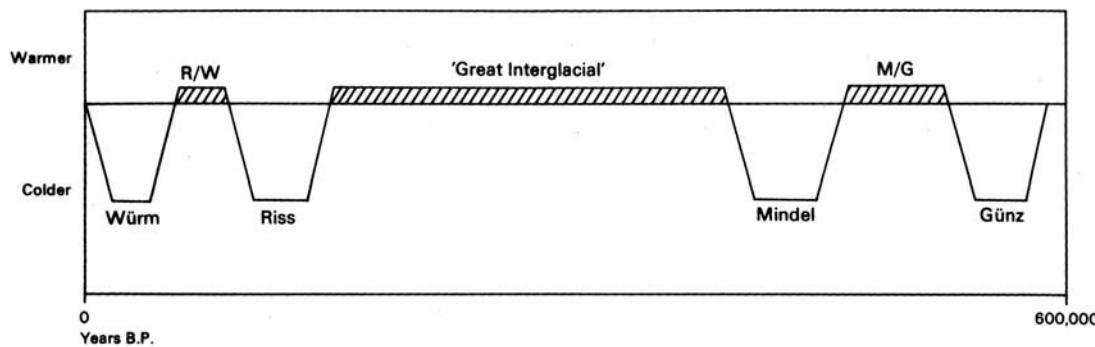

Figure P6 Simple Penck and Brückner model of Pleistocene glaciations showing the four main glacials. Note the extent of the "Great Interglacial".

Quaternary glaciations was proposed by Penck and Brückner between 1901 and 1909 in a major three-volume work *Die Alpen in Eiszeitalten*. By studying what was left of old moraines, they were convinced that there had been four great glaciations of different intensities in the alpine region of Europe. They also proved, from the preservation of plant remains at some sites such as Hötting, that some of the intervening periods were fairly mild. They named the four glacial periods after valleys in which evidence of their existence occurred: the Güiz, Mindel, Riss, and Würm. Of particular note was their belief that the interglacial between the Mindel and the Riss lasted a longer time than any other. In the classic model this event was therefore termed the *Great Interglacial*. Their model is summarized in Figure P6.

The various terrestrial sequences that have been laboriously compiled by classic stratigraphic techniques have demonstrated beyond doubt that the Quaternary was a period of remarkable geomorphological and ecological instability. However, because of the incomplete nature of the evidence created by hiatuses in the depositional record occasioned by erosion, it is not possible to use this information to construct a correct, long-term model of environmental changes for this period. For this to be achieved it is necessary to look at the more complete record of deposition preserved in the ocean core sediments.

A Pacific Ocean piston core, V-28-238, taken from near the equator at a depth of over 3000 m, has been used as the type locality of the $\text{O}^{18}/\text{O}^{16}$ record. The upper 14 m of the core have been subdivided into 22 oxygen isotopic stages numbered in order of increasing age. Odd-numbered units are relatively deficient in O^{18} (and thus represent phases when temperatures were relatively high and the ice caps small), whereas the even-numbered units are relatively rich in O^{18} and represent the colder phases when the ice caps were more extensive. Boundaries separating especially pronounced isotopic maximums from exceptionally pronounced minimums have been called *terminations*. They are in effect rapid deglaciations and are conveniently numbered by Roman numerals in order of increasing age. The segments bounded by two terminations are called glacial cycles. The youngest glacial cycle, which starts with isotopic stage 1 and follows Termination I, is not yet completed.

The results of the analysis of this major type core, illustrated in Figure P7, can be summarized as follows. There have been eight completed glacial cycles (named *b* to *i*) and nine

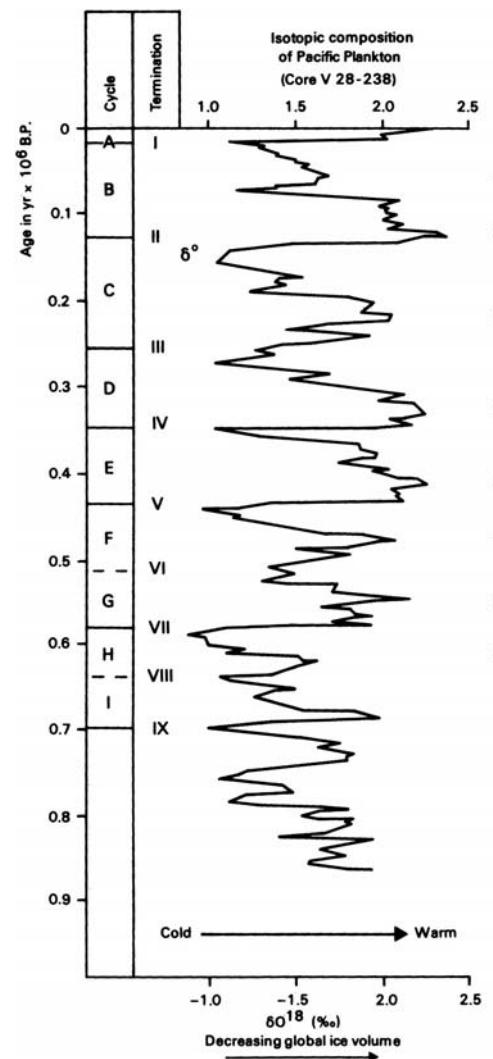

Figure P7 History of the last 900,000 years as revealed in isotopic composition of a Pacific core (V-28-238).

terminations (I-IX) in the last epoch of normal polarity (the Brunhes), which lasted just over 0.7 million years. There are 10 completed glacial cycles and 11 terminations in the 1 million years following the Jaramillo normal polarity event. Oscillations of the ice cap volume within each glacial cycle seem to follow a sawtooth pattern, progressing from an early minimum to a late maximum. The number of secondary fluctuations in isotopic composition within each glacial cycle varies, commonly between four and six. Over the last million years the general shape and amplitude of the last nine completed glacial cycles shows no great variation. However, cold stages 2, 6, 12, 16, and 22 are marked on the average by deeper and/or longer-lasting isotopic highs than the remaining cold stages, with cold stage 14 seeming to be one with an exceptionally low ice volume. The warm peaks (except stage 3) all seem to approach a similar level, indicating that global ice volume and sea-surface temperatures in peak interglacials were similar to those of the present day. During the last 0.9 million years there have been nine episodes with global climate comparable to today; in other words, there have been nine interglacials. The interglacials only constitute about 10% of the time, and seem to have had a duration of the order of 10^4 years, whereas a full glacial cycle seems to have lasted on the order of 10^5 years. Conditions such as those experienced in the twentieth century have thus been relatively short-lived and atypical of the Pleistocene as a whole. There appears to be scant evidence in the deep-sea cores for the Great Interglacial of Penck and Brückner.

The oxygen isotope record in the ocean sediments reveals a number of cycles or pacings related to the orbital variations of the Earth around the sun (the Milankovitch cycles) at 100, 41, 23, and 19 thousand years. There are also many shorter changes of an abrupt nature that have been identified both in the ocean cores and in ice cores (Pettit et al., 1999). The rapid temperature oscillations that hav been identified from ice cores are known as Dansgaard–Oeschger events. Dansgaard et al. (1993), for example, documented no less than 24 interstadials (warmer phases) from the GRIP ice core in the last glacial period. In ocean cores, high-frequency abrupt changes have been termed Bond cycles (Oppo et al., 1998). Also within the ocean core record are deposits interpreted as the result of deposition by massive armadas of icebergs (Bond et al., 1992). These are called Heinrich events and represent stadials (colder phases) of short duration (less than 1000 years) (Andrews, 1998). The causes of such abrupt short changes may include changes in the thermohaline circulation of the oceans and various feedback processes (Adams et al., 1999).

Going further back, the record seems less clear. Shackleton and Opdyke (1977) found from their study of Core V23-179 that glacial-interglacial cycles had been characteristic of the last 3.2 million years but that the scale of glaciations increased around 2.5 million years ago. In all there have been about 17 cycles in the Pleistocene *sensu stricto* (i.e. in the last 1.6 million years).

A fairly precise comprehension of the nature of one glacial cycle, the last, has been gained from other relatively continuous depositional sequences (Figure P8), including the polar ice caps and some large bogs such as Grand Pile in France (Woillard, 1979). From about 116 000 years ago until 60 000–70 000 years ago there was a relatively warm interval. The onset of the last glacial was about 60 000 BP, but the cold period following the initial fall in temperature lasted for only a few thousand years and was followed by a relatively clement period (an interstadial)

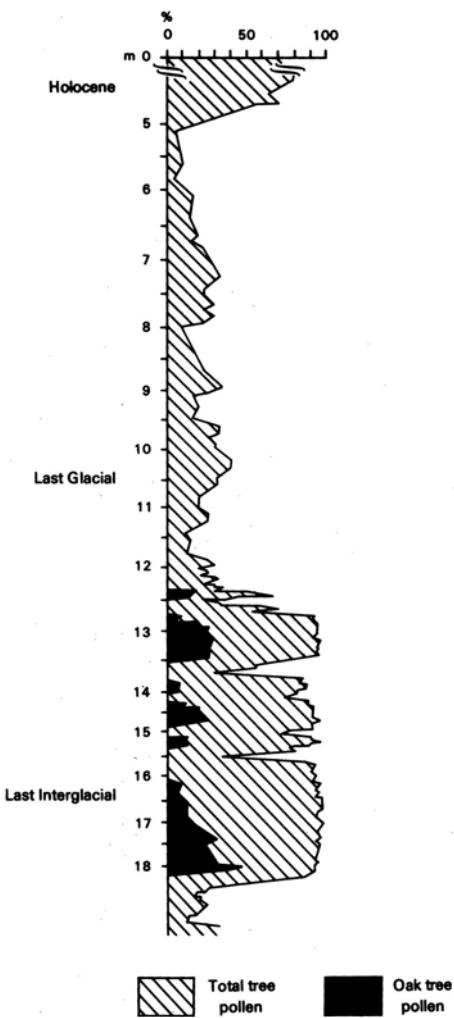

Figure P8 Pollen record from Grande Pile, France.

that lasted until about 30 000 BP. A further cold period, the Glacial Maximum, followed. This lasted about 10 000 years and the lowest temperature and the greatest extent of ice sheets of this entire glacial episode were attained at about 20 000–18 000 BP. Widespread deglaciation began abruptly about 14 000 BP, so that by 10 000 BP the North American Cordilleran Ice Sheet had disappeared.

The Holocene has been a time of relative warmth – an interglacial – though it has also seen some substantial changes in climate. Glaciers have oscillated during a series of Neoglacial advances and retreats (Grove, 1988), and there is evidence that there have been some warmer phases than the present, such as the so-called *Climatic Optimum* of the mid-Holocene when temperatures may have been 1–3°C higher than now. There have also been a number of abrupt events at ca. 8200 BP and between 3500 and 3900 BP (Alley et al., 1997; Anderson et al., 1998).

Low-latitude conditions

The glacials and interglacials of the Pleistocene were complemented in lower latitudes by changes in precipitation

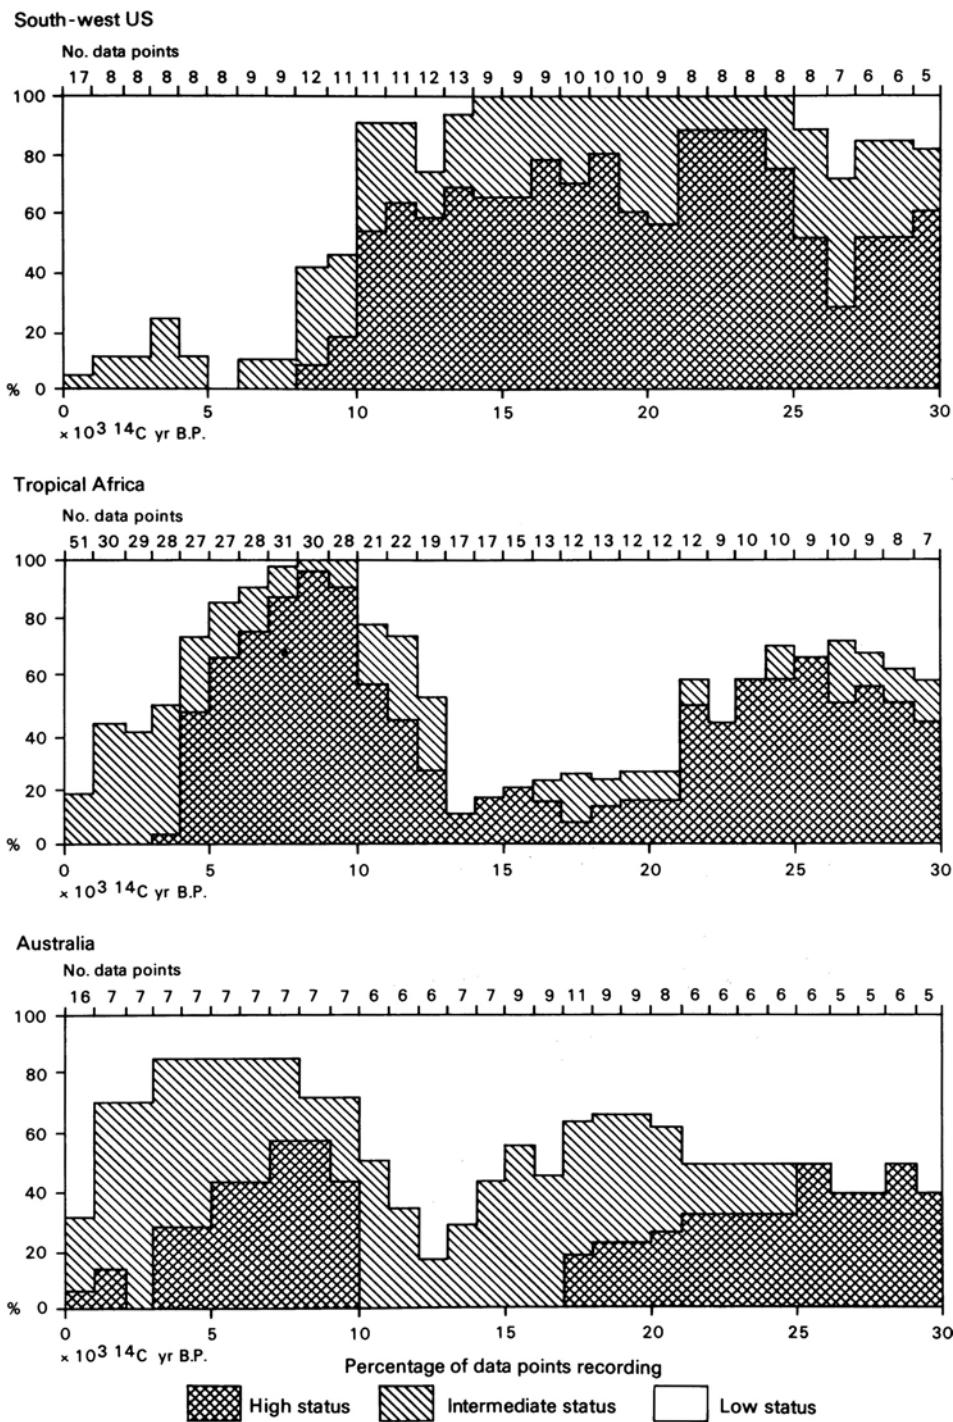

Figure P9 Histograms showing lake-level status for 1000-year time periods from 30 000 BP to the present day for three areas: southwestern United States, intertropical Africa, and Australia (source: Goudie, 1983).

(Street, 1981). At certain times there appears to have been greater humidity (pluvials or lacustrals), whereas at others aridity was increased so that the major deserts of the world expanded. In many parts of lower latitudes the last Glacial

Maximum (ca. 18 000 years ago and slightly after) was a time of low rainfall, and it has been calculated that deserts then characterized 50% of the land area between 30°N and 30°S, forming two vast belts. In between, tropical rainforests

and adjacent savannas were reduced to a narrow corridor. The prime evidence for this aridity is provided by fossil dune systems (ergs) (Goudie, 2002). There is also dramatic evidence for wetter conditions in the form of ancient lake shorelines. The greatest concentration of pluvial lakes in the western hemisphere, and possibly in the world, occurred in the Basin and Range Province of the United States. Lake Bonneville, for example, as its maximum extent was almost the size of Lake Michigan but now contains only 2600–6500 km² of water (the Great Salt Lake in Utah). The dates for such high lake levels vary in different parts of the world (Figure P9). In the southwest United States the Glacial Maximum appears to have been a time of high lake levels compared with the Holocene, whereas in tropical Africa and Australia, lake levels seem to have been low (especially about 14 000 years ago) and then became very high in the early Holocene (*ca.* 9000 years ago). At that time the Sahara became green, had through-flowing rivers, large populations of herbivores and pastoralists, and many freshwater lakes.

PALMER INDEX/PALMER DROUGHT SEVERITY INDEX

In 1965 Wayne C. Palmer, a scientist in the Office of Climatology, Weather Bureau, US Department of Commerce, Washington, DC, published a research paper entitled "Meteorological drought". Applications of the analytic procedures set forth in this paper have become widely known as the Palmer Index or the Palmer Drought Severity Index (PDSI). It is a hydrologic or persistent climatological drought index, since it attempts to quantify the scope, severity, and frequency of prolonged periods of abnormally dry weather. It works reasonably well for this purpose.

The Palmer indexing procedure was developed to help fulfill the need to define and quantify droughts. This need is very real to agencies at all levels of government since drought means various things to people, depending on their specific problems related to it. To a farmer drought means a shortage of soil moisture in the rooting zone of crops. To the hydrologist or urban water system engineer it means low levels in groundwater, reservoirs, lakes, and stream flow. To the economist or businessperson it means a water shortage that has adversely affected the economy. The only common denominator among these many concerns is that drought is caused by a prolonged weather anomaly of less than expected precipitation.

Basically, the Palmer Index is an index of relative moisture deficiency under a wide range of climatic conditions. Its general concept is one of supply vs. demand. The supply is represented by precipitation and stored water in the form of soil moisture, groundwater, lakes, and reservoirs. The demand is the

combination of potential evapo-transpiration and the amount of water needed to recharge soil moisture, plus the runoff needed to keep lakes, reservoirs, and stream flow at a normal level. It is a water balance accounting procedure that results in a positive or negative anomaly estimate weighted by the climatic conditions in time and space. The final product is an index that expresses the abnormality for a given place over a particular time period. These calculations produce an index value that can be compared across a wide variety of climates. In practice the time period increment is added to a portion of the previous time period value. In this manner the index value is weighted for the duration of the anomaly.

The generalized equation for the moisture-balance accounting assumes a given soil surface under natural climatic conditions. It is assumed that evapotranspiration takes place at the potential rate from the surface until all available moisture is removed. Likewise, it is assumed that there will be no recharge to the underlying soil body until the surface has been brought to normal holding capacity under the pull of gravity. It is further assumed that water loss from the underlying soil body depends on the initial soil moisture content as well as on computed potential evapotranspiration and the available capacity of the total soil system. Further, it is assumed that no surface runoff or runon occurs. Therefore:

$$L_{sm} = (PE - P - L_{ss}) \frac{S_{sm}}{ASM} L_{sm} \leq S_{sm}$$

where L_{sm} is moisture loss from soil body, PE is potential evapotranspiration, P is precipitation, L_{ss} is surface soil moisture loss, S_{sm} is available surface moisture, and ASM is available soil moisture. These generalized accounting procedures produce quantitative estimates of the moisture balance from one time to another. In this manner estimates of positive or negative anomalous values can be produced. These anomalous moisture balance values are then assigned an index scale of severity with reference to that expected for the area and the season of the year. It is these scale values that have become known as the Palmer Index.

Palmer arbitrarily selected the classification scale of moisture conditions based on his original study areas in central Iowa and western Kansas (Table P4). Ideally, the Palmer Index is designed so that a -4.0 in South Carolina has the same meaning in terms of the moisture departure from a climatological normal as a -4.0 in Idaho. The Palmer Index has been calculated on a monthly basis, and a long-term archive of the monthly PDSI values for every Climate Division in the

United States exists with the National Climatic Data Center from 1895 through the present. In addition, weekly Palmer Index values are calculated for the Climate Divisions during every growing season and are available in the *Weekly Weather and Crop Bulletin*. This is jointly prepared by the US Department of Commerce, National Oceanic and Atmospheric Administration, and the US Department of Agriculture. The bulletin is published weekly on Tuesdays. These are also available on the worldwide web from the Climate Prediction Center.

The Palmer Index is popular and has been widely used for a variety of applications across the United States. It is most effective in measuring impacts sensitive to the soil moisture conditions, such as agriculture. It has also been useful as a drought monitoring tool and has been used to start or end drought contingency plans. There are three positive characteristics of the Palmer Index that contribute to its popularity: (1) it provides decision makers with a measurement of the abnormality of recent weather for a region; (2) it provides an opportunity to place current conditions in an historical perspective; and (3) it provides spatial and temporal representations of historical droughts. It does, however, work best east of the Continental Divide.

Another index used to evaluate moisture is the Crop Moisture Index (CMI). Developed by Palmer subsequent to his development of the PDSI, the CMI is designed to indicate normal conditions at the beginning and end of the growing season. It uses the same levels as the PDSI but differs from it by placing less weight on the data from previous weeks and more weight on the recent week. As a result, the CMI responds more rapidly than the Palmer Index and can change considerably from week to week. It is thus more effective in calculating short-term abnormal dryness or wetness affecting agriculture.

Other indices include the Standardized Precipitation Index (SPI), a relatively new drought index, based only on precipitation. The SPI can be calculated for a variety of time-scales. This flexibility allows the SPI to be of value in both short-term agricultural and long-term hydrological applications. The index is based on data from the National Climatic Data Center, and on analysis by the Western Regional Climate Center and by the National Drought Mitigation Center. Also used as a drought indicator are values for Percent of Normal Rainfall for the past 30 and 90 days. These are updated daily and are derived from comparisons with data from earlier long-term data.

The PDSI has become a management tool for decision making in government, industry, and agriculture (Strommen, 1981). It is used as a standard of comparison by government for defining drought intensity throughout the United States. Industry and agriculture use the index in water resource planning as well as in estimation of current water supplies. Perhaps the most significant evidence of its place in meteorological practice is its adoption by foreign national meteorological services and agricultural ministries. This is particularly true among the nations in the third world within the semiarid tropics.

PHASE CHANGES

Most substances can exist in three phases or states of matter – solid, liquid, and gaseous – and changes from one state to another can occur. In terms of atmospheric sciences, such phase changes are most significant in relation to water, whose phases include ice (solid phase), water (liquid phase), and vapor (gaseous phase).

Table P5 provides a listing of the reversible changes of the phases of water. Under normal conditions ice melts at a temperature of 0°C, its melting point. Below this temperature ice is the stable phase of water. Above 0°C the stable phase is water. Although ice cannot normally exist above 0°C, water can exist in the liquid phase at temperatures below 0°C and even to a temperature of –40°C. In such a state the water is said to be supercooled. This is a metastable phase, meaning that, although the supercooled water is stable, it is not the most stable phase and has a tendency to change to ice. The presence of supercooled water in the atmosphere is highly significant in the precipitation process and in potential

rainmaking operations. The significance rests with the fact that when metastable supercooled water is in contact with ice it will freeze.

Phase changes involving water vapor can occur up to a maximum of 100°C, the boiling point of water. Below this temperature vapor can exist in contact with both ice and water but above 100°C, vapor is the only stable phase. Under set conditions water can exist above 100°C, superheated water, but in the atmospheric sciences this condition can be ignored.

The values of both melting and boiling points of water depend on pressure exerted at their surfaces. Within the normal confines of surface atmospheric pressure, the 0°C and 100°C values can be considered operative. It is mostly in relation to increased elevation that the values, especially the boiling point, are significantly changed.

When phase changes occur there is an exchange of energy. Table P6 provides a summary of the amount of heat transferred. As noted in other entries (see cross-references) this exchange plays a very important part in the transfer of energy over the globe.

Precipitation

PRECIPITATION

Precipitation refers to solid or liquid phase water particles that are formed in the atmosphere and that fall and reach the Earth's surface. It also refers to the quantity of such particles that have reached the Earth's surface at a given location over a given period of time. This quantity is generally measured in linear units of liquid water (e.g. millimeters or inches) – with an assumption that this measurement is per unit area.

Formation of precipitation

Condensation of water vapor in the atmosphere may take place when the air is saturated. Air is typically brought to saturation by cooling and this cooling is generally accomplished by upward motion and the resulting adiabatic expansion of the air. The saturation vapor pressure over a curved surface is much higher than that over a flat surface. To form a stable water droplet would require much larger supersaturations than are observed in the atmosphere unless the water condensed on some other substance. Condensation on another substance reduces the radius of curvature of the water droplet. Thus, water vapor requires solid and liquid particles known as *Condensation nuclei* on which to condense. The concentrations of these nuclei vary greatly in the atmosphere from the order of 10 to 1000 cm^{-3} . Larger values are found over the continents and urban areas. Some condensation nuclei, known as *hygroscopic nuclei*, have a particular affinity for water and water may condense on them at relative humidities which are less than 100% (with respect to a flat surface of pure water).

Deposition of ice in the atmosphere requires that the atmosphere be saturated and also that the temperature be below the freezing point of water. At temperatures above -40°C deposition requires, in addition, that suitable particles known as *ice nuclei* are present. The number of ice nuclei in the atmosphere varies with temperature – more ice nuclei activate at lower

temperatures – but averages about 1 per liter at -20°C . Thus, ice nuclei are considerably scarcer than condensation nuclei.

Water droplets and ice crystals fall under the influence of gravity but their fall is impeded by air resistance. Therefore, they do not continue to accelerate indefinitely but reach a terminal velocity. The terminal velocities for water droplets and ice crystals are given in Figures P10 and P11, respectively. Since cloud droplets are typically $2\text{--}50 \mu\text{m}$ in diameter, it can be seen that they must grow considerably larger to reach the Earth's surface in a reasonable period of time. Ice crystals must grow larger still.

Water droplets can grow larger by additional condensation. Condensation is favored on larger droplets as well as on droplets containing dissolved substances. Water droplets can also grow by encountering and merging with other cloud droplets in a process known as collision and coalescence which also favors the growth of larger droplets as opposed to smaller ones. Precipitation can and does develop in clouds whose temperatures are not low enough for ice crystals to form. Such conditions are more likely to occur in the tropics and subtropics than in middle or polar latitudes.

Ice crystals can also grow larger by additional deposition of water vapor. But since there are relatively few ice nuclei in the atmosphere, ice crystals and supercooled water droplets often coexist in clouds whose temperature is below freezing. The saturation vapor pressure over water is greater than that over ice. Thus, conditions can exist where the water droplets are subsaturated and the ice crystals are supersaturated. The ice crystals grow at the expense of the water droplets in what is known as the *Bergeron* process. The *Bergeron* process is responsible for the vast majority of precipitation (including rain) in middle and higher latitudes as well as in tropical thunderstorms. Ice crystals are always six-sided but may take a variety of forms: columns, needles, plates and the elaborate branching structures, known as dendrites, of the stereotypical snowflake. The structure of the ice crystal is dependent on the temperature and humidity of the air in which it forms. Ice crystals may collide and merge in a process called *aggregation*. In addition ice crystals may encounter water droplets that freeze on impact with the ice crystal. This process is known as *riling*.

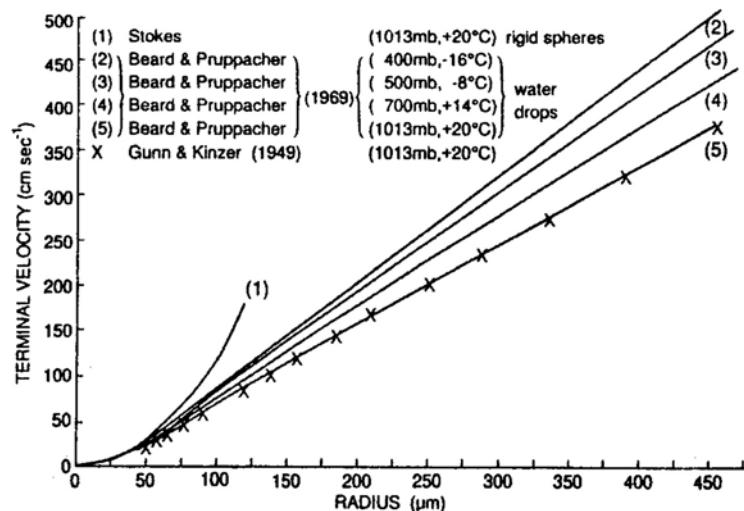

Figure P10 Variation with size of the terminal fall velocity of water drops smaller than $500 \mu\text{m}$ radius in air (from Pruppacher and Klett, 1997).

Types of precipitation

Precipitation in the liquid form when it reaches the Earth's surface may be divided into two categories: *rain* and *drizzle*. The distinction between them is entirely based on size – drizzle drops are less than 0.5 mm in diameter and rain drops are at least 0.5 mm in diameter. Drizzle typically falls from fog or low stratus clouds and generally produces small quantities of precipitation. Rain will fall from nimbostratus or cumulonimbus clouds.

Likewise, frozen precipitation that has experienced little or no riming and has not previously melted may come in the form of *snow* or *snow grains*. Snow is larger in size having often experienced aggregation, especially if the temperature is near

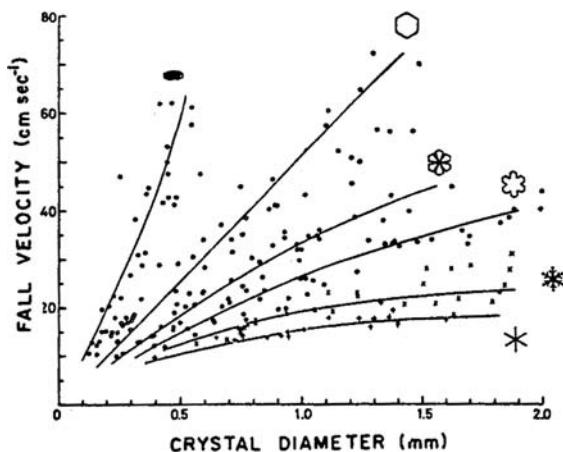

Figure P11 Variation with size of observed terminal fall velocities (symbols) and velocities computed from drag data (lines) for ice crystals of various shapes, -10°C , 1000 mb (from Pruppacher and Klett, 1997).

freezing. Snow grains are the frozen equivalent of drizzle and typically fall from fog or low stratus clouds. They are small, white and opaque with diameters less than 1 mm. Snow crystals that are moderately rimed are called graupel, snow pellets or soft hail. They are white due to their core, which was formed by deposition. They are typically 2–5 mm in diameter and may bounce when they hit the ground.

When ice crystals fall through a thick enough layer that is above freezing they will melt. If they then fall through another fairly thick layer that is below freezing before they reach the ground, they will refreeze. The resulting precipitation is called ice pellets or sleet (in the United States). (In British English, sleet refers to a mixture of rain and snow.) Ice pellets are transparent or translucent because they were formed by freezing liquid and not deposition of vapor. They are less than 5 mm in diameter. If the layer which is below freezing next to the Earth's surface is very thin, a falling water drop may not have time to freeze before it hits the ground. In this case the liquid water drop will freeze on contact with the ground, creating a thin sheet of ice. The precipitation is then known a freezing rain. Figure P12 illustrates the environment in which the various types of precipitation form. Freezing rain (and to a lesser extent, ice pellets) can be extremely hazardous to ground transportation because friction with a surface coated with freezing rain is even less than for a surface coated with snow. Freezing rain can also coat trees and power lines, unlike snow which will fall off both if accumulations are high enough. Heavy coatings can break tree branches and power lines, resulting in substantial damage.

Hail may be considered an extreme case of rimed ice crystals. Hail is greater than 5 mm in diameter. Hail typically has had several coatings of liquid water freeze on it. On larger hailstones these layers can be seen if the hailstone is cut open. To collect enough water to grow to even minimum size, the embryo hailstone must remain in the cloud longer than other types of precipitation. Although there is some disagreement as to all the processes involved in forming a hailstone, it is generally agreed

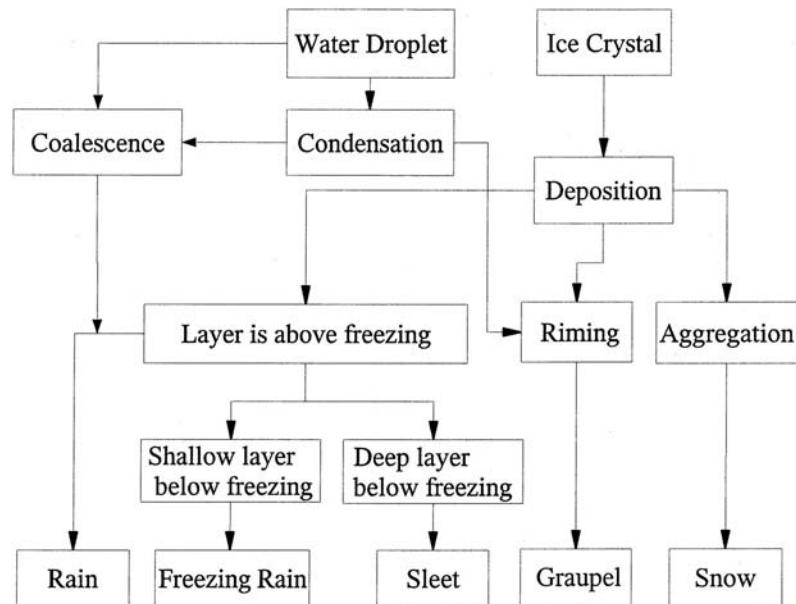

Figure P12 Processes forming different types of precipitation.

that the storm must have at least a moderately strong updraft to prevent the precipitation from falling out too soon. Thus, hail falls almost exclusively from cumulonimbus clouds. The shape and thickness of the thunderstorm updraft may be important factors as well as its orientation with respect to the downdraft.

Measurement of precipitation

Precipitation has traditionally been measured directly at the Earth's surface with a container into which the precipitation falls. Although the depth of frozen precipitation can be measured, its water equivalent varies greatly and the depth of snow changes depending on the length of time since the snow fell. Therefore, the liquid equivalent of the frozen precipitation has typically been a more useful measurement.

The standard rain gauge has a wide, usually circular, opening converging to a narrower inner tube. The cross-sectional area of the inner tube is generally one-tenth that of the outer opening. The depth of precipitation is measured manually with a specially calibrated ruler. This method can be economically advantageous because of the low cost and durability of the equipment. Its disadvantage lies in the difficulty of determining the rate at which the precipitation fell.

A weighing gauge can record the rate of precipitation accumulation. It measures the change in weight as liquid accumulates in a container. The liquid equivalent of frozen precipitation can also be measured if a known weight of antifreeze solution is in the container. The antifreeze can also reduce evaporative losses of accumulated precipitation. The minimum amount of precipitation recorded depends on the sensitivity of the gauge. This type of gauge is more costly and needs to be calibrated often.

Remote readings of precipitation accumulation are easier with the tipping bucket type of rain gauge. This instrument has a small container which is divided in two. The container pivots around its center in a seesaw manner such that only one side of the container accumulates precipitation at a time. When a known weight of precipitation accumulates in one side of the container, it will tip, empty its load and allow the other side to accumulate precipitation. The number of tips is recorded electronically. This type of gauge makes no record of less than some minimum precipitation accumulation – i.e. less than one tip's worth. It may have difficulty keeping up in very heavy rain and it tends to have more splash errors than other types of direct measurements.

Overall these direct measurements are subject to a number of errors. One is that precipitation in the gauge may evaporate before it is recorded. Another is that moisture may adhere to the collecting tube and not be measured. The most serious errors occur because catch decreases with increasing wind speed. Gauges are usually mounted as close to the Earth's surface as possible, to minimize this error. Some gauges may be fitted with a wind shield to help reduce this bias. It should be kept in mind that places with high average wind speeds may have precipitation measurements which are consistently lower than the actual amount which fell. Even outside of windy areas, errors in gauge measurements trend more towards underestimating rather than overestimating the amount of precipitation that actually fell.

Precipitation displays extreme areal variability and it is not usually feasible to have enough gauges to measure most of the variability. Generally the horizontal resolution of observations is very uneven. Thus, there is considerable incentive to estimate precipitation amounts with techniques yielding more spatial resolution.

Satellite measurements of infrared radiation (IR) in a narrow wavelength band have been related to precipitation. These

estimates have been based on the assumption that higher clouds emitting less IR are more likely to be generating precipitation. This method works better in regions such as the tropics, where most precipitation is convective in nature. The total outgoing IR radiation (i.e. wide band of wavelengths) has also been related to precipitation as it is also sensitive to soil moisture. Microwave radiation is more sensitive to cloud water and ice and thus easier to relate to precipitation directly. But the best algorithm for doing so varies by location and season.

Radar reflectivity has also been used to estimate precipitation amounts. To use this technique a drop size distribution must be assumed. Estimates of precipitation may be poor if drop size distribution in a particular storm is unusual. This method cannot directly determine how much of the precipitation in the air will reach the ground without evaporating. This technique is more difficult to apply to frozen precipitation as radar is less sensitive to it. Obviously, it is only applicable in parts of the world with reliable radar measurements.

Perhaps the most promising way of determining how much precipitation has fallen is to combine remotely sensed and gauge data. These methods use the gauge data to reduce the impact of the assumptions which must be made in remote-sensing estimates. They are therefore able to take advantage of the high resolution of the remotely sensed data as well as the greater (but not perfect) accuracy of the gauge data.

PRECIPITATION DISTRIBUTION

The amount of precipitation received at any place on the Earth's surface and over any given time period depends on a variety of factors and results from several complex causes and interacting processes that are themselves time- and space-dependent. Atmospheric water vapor, the basic element in precipitation, varies geographically and temporally. For example, the mean precipitable water content of the atmosphere at any given moment is 25 mm with a maximum near the equator of

44 mm and a minimum in the polar regions of 2–8 mm depending on the season. Between 40° and 50° latitude, precipitable water ranges above 20 mm in the summer and drops to 20 mm in the winter. However, the presence of atmospheric moisture is a necessary but not a sufficient condition for precipitation. Precipitation totals depend not only on amount of precipitable water in the atmosphere but also on lifting mechanisms that causes the moisture to precipitate. Except for irregularities induced by rugged topography, the greatest amount of precipitation occurs along portions of the Intertropical Convergence Zone (ITCZ). Any discussion of precipitation distribution, therefore, must of necessity address variations both in time and space. This can be accomplished by examining the major features of global patterns of precipitation and the factors that combine to influence those patterns, by looking at the nature and causes of seasonal, diurnal and other temporal variations in precipitation distribution to discern major temporal regimes and their forcing mechanisms, and finally, by examining distribution from a statistical perspective rather than from a purely climatological one. In this last case, distribution characteristics such as variability, persistence, frequency and intensity become important.

The distribution pattern of precipitation is considerably more complex than either temperature or global radiation because of the influences of several factors which can be classified into those influencing vertical motion in the atmosphere and those relating to the nature of the atmosphere itself. Of the latter group, the stability and instability of the atmosphere and its thermal and moisture characteristics, which in turn are determined by the nature of the source region of the air masses and their subsequent trajectory, are particularly noteworthy. Practically all precipitation results from the adiabatic cooling of ascending moist airmasses. The areas of most frequent and rapid airmass ascent are the zones of convergent horizontal air flow in the equatorial belt and areas affected by the midlatitude cyclonic disturbances, as well as along the windward side of high mountain ranges adjacent to extensive sources of moisture (Figure P13). Additionally, the distribution patterns of precipitation may be influenced by the distribution and density of the data collection network and the accuracy of the precipitation measuring instruments. Most measuring stations tend to be in highly populated areas with few stations over the oceans and in sparsely peopled regions. Moreover, gauge measurements tend to be underestimates of the true precipitation, largely because of wind-induced turbulence at the gauge orifice and wetting losses on the internal walls of the gauge. Monthly estimates of the bias often vary from 5% to 40%, are larger in winter than in summer, and over landmasses in the northern hemisphere, increases to the north due largely to the deleterious effects of wind on snowfall.

Geography of annual distributions

The mean annual precipitation for the Earth is about 1000 mm but its spatial distribution is variable (Figure P13). Several factors combine to influence the global distribution of precipitation. Mean annual totals are greater in the equatorial belt, where the general circulation of the atmosphere is characterized by the rapid ascent of warm moist air in the tropical zone of converging winds, than they are in the subtropical area of dominant subsidence and high surface pressure which inhibit precipitation and lead to much lower totals. The tropical convergence zone with its widespread uplift of warm, humid airmasses is the

most effective precipitation-producing part of the general circulation of the atmosphere. From this zone of heavy precipitation, amounts decrease irregularly toward the poles, and at high latitudes the lower moisture-carrying capacity of the colder atmosphere, fewer incursions of moist warm air and less active thermal convection result in limited precipitation. The minimum in precipitation at latitudes between 20° and 30° is caused by subsidence in the high-pressure zones and the adjacent stable portions of the trade wind inversion. In midlatitudes, precipitation increases again because of synoptic storm systems there. The forced ascent of moist surface air in midlatitude cyclones and orographic uplift in the westerly flow give rise to heavy precipitation. Although the distribution of annual precipitation shows a strong latitudinal zonation, there are non-latitudinal differences, especially in the tropics. Mount Waialeale on the island of Kauai, the northwesternmost of the large islands of the Hawaiian chain, averages 11 675 mm of rain annually; Cherrapunji, at an elevation of 1313 m on the southern slope of the Khasi Hills in northeastern India, averages 11 419 mm; and Debundscha, near the base of the Cameroon Mountain just north of the equator in western Africa, averages 10 279 mm annually. Areas with the least rainfall are Arica in northern Chile, which over a 59-year period averaged 0.75 mm, and Wadi Haifa, Sudan, averaged 3.0 mm over 39 years. Most of the coast of Peru and northern Chile averages less than 25 mm, as do portions of the southwest coast of Africa. In some places years may pass with no measurable precipitation and then a rare shower will account for the long-term average.

In middle and high latitudes the interannual differences in precipitation distribution patterns that lead, for example, to extensive areas of drought existing concurrently with other and equally extensive areas of severe flooding, can be traced to interannual differences in the configuration and intensity of the mid-tropospheric jet stream that is responsible for steering storms and storm systems through a series of troughs and ridges, the wavelengths and amplitudes of which vary from year to year and place to place. This upper-air steering mechanism is directly related to the magnitude of the internal energy of the atmospheric system, which in turn is related to the amount of solar energy absorbed by radiatively active surfaces in the boundary layer and its apportionment into sensible heat energy, latent heat energy and energy stored in the submedia modulated by the heat capacity and the response time of each storage medium. Interannual variability of precipitation over a large part of the tropics and subtropics is related to the El Niño/Southern Oscillation (ENSO) phenomenon.

The distribution of land and water greatly influences the precipitation patterns in middle and high latitudes. Regions in the interior of continents remote from oceanic sources of moisture receive less precipitation than coastal areas. Windward coasts tend to receive more precipitation than leeward coasts in regions where favorable prevailing winds transport moisture toward the land. Ocean currents or drifts may introduce further modifications since warm currents such as the North Atlantic Drift increase the moisture content of the air in contact with it, and in some cases induce atmospheric instability that may lead to precipitation. Cold currents, on the other hand, decrease precipitation over the adjacent land areas by cooling the lowest layers of the atmospheric column, increasing atmospheric stability, inhibiting vertical mixing and hence precipitation. The cooling process in the lower atmosphere may lead to fog or low stratus but no precipitation. Large lakes and lake systems in the middle and high latitudes produce extensive lake-effect

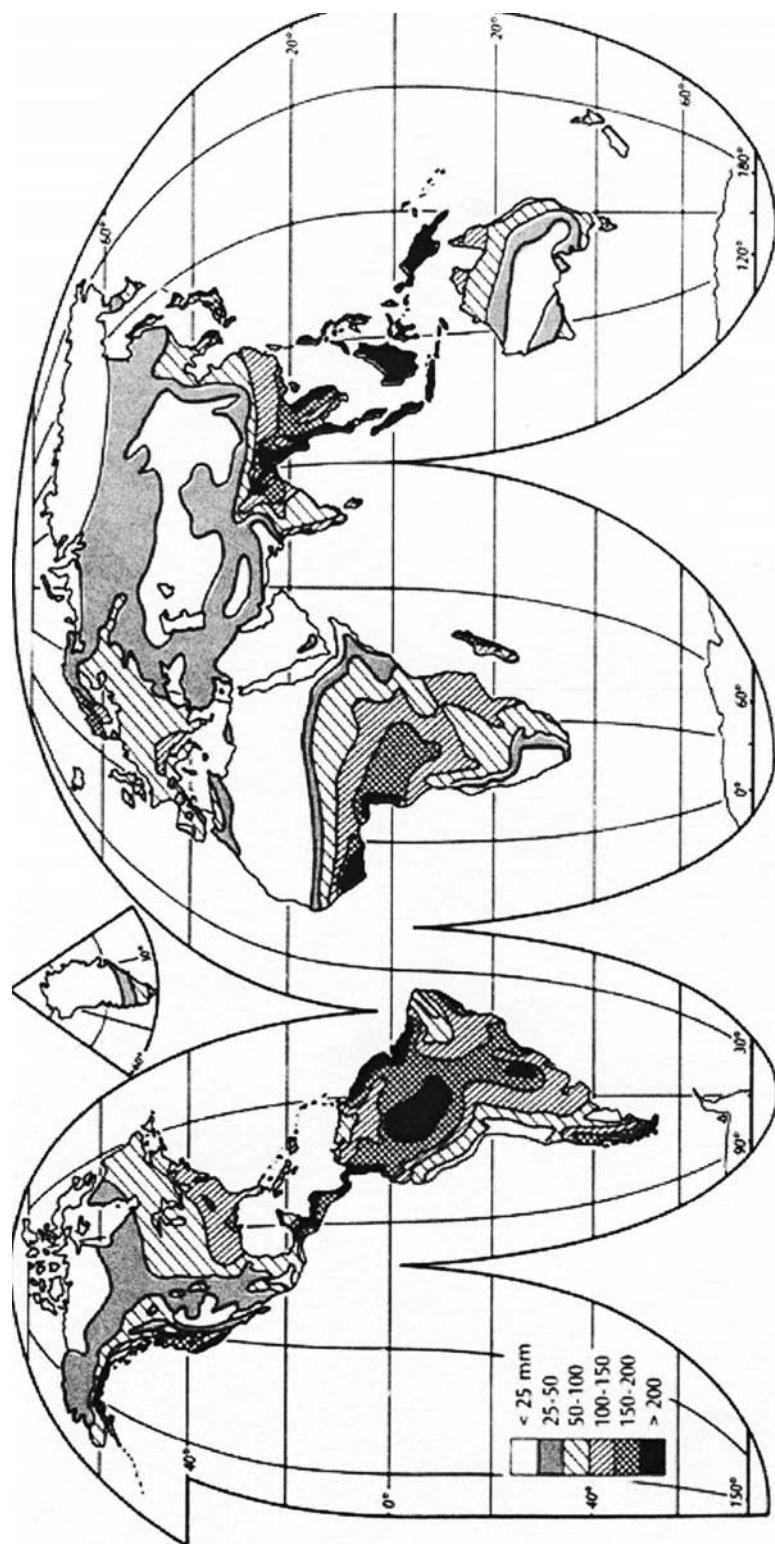

Figure P13 Mean precipitation (mm) over the Earth.

snowfall on their downwind edge in winter (Dewey, 1970; Brahan and Dungey, 1984). Cold moist air, in its trajectory over the lake, becomes unstable as a result of heating from below. This instability and uplift, accentuated by convergence in the lower layers as the airmass moves from an aerodynamically smooth lake surface to a comparatively rough land surface, result in comparatively higher snowfall totals from given air-masses on the downwind edge of the lake.

Forced ascent of moist air by topographic barriers concentrates precipitation on the windward slopes but creates a rain-shadow to leeward, by causing descending motion and hence heating of the already wrung-out air. Apart from tropical regions, the wettest places are on the windward side of mountains exposed to winds with long fetches across warm ocean surfaces. Mountains therefore tend to contribute to the spatial inequality in precipitation distribution. Examples of topographically induced inequalities in precipitation distribution are mountainous islands in the trade wind belt, the southern Andes along the Chilean–Argentine border, the Southern Alps of New Zealand and the coastal ranges of western North America (Figure P14). A cogent example is afforded by the state of Washington in the western United States (Figure P15). Along the Pacific coast where topographic variations are small the rainfall averages about 1525 mm; with increasing topographic variations annual totals may increase by 500 mm to totals of 2050 mm. On the western slopes of the Olympic Mountains up to 3800 mm are recorded. However, just to the east in the Puget Sound–Williamette Valley region, totals average around 1020 mm. Farther east, the western slopes of the Cascades receive amounts of 1525–1780 mm. Across the Cascade Divide there is a sharp transition spanning the range from 180 mm in Yakima to about 510 mm around Spokane. Orographic barriers also affect the vertical distribution of precipitation such that totals tend to increase with elevation on the windward slopes up to a certain level. Very high totals due to orographic lifting also occur in monsoonal areas and where tropical cyclones occur frequently, such as the western coast of India, Burma, Sumatra and Borneo in the first case and in the Caribbean region in the second case.

The major features of global patterns of annual precipitation distribution ascertainable from the preceding discussion and Figure P13 are (1) large totals in the equatorial zone and moderate to heavy amounts in the middle latitudes; (2) comparative dryness in the subtropical belts and in the regions around the poles; (3) within the subtropics, the west coasts of continents tend to be dry whereas east coasts tend to be wet; (4) in higher latitudes, west coasts tend to be wetter than east coasts; (5) in mountainous regions, especially where the mountains are transverse to prevailing winds, precipitation tends to be abundant on windward slopes but sparser on leeward slopes; and (6) maritime locations receive more precipitation than interiors of continents that are remotely located with respect to sources of moisture in the oceans, except perhaps in innermost Amazonia where prevailing winds, extensive horizontal convergence, large evapotranspiration rates and orographic effects combine to produce large amounts in a continental interior (Lettau et al., 1979).

Seasonal distribution of precipitation

Variations in the spatial distribution of annual precipitation and the accumulated totals over a given year are quite important climatically, but total annual precipitation is an insufficient measure of moisture availability because it does not take into

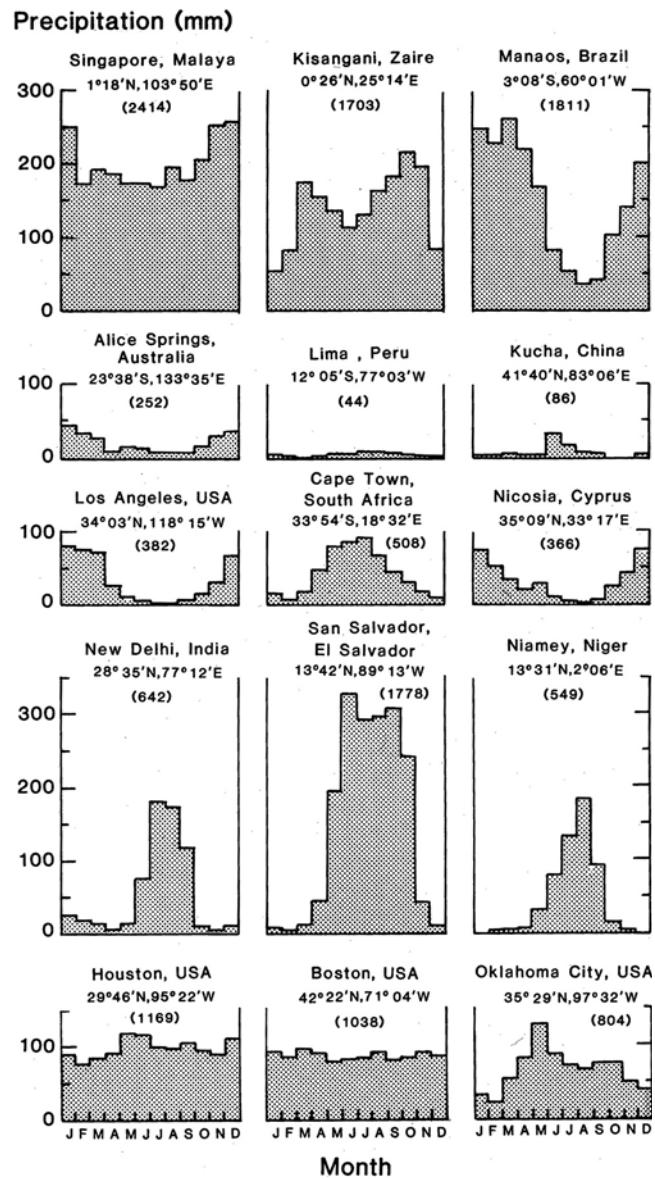

Figure P14 Seasonal precipitation distribution at selected groups of stations.

account how precipitation is distributed over time. Equally significant from the point of view of agriculture, hydroelectric power generation and water resources planning are the seasonality, the interannual dependability, month-to-month variations and the frequency and intensity. Precipitation-inducing mechanisms and processes do not operate in the same way throughout any given year. Belts of convergence shift poleward in summer and equatorward in winter, causing a shift in the associated precipitation belts. In these convergence belts, rainfall is comparatively well distributed throughout the year, but a few degrees of latitude poleward, where alternating convergence and subsidence predominate, marked dry and wet seasons exist. Near the equator two precipitation maximums are discernible, one occurring approximately 1 month after the equinoxes. With

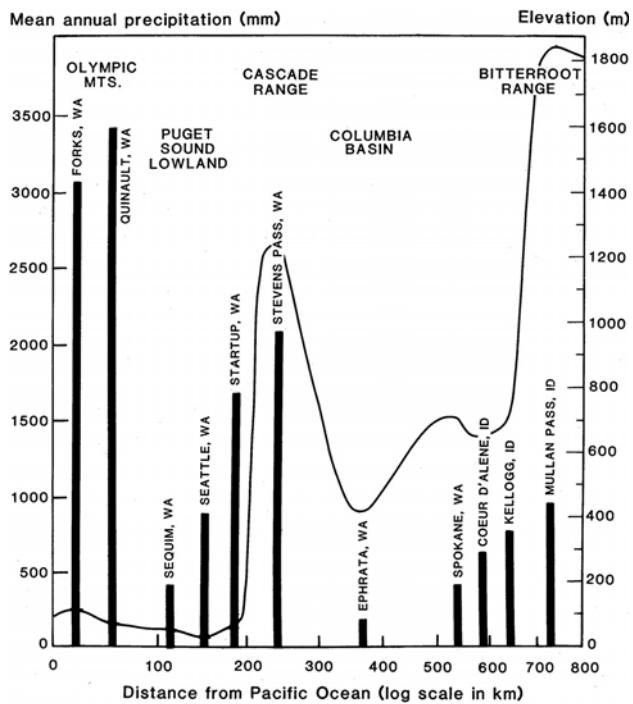

Figure P15 Orographic influences on precipitation exemplified by a transect of mean annual precipitation distribution along the 48°N parallel in western North America.

increasing distance from the equator the two maxima move closer together in time, reducing one minimum in length while the other dry season becomes longer and more intense. The total amount of annual rainfall is less here than closer to the equator. Between 15° and 20° latitude the short dry season disappears completely and the two maximums merge. North and south of this wet-dry precipitation regime, the influence of the subtropical quasistationary high leads to dry summers, whereas wet winters generally follow with the increasing influence of the westerlies and migrating cyclones and frontal disturbances. In India and Southeast Asia, monsoonal variations result in even more striking differences in the seasonal distribution of precipitation. Monsoons are seasonally prevailing winds that blow from one direction in summer and an approximately opposite direction in winter. These winds are best developed in India and Southeast Asia and are the result of differences in heat capacities of land and water, seasonally unequal heating and the pressure differentiation it produces, and the influence of mid-tropospheric circulation patterns, especially the subtropical jet and its interaction with the Himalayas. Northern Australia experiences a similar, though less well-developed, monsoon circulation, which is also related to seasonal migration of components of the general circulation. Along the east coast of Asia and across central Africa there are monsoon effects that merge into other shifting patterns of the general circulation. The southeast monsoon of India, which blows from the Arabian Sea across much of India from June to October, brings with it general rains that, along the west coast and the foothills of the Himalayas, are among the heaviest on Earth. In monsoon regions there is usually a marked summer maximum in precipitation (Figure P14), and delays in the onset of the west

monsoon season have disastrous consequences for agriculture and water supplies. In East Africa, agricultural practices are predicated on two maximums, the larger of which is monsoonal whereas the smaller is due to the shifting tropical convergence zone. Over the tropical continents, seasonal rainfall distributions are further complicated by intense convectional processes that increase the amounts of rainfall locally.

The seasonal distribution of precipitation is as important as the total distribution over large portions of the Earth's surface. In many parts of the tropics precipitation is strongly seasonal and the times of initiation, duration and end of the rainy season control agricultural activities and water resources allocations. In the tropics, seasonal rainfall distribution is so important that it forms the basis of most classifications of tropical climates. This does not imply, however, that the seasonal distribution of precipitation is not important in middle latitudes; tropical rainfall is effective for plant growth no matter what time of year it falls, but in middle latitudes only that part of the annual precipitation that falls during the non-freezing season may be effective. In middle latitudes there is a fairly pronounced summer maximum of convective activity in continental interiors, where the summer maximum tends to lag later into summer the farther poleward one goes because of the lateness of snowmelt and ground thaw that delay convective activity.

In general terms, it is possible to discern the following seasonal regimes: (1) abundant rainfall, largely convectional, occurring year-round in equatorial regions; (2) largely convectional rainfall occurring mainly in summer months; (3) low rainfall totals in all seasons; (4) mainly cyclonic precipitation in midlatitudes occurring in winter whereas summers are dry; (5) cyclonically induced precipitation more abundant in winter than in summer; (6) mainly summer precipitation in continental regions; (7) abundant precipitation on east coasts due to onshore winds in low latitudes and inflowing warm moist air-masses in summer and traveling cyclones in winter in middle latitudes; and (8) low levels of precipitation in polar regions with a maximum in summer.

Diurnal distribution

Diurnal rainfall distribution is generally not as important as seasonal distribution except in low latitudes. The diurnal regime influences transportation systems, many outdoor activities and evapotranspiration losses. Daytime precipitation input is subject to very heavy evaporation losses. Diurnal precipitation distributions are more regular in low latitudes than in higher latitudes because of the differences in the dominant rain-producing mechanisms. In the tropics the convectional processes that predominate are forced by the diurnal march of global radiation input and are therefore considerably more regular than the midlatitude disturbances and fronts responsible for a large proportion of the diurnal variations in middle and high latitudes, especially in winter and spring. The nocturnal maximum in the midwestern United States as compared with the late afternoon maximum in the eastern part of the country indicate that, even within midlatitude regions, there can be distinguishable diurnal variations, particularly in summer. At almost all latitudes diurnal regimes are also influenced by the effects of local factors, such as topography, on small-scale atmospheric processes, such as thunderstorms, and by the form and physiographic configuration of the coastline. Two types of diurnal regimes are recognizable in low latitudes: (1) the inland or continental type characterized by a late morning or afternoon maximum attendant on convection

initiated by surface heating of the land; and (2) the maritime or coastal type with a maximum during the night or early hours of the morning caused by severe nighttime instability and convection predicated on the steepened lapse rate attendant on radiative cooling of the upper troposphere while the lower layers remain warm due to its thermal coupling with the warm ocean surface (Kraus, 1963; Malkus, 1964). Ramage (1952) questioned the validity of this explanation but substituted no generally accepted theory. In the Caribbean region both types coexist, leading to the expectation of showers soon after solar noon, especially during the wet season. Equally expected, although not with the same regularity, are nocturnal severe thunderstorms occurring late at night or in the early hours of the morning. Some of the most intense precipitation, rivaled only by that accompanying hurricanes, occurs in these nighttime episodes.

The manner in which precipitation falls is also important. If it falls in infrequent cloudbursts it may cause floods and heavy erosion. On the other hand, prolonged drizzle effectively moistens the soil and provides high-humidity conditions. Europe receives less than 750 mm of precipitation per year but in many areas this is spread over more than 150 days. Under the cool cloudy, humid conditions that prevail there, the rainfall is quite adequate. In some parts of the world precipitation falls nearly every day of the year. Bahia Felix, Chile, averages 325 days per year with measurable precipitation, so that there is an 0.89 probability that it will rain or snow on any given day of the year. Buitenzorg, Java, averages 322 days per year with thunderstorms. Conversely, Arica, Chile, averages about one rain day annually; at nearby Iquique, Chile, there was no measurable rain between 1899 and 1913.

Statistical distribution

It is evident from the foregoing that the character of the spatial and temporal distribution of precipitation can be very important and enlightening but, in order to adequately analyze past sets of precipitation measurements so that conclusions about the future can be drawn, and in order to test the significance of physical experiments and check the validity of hypotheses concerning the distribution of precipitation, we need to know something about the statistical characteristics of the precipitation datasets. Statistical theory is based on the concept that a set of realizations is assumed to be representative of their population and therefore deductions can be made from that sample concerning the nature of the population. In order to draw inferences about a population, the values within the data sample must be random, independent and homogeneous. The precipitation datasets we work with, however, rarely meet all these criteria at once. In the first place there can be very little control over the selection of a sample, and whatever nature provides over a period of time must be used; second, the degree of independence varies with the precipitation-inducing mechanisms, season and location, and, in some cases and places, persistence is prevalent. In many regions, sample data lack homogeneity because station sites have shifted due to urbanization or development and because separate and distinct causal mechanisms contribute to the precipitation sample. Moreover, precipitation is not an infinite continuum in both directions; it cannot be less than zero. Therefore, variations on the dry side of the average cannot be as great in magnitude as variations on the wet side, and a few wet years can balance a great number of comparatively dry years. Despite all this, precipitation samples tend to follow one of several types of statistical distributions. The most important of these is the normal or Gaussian distribution,

which is a bell-shaped curve that is symmetrical about the mean value for the sample. If the sample is not normal it can be normalized by various methods such as using the logarithms or cube roots of the variates in the sample. Other types of distributions include the gamma distribution, the Pearson types I, II and III distributions and, as already alluded to, logarithmically transformed lognormal, logextremal and truncated lognormal distributions. Each of these distributions has special characteristics that allow researchers to extract the maximum amount of information from the many and diverse precipitation records available throughout the world.

The characteristics of the statistical distribution of a precipitation sample are described by statistical parameters. The most important of these relate to measures of central tendency, variability and skewness. The parameters that generally represent measures of central tendency are the mean, the median and the mode. The mean can be arithmetic, geometric or harmonic. The arithmetic mean is the most familiar and generally used. The geometric mean is the n th root of the product of n terms, so that if one takes the logarithm of the individual values of a precipitation record and takes the mean, the logarithm of the geometric mean will result. The harmonic mean is the reciprocal of the mean value of the reciprocals of the individual values (Chow, 1964; Munn, 1970; Panofsky and Brier, 1968). The arithmetic mean is used more often than any other measure of central tendency because of its computational simplicity and, in general, its greater sampling stability. However, in extremely skewed precipitation distributions such as would be found in samples taken in arid and semiarid regions, the mean may be misleading because, although it is based on sound mathematics, weight is given to each occurrence according to its magnitude so that extreme values are excessively stressed in comparison with middling values. In a distribution that approximates the normal, this is of minor importance at most. The median is the middle value or the variate that divides the frequencies in a distribution into two equal parts so that all variates greater or less than the median always occur half the time. In the distribution of discrete variables the variate that occurs most frequently is the mode. In a distribution of continuous variables the mode is the variate with the maximum probability density. In many stations, particularly in the tropics, precipitation distributions are not unimodal but bimodal, and in that case it becomes difficult to decide exactly where the mode is, especially since the actual value arrived at may in part result from a subjective choice of groupings. Furthermore, the mode does not possess any true mathematical quality, having at best only a generalized relationship to the average.

The parameters representing variability or dispersion are the standard deviation, the variance, the range and the coefficient of variation. At many stations the frequency distribution of precipitation totals for individual years is positively skewed – the negative departures from the annual mean are more numerous than the positive ones. Such skewness is generally strongest where rainfall totals are low and where correct estimation of the rainfall that can be expected is most critical but where the annual mean is inflated by a few very high annual totals. For predictive purposes, medians and other probabilistic estimates such as quartiles, quintiles and deciles are more reliable despite the computational complexities and the requirement of long records. The standard deviation is the square root of the mean squared deviation of individual measurements from their mean, whereas the variance is the square of the standard deviation. The curve representing a particular normal or Gaussian distribution is completely determined by its standard deviation. Generally, for such

a curve the standard deviation is the distance on either side of the center of the point where the slope is steepest. The coefficient of variation is the standard deviation divided by the mean, whereas the range is the difference between the largest and smallest values. Finally, skewness is a measure of the lack of symmetry of a distribution. The simplest measure of variability is the range but, because it is based on two observations only, there are large variations from sample to sample, making the range very unstable.

Precipitation intensity, which relates the total amount of precipitation to its duration over some specified finite time period, is another descriptor of precipitation. It may be taken as the amount of precipitation occurring on an average rainy day of a certain period. It is an important measure because it controls the probability and seriousness of local floods and is critical in planning dams, reservoirs and drainage canals. In addition, when intensity exceeds the maximum infiltration rate of the soil, surface runoff results, so that intensity can be related to erosion and sedimentation rates in lakes and reservoirs. In addition to intensity, the frequency distribution of different amounts of precipitation is also important. For example, in the tropical belt, in the wet season as well as in the dry season, the frequency distribution is represented surprisingly enough by a decay curve, demonstrating that days with no or very light rain are the most frequent and days with increasing amounts occur more rarely. Also, in the dry period nearly 85% of all days, and even in the wet season 35% of all days, have no or little rain.

The frequency distribution is used to organize precipitation data so their characteristics may be easily and quickly summarized. Also, an estimate of the frequency with which a given magnitude of precipitation may be exceeded in the future is based on the frequency with which it has been exceeded in the past. The parameters of the frequency distribution can be used in a probabilistic framework to calculate recurrence intervals of specified magnitudes of precipitation events with varying durations – hourly, daily or seasonal.

Precipitation distribution can be viewed from many different perspectives, each of which possesses both diagnostic and prognostic components. The time-space nature of that distribution, and the many and varied causal mechanisms and relationships, render the topic extremely complex, but at the same time immensely useful for an understanding of climate and its spatial and temporal variability and how these interact with the human-use system. At a time when the activities of human societies are modifying the climate system and reducing the margin between water supply and demand for agriculture, hydroelectric power generation and domestic use by an ever-expanding population in many parts of the world, it is imperative that we not only know where the areas of precipitation deficits and surpluses are, and the time periods in which they are most likely to exist, but also how the distribution patterns change over longer time periods.

Precipitation distribution in a warmer world

There is strong evidence in the instrumental records that global temperatures have been increasing over the last century and that the increase has been largest in the last two decades. The consensus, based on the results of general circulation models and higher-resolution regional models, is that most of that warming is due to increasing concentrations of trace gases in the atmosphere, and at the present rates of greenhouse warming, significant global environmental change will ensue. Among these changes are increased air and ocean surface temperatures, sea-level rise, an increase in the intensity of tropical storms, and a probable increase in the

frequency of extreme climatic events. If temperatures change because of trace gas-induced warming, changes in other elements will occur also. Precipitation patterns are likely to be altered. Total precipitation over the globe will increase as the water-holding capacity of the air and evapotranspiration increase, but it is difficult to predict precisely how the additional moisture will be distributed either spatially or temporally. The IPCC estimates that summer precipitation will decline by 5–10% and soil moisture by 15–20%. The American Mid-West will become drier in summer. Confidence in these estimates is low, however (Mitchell et al., 1990). Precipitation would be less frequent over most of Europe in summer and fall and throughout the year in the south. According to some projections, more rainfall is possible in parts of Africa and Southeast Asia. In parts of Africa such as the Sahel, winter rainfall will decline by 5–10% and summer precipitation will increase by as much as 5% (Wigley et al., 1986; Kellogg, 1987). Hurricane intensity is expected to increase, as is the precipitation and the flooding associated with such storms. Whatever the magnitude and specific distribution of precipitation that a warmer atmosphere and ocean will foster, global warming is sure to change the distribution of precipitation in ways that may be beneficial to some regions of the world but detrimental to others. Finally, the knowledge about and understanding of precipitation and its distribution should culminate in an improvement in our predictive capability if it is to serve as a useful input into decision-making processes in agriculture, water resources and precipitation-related disaster mitigation, if only in a probabilistic form.

PRESSURE, SURFACE

The atmosphere consists of a variety of gases, collectively called air, that form an envelope around the Earth and that are held there by gravity. The molecules of air are attracted toward the Earth and become more densely packed as sea level is approached because each layer of the atmosphere is being compressed by the mass of air above it. If this mass is multiplied by the force of gravity, the result is the weight of the air, which is described in terms of the area over which it is measured (i.e. pounds per square inch, grams per square centimeter). This weight of air is the atmospheric pressure, first mentioned by Robert Boyle in 1660, only 17 years after Torricelli invented the barometer. During the next 150 years barometric measurements gradually accumulated, mainly in Europe but also in scattered locations in North America and Siberia. Some of these were collected and published during the eighteenth century by the Royal Society of London (1732–1742) and by the Palatine Meteorological Society of Mannheim (1781–1792), the latter including data from Cambridge, Massachusetts.

Measurements and corrections

The need to correct barometer readings for variations in the temperature of the mercury was first noted by Halley in 1693 and recommended by Amontons in 1704. Similarly, Laplace, in 1805, pointed out that, since barometric pressure measured the weight of the atmosphere, it would vary with gravity at different latitudes; therefore, readings required a gravity correction before they could be used for comparative purposes. The variation of pressure with altitude was demonstrated by Perier in 1648, but it was not until the middle of the nineteenth century that a need to compensate for station altitude was generally accepted. Other corrections noted and allowed for in the eighteenth and early nineteenth centuries were due to the minor variations in the manufacture of barometers. These were overcome by comparing barometers with standard instruments held at main national laboratories. Various sets of tables giving these corrections were published in Europe during the eighteenth century, together with additional tables that allowed results to be reported in relation to standard atmospheric conditions. Unfortunately these standard conditions also varied from place to place. For example, the Palatine Meteorological Society followed De Luc (1755) who adopted 10°R (54.5°F) as a standard; the Royal Society of London adopted 50°F (1776), and Cotte (1788) decided on freezing point. By the middle of the nineteenth century the ideal of freezing point at sea level, at latitude 45°, was agreed on as the standard condition.

Units

These early measurements were reported in the form of the length of the mercury column in the barometer tube, which naturally balanced the weight of the atmosphere. Consequently, a variety of units of length were used. Conversion tables were produced during the nineteenth century that allowed comparisons of barometric readings originally published in English inches, European millimeters, or Paris lines. Foremost in this respect were the tables produced for the Smithsonian Institution by Guyot, beginning in 1852. During the nineteenth century attempts were made by the scientific community to define internationally acceptable units. The first system was the centimeter–gram–second (cgs), agreed on in 1870, in which the unit of force is the dyne and the derived unit of pressure is dynes per square centimeter. Since this unit is extremely small, for several years (until the beginning of the twentieth century) a much larger unit, the megadyne (= 1 million dynes), was used to report atmospheric pressures in addition to inches or millimeters of mercury. The more familiar millibar (103 dynes cm⁻²) came into regular use early in the twentieth century following the introduction of the terms bar, decibar, and centibar by V. Bjerknes in 1906 and the proposal by W. Kjøppen at a conference in Monaco in 1909 that the term bar be used to indicate megadynes per square centimeter. The meter–kilogram–second (mks) system was initially suggested by Giorgi in 1906 but did not become widely used until the 1930s. The unit of force was the newton (N), but this was never popular with meteorologists, who preferred to retain the millibar (mb or mbar), which was defined as 102 N m⁻². The mks system was refined in 1954 and in its new form (Le Système International or SI) was internationally approved in 1960. Again the newton was the unit of force, but a derived unit of pressure – the pascal (pa = 1 N m⁻²) – was introduced. The American Meteorological Society accepted the SI system in 1974 but agreed that the mb (= 1 hPa = 100 Pa) should be retained while it was used by the international meteorological community.

Periodic variation: diurnal

Once comparable measurements of pressure were collected together, it became possible to analyze variations of pressure at different time-scales. The first major periodic variation to be noted was the diurnal oscillation with maximum pressures occurring around 10 a.m. and 10 p.m. local time and minimum pressures at about 4 a.m. and 4 p.m. local time. The decrease in the amplitude of the diurnal pressure wave away from the equator, and its slight variation with the season, was shown by Bouvard in 1829 and by Forbes in 1832. As data from polar stations became available during the nineteenth century, it was found that in these high latitudes the diurnal oscillation did not occur at the same local time but varied longitudinally instead. From the evidence now available it is clear that this diurnal variation in pressure consists of three elements:

1. A progressive 12-hour zonal oscillation that travels from east to west, decreasing in intensity from the equator (3 hPa) to the poles (0 hPa).
2. A standing 12-hour sectorial oscillation that oscillates north and south between the equator and the poles (0.1 hPa).
3. A progressive 8-hour tesseral oscillation traveling from east to west with a maximum intensity of about 01.1 hPa at 30°N and S. Three highs and three lows appear in each hemisphere, a high in one balanced by a low in the other. The pattern in each hemisphere is valid only for a solstice and reverses at the equinoxes when these tesseral oscillations disappear.

The first and second oscillations are undoubtedly caused by the tidal influences of the sun and moon and are amplified by the natural 12-hour resonance of the atmosphere. The third oscillation can only be thermally induced since no 8-hour tidal influence is known. The result is that oscillations 1 and 3 produce the diurnal wave of maximum and minimum pressures that occurs at fixed local times between the equator and about 50° latitude. Oscillation 2 produces the pressure increases and decreases that occur at the same Greenwich meantime in polar areas. The

composite result in the diurnal pressure varies from about 3.5 hPa at the equator to about 0.3 hPa at the poles. Buchan (1889) showed the geographical distribution of the composite oscillation in July. Maximums (3.4 hPa) appeared over the tropical continental areas and minimums (0.3 hPa) over the North Atlantic and the Arctic regions. His isopleths did not extend into the Pacific Ocean. He also provided tables of the diurnal variation for 146 stations throughout the world, of which 13 are shown to illustrate the diurnal curve and its geographical variation (Figure P16).

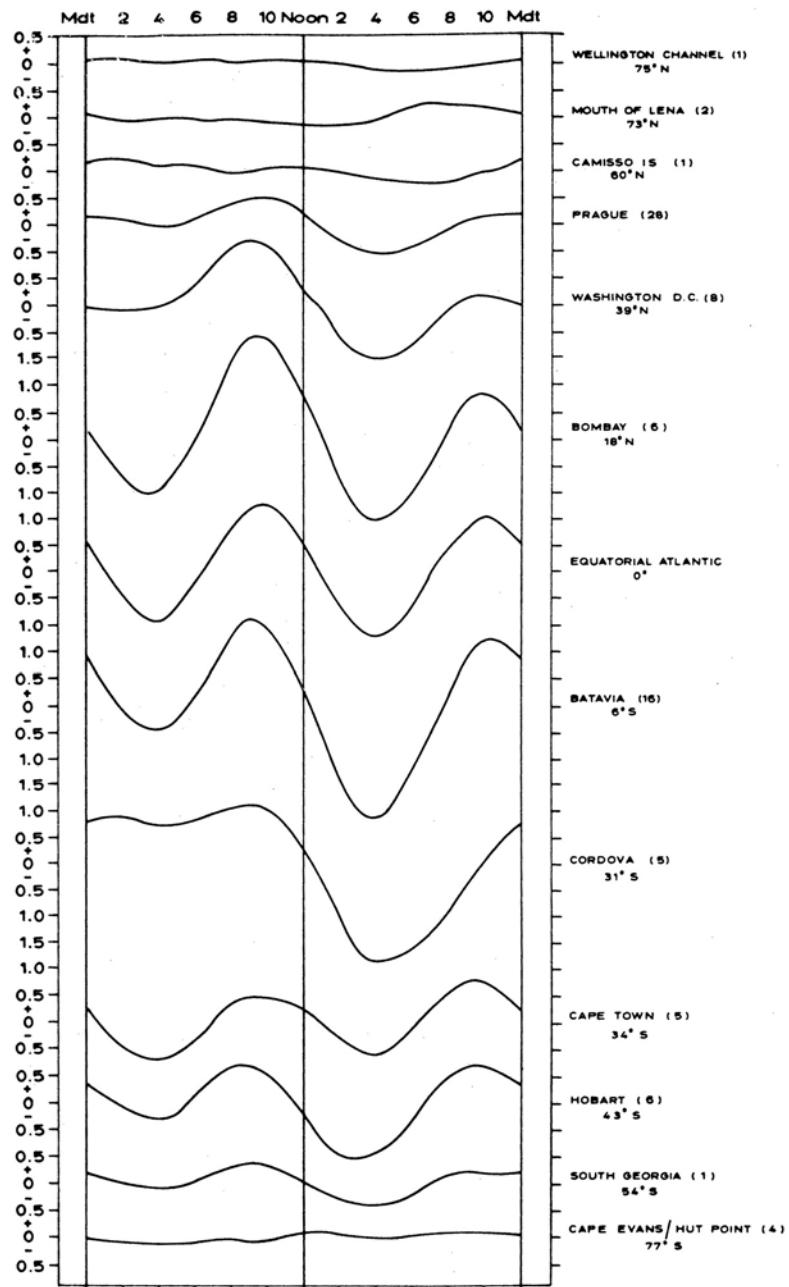

Figure P16 The diurnal variation of pressure of 13 stations situated at varying latitudes between 75°N and 77°S. The gradual disappearance of the normal double wave in high latitudes is clearly visible.

Periodic variation: monthly and seasonal

The second major periodic variation was the annual change considered on a world scale. The proliferation of hourly and daily observations allowed learned societies and various national organizations to publish monthly means of pressure. Many of these were collected together by Buchan and the results published in three papers. The first (1868) described the worldwide variation in sea-level pressure in January and July, and for the year. He described (but did not publish) the three charts "showing, by isobarometric lines, the mean pressure over the globe ... drawn for every tenth of an English inch" with 30 in (762 mm or 1015.9 mb) considered to be the world average. These charts were based on the records of 358 stations: 167 in Europe, 63 in North America, 51 in Asia, 35 in Latin America, 22 in Africa, and 20 in Australia and the Southern Ocean. They enabled Buchan to define the major pressure belts of the world, which can be found in virtually the same form in many textbooks (Oliver, 1979, p. 153; Moran and Morgan, 1994, p. 219; Sturman and Tapper, 1996, p. 87) or atlases. He described what Humboldt had surmised 50 years earlier from much more limited data, that pressure was lower at the equator than in temperate latitudes and that it might also be low at the poles. Buchan clearly identified the low-pressure belt at the equator, the two subtropical high-pressure belts (of which the southern hemisphere one is more continuous), and the low pressures around the two poles. Buchan says "the region of low pressure round the south pole... is subject to little variation throughout the year. The depression in the neighborhood of the north pole is divided into two distinct centres...these are the north part of the Atlantic and the north part of the Pacific oceans." He also noted the major reversal of surface pressure that occurs in Siberia between January and July. Buchan followed this pioneering work by publishing in 1869 a much-extended paper containing mean pressure charts for each month of the year, as well as an annual chart based on 478 stations, most of the additional data coming from the southern hemisphere. This paper (1869) included an in-extenso table giving the mean monthly and annual pressure for each station in English inches (and thousandths) as well as the 105 sources he used. In 1882 Buchan was invited to write the meteorological report of the *Challenger* Expedition. The task of analyzing the *Challenger* data (439 pages) and incorporating it with information published during the 1870s took Buchan 7 years. The result was a monumental work (Buchan, 1889) of 342 pages and 52 plates of the world that included, from the point of view of surface pressure, the data from 1366 stations. For each month and for the year there were two mean pressure charts, one on a rectangular projection and the other on a polar projection for the northern hemisphere. This was the first time a polar projection had been used to illustrate the mean pressure distribution. (Equivalent southern hemisphere charts did not appear until 1915 when Meinardus and Mecking published the results of the German South Polar Expedition, 1903–1904.) The isobars of the *Challenger* charts were once again in English inches (and hundredths) with color being used to differentiate values above or below 29.95 in. The isobaric pattern for each month was described in detail with the main areas of high and low pressure noted. The January and July charts were updated by J. Hann in 1887 (isobars at 2 mm intervals and again color was used to differentiate areas above and below 760 mm) and again in 1901. For the next 20 or 30 years these major compilations were used in textbooks and atlases with either or both inch and millimeter as units. Although millibars had been in use since before World War I on daily charts (see

below), their use on mean monthly charts in textbooks was very slow. Even in the late 1950s some US textbooks continued to give world mean pressure distribution charts in inch units. Generally, European textbooks adopted millibar on mean charts in the 1920s and 1930s and US textbooks followed suit, using Weather Bureau data, in the 1940s and 1950s. A much-simplified version of the surface pressure patterns in January and July is shown in Figure P17. These maps indicate the great extent of the subtropical high-pressure areas in the summer season when they almost encircle their respective hemispheres; in winter they withdraw to the oceanic areas. In contrast, the major low-pressure areas differ in each hemisphere. In the north they are clearly seen in the Aleutian and Icelandic areas in winter, but they virtually disappear in the summer when the main low-pressure area is found in southern Asia. In contrast, in the southern hemisphere there is a low that encircles the Antarctic continent in both summer and winter apart from a major break in the southeast Pacific in the vicinity of Ellsworth Land. In summary, the subtropical oceans have permanent high-pressure areas whereas the continents (apart from South America) generate high-pressure areas in winter. Low-pressure areas are found in temperate oceanic areas, particularly in winter, and in southwest Asia in summer. These semipermanent pressure areas were given the name of "des grandes centres d'action de l'atmosphère" or centers of action, by Teisserenc de Bort in 1881 (Mossman, 1913).

Aperiodic variations

There is some controversy concerning the first weather map or synoptic chart. Although not now in existence, it is most likely that Brandes drew, at some time in the first few years of the nineteenth century, the first weather chart for 6 March 1783, using data collected by the Palatine Meteorological Society. The first published weather map was presented by Elias Loomis in a paper to the American Philosophical Society in 1846. Both Brandes and Loomis depicted surface pressure in terms of deviations from a normal pressure. The pattern of using surface pressure charts to illustrate particular days or weather features continued until railroads and the telegraph enabled many reports to be collected and published quickly. The first daily weather report was published in the *British Daily News* on 31 August 1848 and was based on reports sent by train to London from 50 railway stations. In 1849 both Henry in the United States and Glaisher in England organized telegraphic reports and portrayed the results. The first printed daily weather maps were on sale at the Great Exhibition in London from 8 August to 11 October 1851 and included pressures in inches and hundredths from numerous English stations. Commercial daily weather maps appeared in England in 1861 and weather services began producing them in France (Paris Observatory, 5 September 1861), in the United States (Army Signal Service, 1 January 1871), and in England (Meteorological Office, 11 March 1872). The units varied with country of origin, but slowly mb became the standard in the early part of the twentieth century. Lines of equal pressure, or isobars, replaced lines of equal pressure variation, or deviation, in the middle of the nineteenth century, although isobars had been used by Berghaus in his *Physical Atlas* of 1845. The first patterns to be noted on the daily charts were the low- and high-pressure areas studied so assiduously in the United States by Elias Loomis. The low-pressure areas were initially considered as storms, but slowly the term cyclone became common, and by 1887 Abercrombie was able to define seven fundamental shapes of isobars: three low-pressure

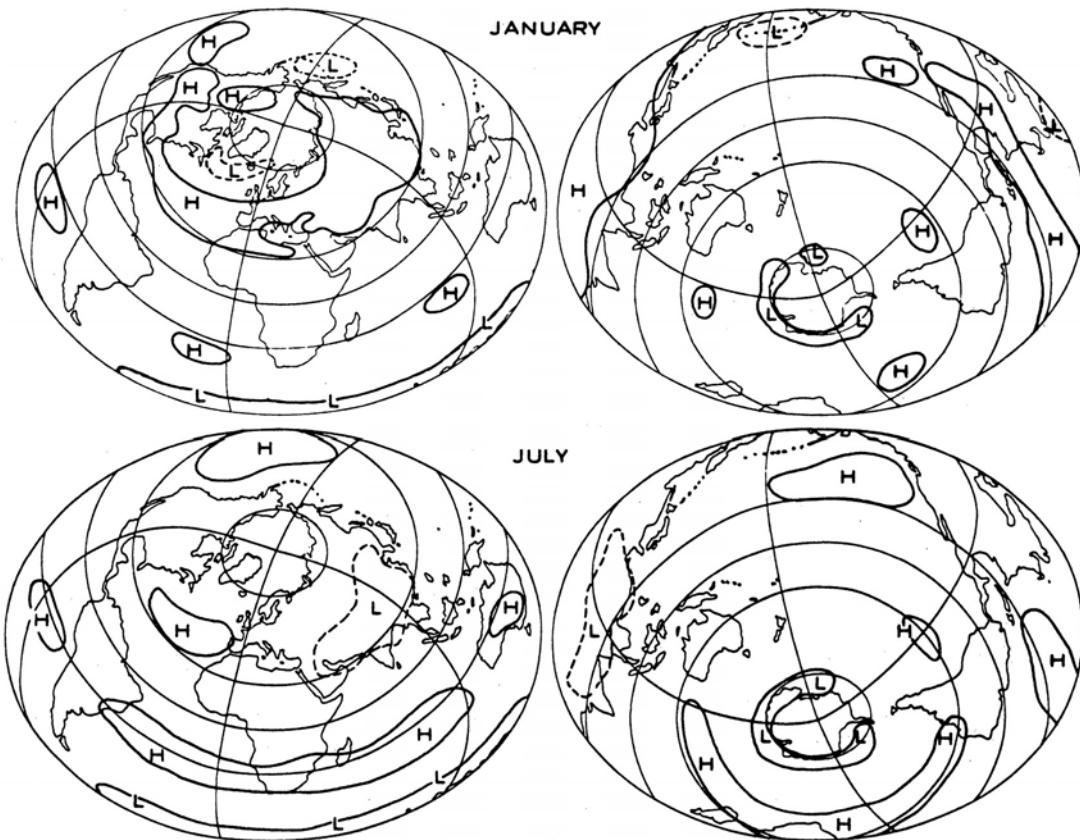

Figure P17 The main areas of high and low sea level pressure in January and July (after *Pergamon World Atlas*, 1968).

(cyclone, secondary cyclone, V-shaped depression); two high-pressure (anticyclone, wedge); the col and straight isobars. During the last quarter of the nineteenth century, English and French writers began to use depression synonymously for cyclone, and today depression is the normal expression (apart from the United States) for a large area of low pressure. The word is simply a contraction of "areas in which there is a depression of the barometer". In contrast, the word anticyclone was deliberately coined by Galton in 1863 and has remained in the literature since. These aperiodic isobar patterns that form and dissipate on the daily weather charts remain in vogue today. The major addition has been the frontal depression, which arrived with the model of fronts published by Bjerknes and Solberg in 1922.

Once long series of daily weather charts were available and collated, it was possible for climatologists to use them in a variety of ways – a development known as synoptic climatology (Barry and Perry, 1973). Thus W. K  pen (in 1880) and Van Bebber (in 1891) noted and analyzed the tracks of high- and low-pressure centers over the North Atlantic and Europe, while Elias Loomis, in a series of papers in the *American Journal of Science and Arts* between 1874 and 1888, did the same for tracks across the United States. Such studies on a hemispheric scale began in the 1950s in the northern hemisphere and in the 1960s in the southern hemisphere. Pressure pattern classification developed from this work, particularly in Europe, and resulted in the weather types of Lamb (1950) in the UK and Muller (1977) in the USA, and in Europe the *grosswetterlagen*

of Baur (1936). With the advent of computers and advanced statistical methods a second generation of automated classification procedures appeared in the 1970s and 1980s. These are fully explained with worked examples by Yarnal (1993).

Extremes of surface pressure

The highest sea-level pressures have been reported at the centers of continental anticyclones, whereas the lowest pressures have been measured in the centers of hurricanes or typhoons. Table P7 gives the sea-level pressure extremes for the world, North America, and the British Isles.

World sources of surface pressure data

Historical and current-sea level or station-level data are available either as tabular compilations or mean pressure charts. The seven major tabulations

1. *Monthly Climatic Data for the World* (US Weather Bureau).
2. *Climatological Normals (CLINO) for Climat and Climat Ship Stations for the Period 1931–1960* (World Meteorological Organization, 1971).
3. *Climatological Normals (CLINO) for the period 1961–1990* (World Meteorological Organization, 1996).
4. *World Weather Records* (Smithsonian Miscellaneous Collections, Vols 79, 90, and 185; US Weather Bureau and

US Department of Commerce and the US National Climate Data Center (NCDC).

5. The comprehensive ocean–atmosphere dataset (COADS) produced by the US National Oceanic and Atmospheric Administration (NOAA) which is available on the NOAA–CIRES Climatic Diagnostics Center website (www.cdc.noaa.gov/coads); it is described by Woodruffe et al., 1987, 1998.
6. The global mean sea-level pressure dataset which is a blend of existing gridded data sets and a variety of station level data banks (Allan et al., 1996).
7. There are also the two marine atlases produced by the US Navy (1955–59, 1995).

The International Geophysical Year (1957–1958) resulted in a special series of daily weather charts covering the northern and southern hemispheres and the tropics, published in monthly volumes by the United States, Republic of South Africa, and German Federal Republic, respectively. Mean charts of the northern hemisphere have been produced by both the US Weather Bureau (Technical Paper 21, 1952) and the Freie University of Berlin (Meteorologische Abhandlungen, 100, 1969) and for the southern hemisphere in a series of articles in the South African journal (*Notos*). Over the last 20 years there have been a number of gridded, rather than station-based, datasets produced by governmental and university research groups. These are easier to utilize in mainframe and laptop computers. Examples include the following datasets:

- (a) United Kingdom Meteorological Office (UKMO) historical, 1873–1994.
- (b) National Center for Atmospheric Research (NCAR), USA, 1899–1994.
- (c) Climate Research Unit (CRU), University of East Anglia, UK, 1951–1985.
- (d) Scripps Institute of Oceanography (SIO), USA, 1951–1993.
- (e) CSIRO Division of Atmospheric Research (DAR), Australia, 1871–1989 (Allan et al., 1996).

Full details on climatic datasets including pressure for each member country are given in the World Meteorological Organization's world climate data and monitoring program, especially the INFOCLIMA project (www.wmo.ch). In the 1990s several reanalysis projects began which aimed at producing homogeneous global analyses of atmospheric fields.

PRESSURE, UPPER AIR

The decrease of atmospheric pressure as one leaves the Earth's surface was first noted by Blaise Pascal on ascending the 52-m-high Tour St Jacques in Paris in 1643. It was verified by his brother-in-law Péier in 1648 in an experiment that demonstrated that the pressure at the top of the Puy de Dôme (elevation 1467 m) in Clermont, France, was 3 Parisian inches, 1½ lines (8.5 cm) lower than the base. Pascal therefore concluded that a barometer could be used to determine the difference in the altitude between places. The idea was taken up by Mariotte who used both his own experiments at the Paris Observatory and those of others to show in 1679 that: (1) pressure decreased by about 1 line in every 60 ft (1 mm in 8.6 m); and (2) pressure drop with height decreased in a geometric progression; therefore, the atmosphere was 8×10^6 times more tenuous at 30 leagues (133 km) than at the Earth's surface.

During the next 100 years, several formulas were derived that related barometric pressure and height. A complete solution was proposed by P.S. Laplace (1805, pp. 289–293), which superceded all others. Laplace's formula was used as the basis for the tables published by A. Guyot (1862) in the *Smithsonian*

Miscellaneous Collections, No. 153 (1859) that were republished as part of vol. 1 of the *Smithsonian Miscellaneous Collections*. This collection of tables also included a set produced by the American, Elias Loomis, for heights in feet and temperatures in degrees Fahrenheit.

Relationship of pressure and height

The relationship between pressure and height can be expressed in the form of the hydrostatic equation or the barometric equation, which shows that the change of pressure (Δp) with the change of height (Δh) is equal to gravity (g) and air density (ρ):

$$\frac{\Delta p}{\Delta h} = -gp$$

or

$$-\Delta p = gp\Delta h$$

with the minus sign indicating the decrease of pressure upward. Density is difficult to measure directly, but it can be computed using the gas law relationship between pressure, density, temperature, and volume. In this way, by substitution and integration, the height interval ($h_2 - h_1$) between pressure levels (p_2 and p_1) can be calculated using:

$$h_2 - h_1 = 64.7T (\log p_1 - \log p_2)$$

where h is in meters, p is in millibars and T is in Kelvin.

The decrease of pressure with altitude was used in the nineteenth century to ascertain the heights both of mountains and the levels reached by balloons. The first unmanned balloon ascents were made in France in 1782 (hot air) and in Scotland in 1766 and 1783 (hydrogen). The first manned balloon ascent was by Jeffries in November 1784 from London, and this was followed by several from Hamburg, St Petersburg (now Leningrad), and Paris in 1803 and 1804. These ascents were mainly concerned with temperature and humidity changes and the barometers were instruments for indicating the elevations reached. There was a lull in such flights until the middle of the nineteenth century when a considerable number were made in England by James Glaisher (who made 28 flights between 1862 and 1866, reaching heights of up to 5 miles), and in France by Flammarion and Tissander in the 1870s. In the last quarter of the nineteenth century there was a move toward captive balloons, kites, and balloons-sondes (now known as radiosondes), which gave strong impetus to improvements in self-recording instruments. The first continuously recording instrument was flown with a kite at the Blue Hill Observatory in 1894. A full contemporary account can be found in Gold and Harwood (1910).

The main thrust of this research was toward temperature and wind variations with height, the latter calculated from barometers. By 1904 Teisserenc de Bort was able to draw a map of the northern hemisphere showing isobars at the level of 4000 m (Figure P18), although these were calculated using surface pressures and the temperatures between sea level and 4000 m. This set a precedent and until the end of World War II it was usual to draw charts at fixed heights (in kilometers or in thousands of feet) on which measured pressures and hence isobars were drawn. Thus linear height was a fixed unit and pressure was a variable unit. Shortly after World War II the format was reversed for mainly aeronautical reasons, and current upper air charts are constant-pressure charts (pressure is the fixed unit) on which variations in height (the variable unit) are plotted; the consequent isopleths were known as contours, i.e. lines of equal height (in decameters or hundreds of feet).

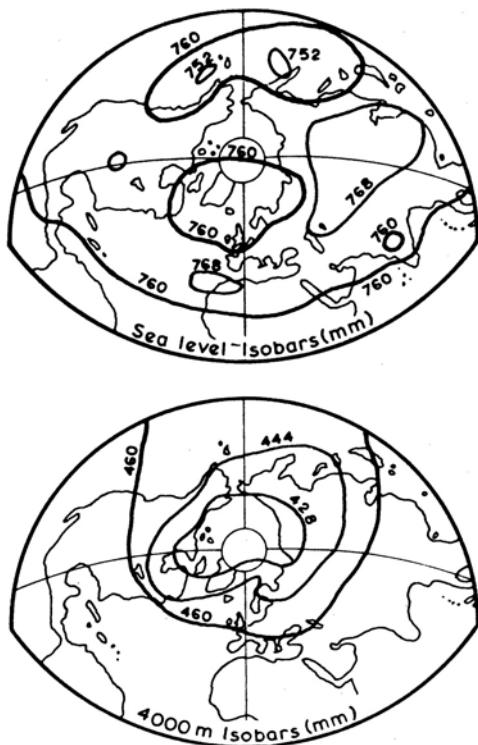

Figure P18 Isobars at 4000 m in the Northern Hemisphere (after de Bort, 1904).

Units

Units describing upper-air pressure have had a far less checkered career than their surface equivalents. Millibars (mb) were usual on fixed height charts (although the earliest ones were in millimeters of mercury) and meters or feet on fixed pressure charts. Millibars have now been replaced by hectopascals (hPa); 1 mb = 1 hPa. The need for fixed pressure charts grew out of the theoretical work of V. Bjerknes who, in 1898, formulated a circulation theorem using the distribution of pressure and specific volume. This and other circulation theorems are beyond the scope of this item, but the point must be made that the theory required that the elevations or heights on such charts took gravity into account.

The atmosphere can be considered in two ways:

- As a series of spheres at fixed distances from the Earth's surface. On each sphere the pressure will vary because of the changes in temperature, humidity, density, and so on.
- As another series of spheres that represent decreasing pressures. On each of these spheres the height above mean sea level varies. This is shown diagrammatically in Figure P19, where the encircling spheres (of either unit) can be considered as surfaces of height or pressure. In the figure, the points A and B are 10 km above the Earth's surface, but the pressure at A is less than, and the pressure at B is greater than, 250 hPa. Similarly, points C and D are both at a pressure of 500 hPa but C is less than 5 km above the Earth's surface whereas D is more than 5 km above. This can be easily visualized in Figure P20, an enlargement of part of Figure P19, in a three-dimensional form. A volume of

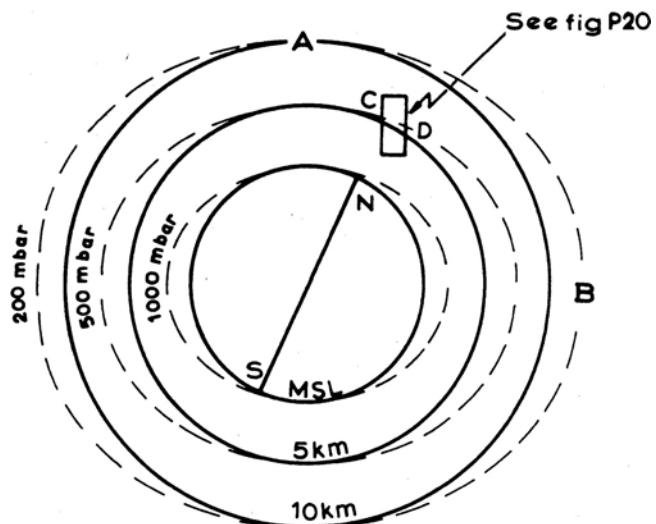

Figure P19 Relationship between surfaces of equal height or equal pressure that surround the Earth (see text).

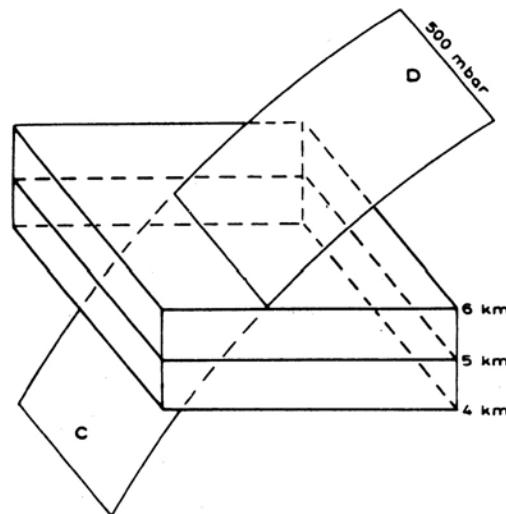

Figure P20 Intersection of a pressure surface and a height surface, enlarged from Figure P19.

atmosphere between 4 km and 6 km is shown through which the 500 hPa pressure surface passes. This clearly shows that D is much higher above the Earth's surface than C. An upper-air pressure surface should be thought of as a sheet of rubber that is distorted out of a flat (horizontal) plane, and the consequent measure of this distortion is the variable height of the sheet above sea level. This three-dimensional conceptualization of a particular pattern is shown in detail by Giles (1976) for a series of upper-air pressure surfaces.

In a very simplified form Figure P19 indicates that pressure surfaces tend to be further from the Earth's surface in equatorial and tropical regions and much closer in polar regions. This is taken into account when a standard atmosphere (q.v.) is defined. A skeleton version of the US Supplemental Atmosphere 1976

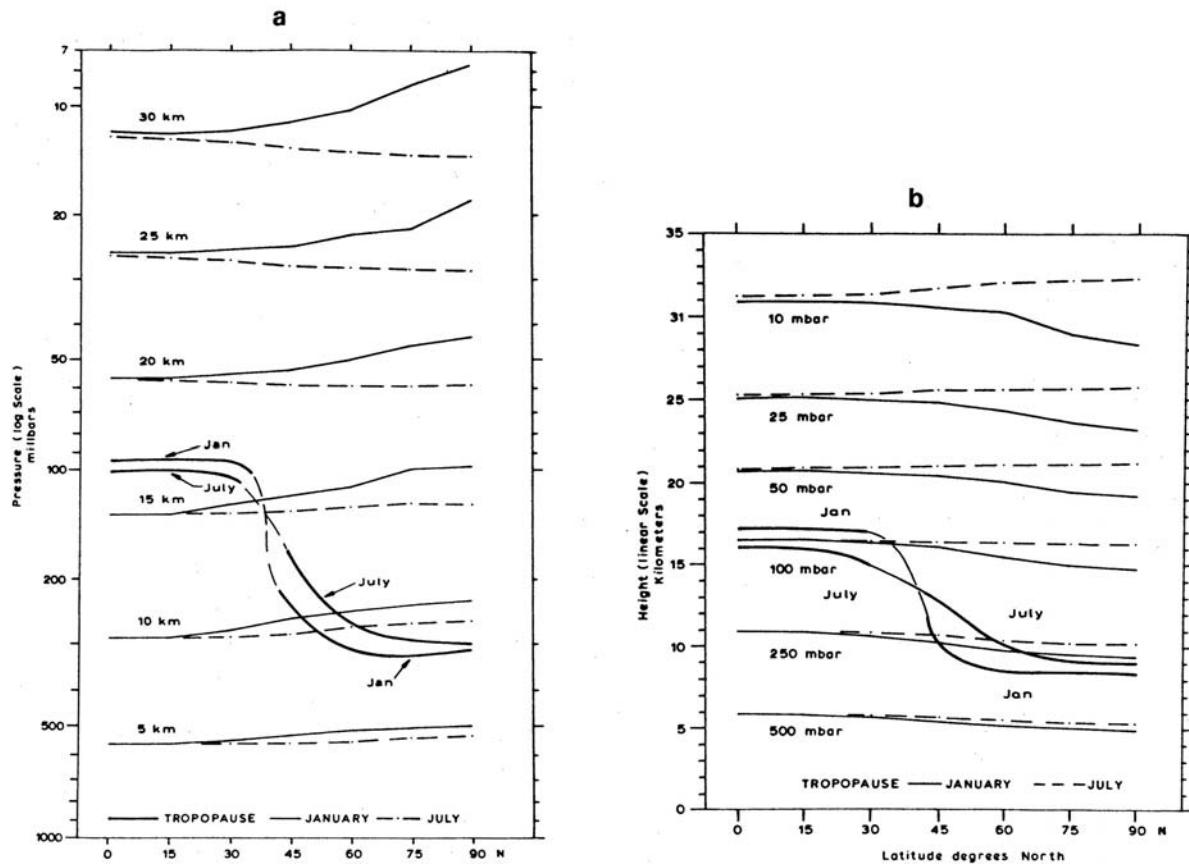

Figure P21 Latitudinal and seasonal variation of pressure with height (a) and height with pressure (b) of the U.S. Supplemental Atmosphere, 1976 (based on data in Cole and Kantor, 1978).

has been drawn in Figure P21, using data given by Cole and Kantor (1978), to illustrate the latitudinal and seasonal variation of pressure with height (Figure P21a) and of height with pressure (Figure P21b) in the northern hemisphere. In the troposphere (q.v.), pressure surfaces decrease in height from equator to pole but are generally higher in summer than in winter. In the stratosphere (q.v.) they increase in height in tropical areas and then decrease toward the poles in winter (January). However, in summer (July) there is an increase in the height of pressure surfaces toward the pole, which becomes greater the farther one goes into the atmosphere. The seasonal difference in pressure surface height increases both poleward and upward (see Figure P21a). Because pressure decreases logarithmically with height, the latitudinal and seasonal variation of the pressure found at fixed heights seems much greater (see Figure P21b). Whereas the pressures at 5 km vary from 560 hPa at the equator to 500 hPa at the pole in January, at 30 km the pressure increases from 12.3 hPa at the equator to 13.8 hPa at the North Pole in summer but decreases from a maximum of 12.5 hPa at 15°N to a minimum of 8.8 hPa at the pole (Figure P21b). Figure P21 also includes the envelope of the tropopause, which shows the marked change in this tropospheric boundary between summer and winter, particularly in the subtropics between 30° and 45°N. The COSPAR International Reference Atmosphere (CIRA) provides data including pressure from 0 to 120 km and from 80°N to 80°S (see Fleming et al., 1988; Rycroft et al., 1990).

Charts

It was pointed out above that upper air charts generally were of the constant level type until the end of World War II when they were replaced by constant pressure charts. Upper air charts were drawn only for research purposes until 1933 when upper air constant level charts were produced on a daily basis in the United States and England. At the same time, daily constant pressure chart analysis began in Germany. The British Meteorological Office changed from constant level to constant pressure in 1941. US meteorologists continued to use constant level charts in North America, but conformed to European practice when they were working in Europe after 1942. The end of constant level charts occurred in 1945 when the Joint Meteorological Committee adopted constant pressure charts on an international basis. Today a series of standard pressure levels (for which charts are drawn) has been agreed on: 1000, 850, 700, 500, 400, 300, 250, 200, 150, 100, 70, 50, 30, 20, 10, 7, 5, 3, 2, and 1 hPa. However, not all these levels are analyzed and drawn routinely, and different countries have individual procedures. Generally speaking, the 500 hPa chart is found worldwide, but the 700 hPa chart is additionally found in American journals.

The main reasons for the comparatively recent arrival of daily upper air charts were:

1. The great expense involved in both the radiosondes and the necessary ground-receiving equipment.

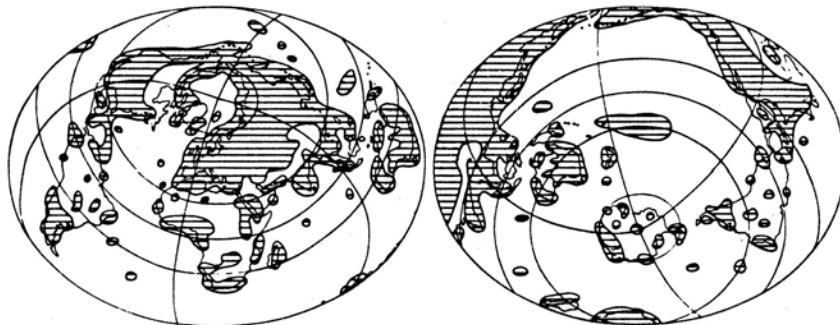

Figure P22 Worldwide upper air coverage during the 1970s.

2. Consequently, there was a much smaller number of upper air stations with wide gaps in areal coverage.
3. The large amount of data that had to be collected and transmitted from each station and analyzed at meteorological centers.

For the First Global Atmospheric Research Program (GARP) Global Experiment (FGGE) in 1978–1979 it was estimated that the exchange of information from 1300 upper air reports for the standard levels up to 30 hPa would constitute about 4.5×10^5 characters each day. Figure P22 shows the worldwide upper air coverage typical of the 1970s. The poor coverage in most of the southern hemisphere and in the North Pacific and North Atlantic oceans is obvious. However, the derived information can be enhanced by satellite-derived information.

Diurnal variations

Because upper air observations of pressure are usually only taken twice a day (at noon and midnight GMT), there has been little work on diurnal variations in the heights of pressure surfaces. From the small amount of data that has been published it is clear that there is a diurnal variation with maximum heights found shortly after local noon and minimum heights just after local midnight. No detailed analysis of the daily periodic variation is possible because of the fixed 12-hourly times of observation based on Greenwich rather than local time. In any case the variation is very small and heavily masked by aperiodic synoptic variations, which are the result of the pressure systems that are continuously changing and modifying the contour patterns found on the upper air charts. These patterns are generally in the form of smooth waves – the long waves that were an important item in the Rossby regime (q.v.) and that are described in more detail in Atmospheric Circulation, Global. In both hemispheres these waves are the result of the effect of topographic barriers such as the Rockies and Andes. The consequence is a series of troughs and ridges extending eastwards from the longitudinal mountain barriers around both hemispheres in extratropical latitudes. Usually there are between one and five such waves around a hemisphere with smaller waves embedded in them. Since the 1970s use has been made of constant level balloons which have been used to show the day-to-day variations of a particular pressure level. These balloons are usually flown at upper tropospheric and stratospheric levels.

Seasonal variations, vertical

The positions of the ridges and troughs vary on daily charts, but they have preferred longitudes that clearly appear if means

over several years are calculated. Figures P23 and P24 are based on data given in Heastie and Stephenson (1960), and show the average heights of the 500 hPa and 200 hPa pressure levels at various latitude circles. On each diagram the mean positions of the ridges and troughs are marked on the height curves. At 500 hPa in January (Figure P23), three ridges and troughs can be seen at 50°N with the troughs found over central North America, European Russia, and the western North Pacific. At 80°N only two waves are apparent with troughs over North America and Central Asia. In the subtropics (30°N) the three troughs are found at longitudes somewhat to the west of their midlatitude positions. The intensity of the waves is indicated by the difference in height of the pressure surface at a given latitude. Thus in January at 500 hPa, the largest fluctuations in height are at 50°N. In July the intensity diminished and three waves are found only in midlatitudes – poleward and equatorward only two waves appear. In the southern hemisphere in both January and July, the height of the 500 hPa pressure surface varies to a smaller extent, and a three-wave pattern occurs only at 50°S in winter. In this hemisphere mean troughs occur over the oceans and ridges are loosely associated with areas to the south of the three major landmasses. Figure P24 is a similar diagram for the 200 hPa level. The height fluctuations are greater in the winter hemisphere than in the summer hemisphere and are largest in the northern hemisphere winter.

By comparing the same hemisphere and season at each level it is clear that the longitudinal position of the mean ridges and troughs does not vary much with height. This means that the two pressure surfaces (and all those between) undulate more or less in unison around the globe, and only over the poles and the equator do the undulations flatten out. In the former case this is simply because there is insufficient distance around the hemisphere to accommodate them. A measure of these undulations at different levels in the troposphere and lower stratosphere is given in Table P8. This shows the difference in decameters between the high equatorial and lower polar mean heights for each hemisphere in summer and winter. The variations in the heights of the pressure surfaces increase upward in summer and winter in both hemispheres to the region of the lower stratosphere, beginning to decline above 200 hPa in the northern hemisphere and above 150 hPa south of the equator. In summer at all levels up to and including 150 hPa in the northern hemisphere, mean height differences are about half their winter values. This is not true of the southern hemisphere, where summer values are only 25% lower than winter values. This indicates a smaller seasonal

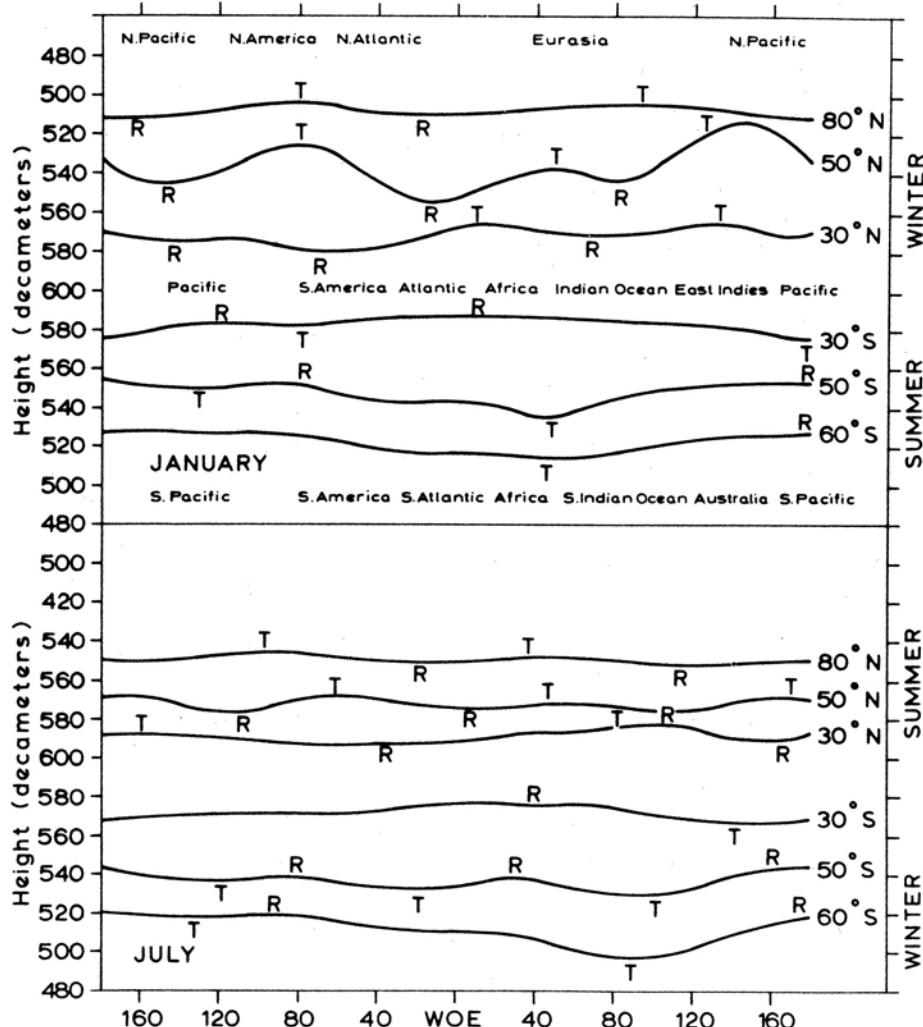

Figure P23 Average height of the 500 hPa pressure level at various latitudes in January and July.

variation in the southern hemisphere than in the northern hemisphere.

Seasonal variations, horizontal

The areal distribution of the pressure surfaces is shown in Figures P25 and P26 for 500 and 200 hPa, these being typical of mid- and upper-tropospheric patterns. Because of the projection used, the ridges and troughs do not stand out as clearly as in Figures P23 and P24. However, the upper air "centers of action" (see Pressure, Surface) clearly show areas of low heights in the regions of the geographic poles. The low in the northern hemisphere is eccentrically placed toward the Canadian Archipelago and Hudson Bay. In the southern hemisphere the low lies over the lower land of West Antarctica (i.e. the part of the continent adjacent to the Pacific Ocean). Thus the major low pressures of the surface

charts disappear rapidly upward in the troposphere to be replaced by polar vortexes. In the tropics the pressure surfaces are generally at their highest. In January the greatest heights straddle the equator, but in July they move northward to the vicinity of the Tropic of Cancer. The exact pattern of the tropical highs varies from pressure surface to pressure surface, and indeed at 100 hPa the greatest heights in January are actually (for the first time) in the southern hemisphere. They go over the Tropic of Capricorn, extending from Madagascar across southern Africa and the South Atlantic to South America.

The marked difference in the mean height of the 500 hPa pressure surface in the two hemispheres and at the solstices (Figure P25) should be noted. In the northern hemisphere the winter polar low is over 40 dam nearer to the Earth's surface than the summer low, whereas the tropical high is some 200 dam higher. In the southern hemisphere there is less difference in height between the summer and winter polar lows.

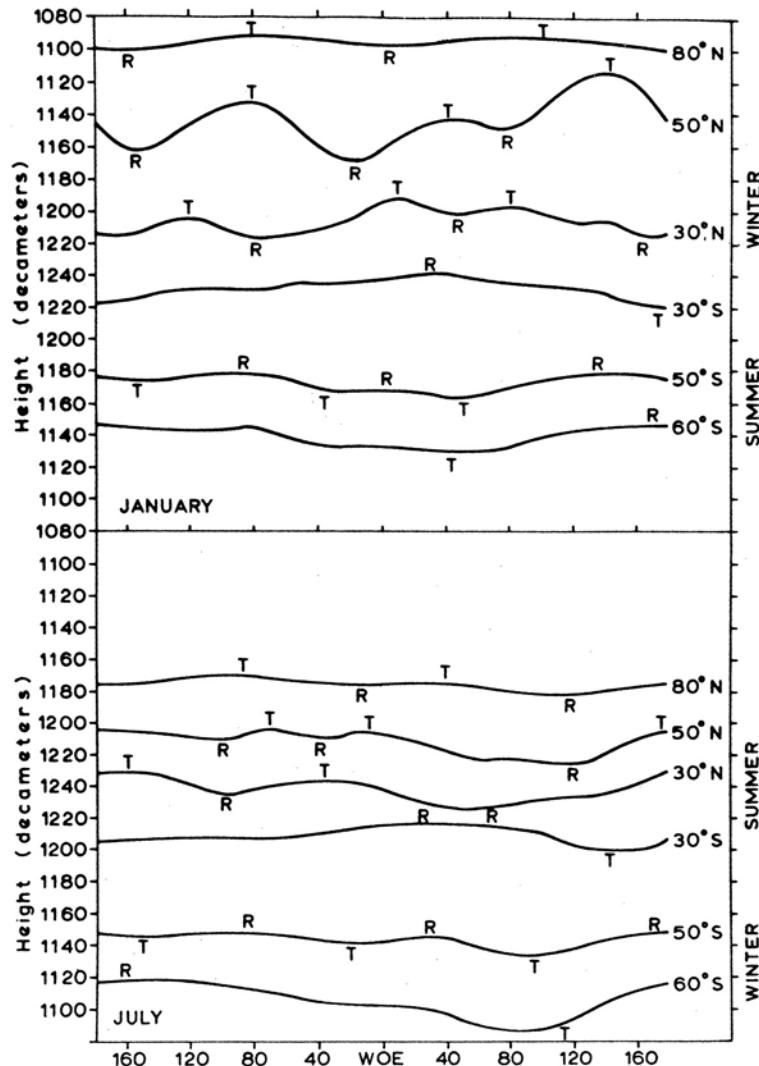

Figure P24 Average height of the 200 hPa pressure level at various latitudes in January and July.

Table P8 Summer and winter differences (decameters) between high equatorial and low polar mean heights for each hemisphere

Pressure level (mb)	Northern hemisphere		Southern hemisphere ^a	
	Winter	Summer	Winter	Summer
700	55	31	60	43
500	92	46	90	75
300	142	74	133	110
200	163	86	157	118
150	160	77	161	105
100	137	49	150	77

^a Southern hemisphere analysis extends only to 60°S.

The pattern around the troposphere–stratosphere boundary is shown in Figure P26, which is for the 200 hPa surface. In the

northern hemisphere the mean height difference of the polar low between winter and summer has increased to more than 1 km; in the southern hemisphere it is over 50 dam. In the tropics the major high lies athwart the equator, over the Indian Ocean, in January and moves north in July to cover an area of the Tropic of Cancer extending from North Africa across southern Asia to the China Sea. The North American equivalent appears over Arizona and New Mexico in July.

Data sources

Mean monthly values of upper air data, including heights of the main pressure surfaces, are published by the US National Oceanic and Atmospheric Administration (NOAA) as *Monthly Climatic Data of the World* under the sponsorship of the World Meteorological Organization. This is based on Climat Temp reports from over 400 upper air stations and comprises the raw

data from which a variety of climatological means at latitude and longitude grid points have been calculated. Data in the form of grid point values are more easily stored and useful than individual station values; they are derived from analyzed computer and statistical checks. Data in this form, including mean heights of pressure surfaces, are considered as the basic dataset for the upper air and are available in magnetic tape and/or CD-rom formats from the National Climatic Data Center. Similar datasets are also available from the National Space Science Data Center (NSSDC) as binary files (<ftp://nssdcftp.gsfc.nasa.gov/models/atmospheric/cira/cira1986>) or in ASCII format (<ftp://nssdcftp.gsfc.nasa.gov/models/atmospheric/cira/cira86as.cii>). In addition Heastie and Stephenson (1960) published tables giving average heights of six pressure levels for January, April, July, and October at various latitude-longitude intersections from the North Pole to 60°S. The data used in this compilation were for the period 1949–1953. Such large amounts of data are better portrayed in chart form, and a number of publications give the mean contour patterns at various levels (Table P9). One of the earliest was by the US Weather Bureau (1952), which included mean contour charts for 700 and 500 hPa for the northern hemisphere. This was followed by the US Navy (1955–1959) whose *Marine Climatic Atlas* had contour charts for five pressure levels for the four seasons over the North Atlantic and North America (vol. 1) and the North Pacific (vol. 2). The publication drew, where possible, on 8 years' data (1946–1954) but in the southern hemisphere, in particular, it was usually for shorter periods and sometimes consisted of data derived solely from the International Geophysical Year (1957–1958). This shortage of data precluded the drawing of contours over the southern hemisphere oceans in volumes 3–5. This sparse data network did not prevent a Russian atlas (Dubencov and Davidova, 1964) from appearing with southern hemisphere contour charts for six pressure levels for the mid-season months of January, April, July, and October. Only 300 copies of the atlas were printed so it is not readily accessible. It used observations from a sparse network of about 70 stations reporting over the 5-year period 1956–1960 in addition to various other compilations published in the Soviet Union.

The next major step was made in the late 1960s when the results of two major research efforts were published. For the

northern hemisphere, Crutcher and Meserve (1970) produced mean charts for six pressure levels using 1950–1964 data. Their analyzed charts were used as the basis for the production of grid point values held on magnetic tape in the National Weather Record Archives. A similar but more difficult exercise for the southern hemisphere culminated in the four-volume work by Taljaard et al. (1969). Only vol. 1 is relevant to this discussion since it contains the mean monthly contour charts for six levels (see Table P9) together with a full report of the data used – data that were widely scattered in both space and time. Finally, in the 1990s the US Navy (1995) updated the *Marine Climate Atlas of the World* (MCA); the latest version of CIRA86 has been made available on the internet (<http://nssdcftp.gsfc.nasa.gov/models/atmospheric>) and reanalysis projects (Kalnay et al., 1996) produce homogeneous global analyses of atmospheric fields including pressure.

Q

QUASIBIENNIAL OSCILLATION

Following the American Meteorological Society *Glossary*, Sir Gilbert Walker defined “oscillation” in a way acceptable to climatology as “a single number, empirically derived, which represents the distribution of pressure and temperature over a wide ocean area” as in Southern Oscillation, North Atlantic Oscillation, for example. In the German literature, von Rudloff (1967) used “Klimaschwankungen” for fluctuations longer than 30 yr, and “Klimapendelungen” for short-term oscillations (Schuurmans, p. 91, in Flohn and Fantechi, 1984). Von Rudloff’s instrumentally based time-series go back to the seventeenth century and the Dutch records at De Bilt started in 1634. Three stations go back to before 1579 (Groveman and Landsberg, 1979). Earlier indications have to be based on proxies such as tree rings and harvests (Lamb, 1977, p. 534, etc.).

In American temperature data a 2-yr oscillation was first recognized by Clayton in 1884, but after several returns it jumps 1 year and hence the name “Quasibiennial Oscillation” (Schove, 1983). It was described in detail by Reed (1961) and even more thoroughly by Ebdon (1975) in its association with tropospheric patterns.

Most significant is the alternation of easterly and westerly equatorial upper-air winds, which have been systematically observed, with increasing precision, since the famous eruption of the Krakatoa (Krakatau) volcano in the East Indies in August of 1883. Its ash reached the lower stratosphere drifting in alternate years either easterly or westerly. The former were labeled the “Krakatoa Easterlies” and the latter the “Berson Westerlies” (see “Krakatoa Winds” in Fairbridge, 1967, p. 524). The alternation has a mean periodicity of about 27 months, corresponding to the QBO link.

Solar forcing mechanism

A key paper on the subject was by Berson and Kulkarni (1968), who related the QBO to the Sunspot Cycle (SSC). Labitzke and Van Loon (1990) found that the correlation was only positive

during the west phase of the QBO in the north polar temperatures, but antiphase in the easterly condition. As remarked by Peixoto and Oort (1992), “if confirmed . . . this will be an important new . . . factor in climate”. The trouble with this linkage is the variable length and amplitude of the SSC (11 ± 5 yr). Short cycles correspond to high-energy phases, and long ones to weak phases.

Furthermore, there are solar emissions (of several varieties, from UV to neutron flux) that disclose periodicities of the order of 2.172 yr (793.3 days). Spectral analyses of SSC by Currie (1973) show a prominent spike at 2.17 yr. The mean high-energy phase, about 8.6 yr ($4 \times$ QBO), contrasts with the low-energy mean of about 13 yr ($5 \times$ QBO). Schove (1983), picturesquely, likens the QBO to the period of a child on a swing, which every fourth or fifth return receives a nudge from the SSC. The analogy does not appear to have been rigorously explored, for the good reason that the long-term cycles that modify solar radiations grossly exceed the range of precise instrumental observations.

For a meeting convened by the Royal Society in London in 1990, a review of solar variability based on astronomic observations was prepared by Elizabeth Ribes (1990), the French specialist. In a series of astrolabe measurements, ranging 1977–1987, and disclosing solar radius (her fig. 3), when compared with Earth’s stratospheric winds at the 10 mb level (Naujokat, 1986), a quasibiennial oscillation in the sun’s diameter is clearly disclosed. Further observations emerged from an Arizona conference the next year (Ribes et al., 1991). The question of solar dimensions has long been controversial, but the Ribes evidence seems to be unarguable.

As noted above, the radiations of the sun are subject to long-term variations, based on the evidence of reliable proxies (ice cores, tree rings, geological history of glaciations and ice ages). Although a sun–planetary link is unavoidable in terms of astrophysics, it has been difficult to prove to universal satisfaction. However, the relationships presented by Fairbridge and Sanders (1987) have never been systematically refuted, and in fact are supported by Charváková and Str čík (1991), Windelius and Carlberg (1995), and others. It will therefore have been assumed below.

The planetary motions in question are based on the NASA-JPL ephemeris and calculations that span time-scales of the

order of 10^5 yr. Individual planetary periods provide a basis for applying the Helmholtz formula for beat frequencies. The most important of these is that for the two largest planets, Jupiter and Saturn, a period of 19.8593 ± 0.8 yr, the so-called "heartbeat" of the solar system. All of the planets become geodetically arranged in approximately 90° quadrants, to reach a general quadrature at intervals of 4448.485 yr. Each quadrant constitutes a 556.06-yr unit that is 256×2.1721 yr, the accepted mean QBO. For a student interested in music, one might note that "middle C" on the piano is generally accepted to correspond to 256 Herz (cycles per second). An Earth-moon connection is provided by a 111.25-yr cycle ($\times 5 = 556$ yr, that appears also to be the precession of the lunar perigee and an approach to maximum terrestrial spin rate). The 111-yr period approximates what Wood (2001) calls the "Proxigee-Syzygy Perihelion Cycle".

The 556-yr period is precisely 50×11.1212 yr, the mean sunspot cycle, but because of its imprecise length, as noted above, it coincides only from time to time with the lunar cycles and likewise with the "ideal" QBO. Over progressively longer intervals, however, the SSC is found to conform to planetary motions, notably the "King-Hele Cycle" (177.9394 yr = $16 \times$ SSC). This cycle reflects the alignments of Jupiter with the center of the sun and the center of mass (barycenter) of the solar system. A rather similar cycle of 178.73 yr (the so-called "Jose Cycle") represents the sun's inertial orbital precession. These two cycles at a ratio of 224:225 create a 40 036.36-yr period; and this in turn is exactly 18 432.0 times the "ideal" QBO. It is also nine times the 4448.485-yr quadrature cycle ($2048 \times$ QBO). Evidently, Currie's discovery of the QBO period in his SSC spectral analysis (1973) is confirmed by the general interlocking of both with the fundamental long-term planetary periods.

Studies of planetary pair beat frequencies have disclosed simple logarithmic relationships. If unity (n) = 0.0678784 yr (approximately the inner sun's sidereal spin rate), then $8^2 \times n^{-2} = 2.17211$ (i.e. QBO). In the same sequence can be found

$$128^2 \times n = 1112.12, \text{ and thus } \frac{1}{2} = 556.06; \text{ or}$$

$$256^2 \times n = 4448.485 \text{ (quadrature cycle: } 224 \times \text{Saturn/Jupiter lap, } = 400 \text{ SSC)}$$

Evidently on a long-term basis the QBO appears to be eminently predictable from the astronomic constants. This, however, is not so simple. It would in fact be foolhardy, if not egregiously mistaken, to make forecasts without considering all the variables.

QBO forecasts

Schove (1983), in a volume that collects many of his earlier papers, recounts his heroic attempts to forecast climatic conditions from the "regularity" of the QBO. In England your vacation plans can often depend on the probability of a warm/dry summer versus a cold/wet one. Schove noticed that odd/even-numbered years could be used with this object. But just when it seemed to be working fine (on a biennial basis), it would break down into a triennial or chaotic interval.

Whereas the solar cycle is complicated by the low-frequency electromagnetic radiations (notably UV), equatorially focused, and the high-frequency volatility of the solar wind focused, on the magnetic poles, especially the northern one, there is also the moon, notably mediated by the lunar year (quite distinct from the solar year), the 18.6134-yr period of the nodal cycle which

strongly influences the geostrophic oceanic circulation, and finally the 18.0303-yr "Saros", the principal tide cycle. Although the seasons and their radiation characteristics are well established on a 365-day basis, the lunar year introduces an eccentricity, so that no two successive years can ever be climatically the same.

As shown by Pettersson (1912, 1914), the lunar apsides cycle of 8.849 yr has a sun-directed orientation only every third return, thus creating a 26.547-yr periodicity. This is repeated at the same season approximately every 53.094 yr. If we calibrate this to the tide cycles (Wood, 2001), the key year is 1912, which was marked by the highest predicted tides in five centuries. Wood pointed out that if the skipper of the *Titanic* had known about this, history would have been different. (The higher tidal buoyancy and warmer waters greatly accelerated the spring production of icebergs that year.) The same triple apsides periodicity is matched by "strong" to "very strong" El Niño. Of importance for the ENSO returns is the perihelion cycle (coming close to the Christmas/New Year season). The proxigee-syzygy-perihelion return coincides with the apsides every 61.943 yr, with triple apsides every 186.17 yr, e.g. AD 1912, 1726, 1540 (each with its matching El Niño).

In summary, the QBO is found to be closely related not only to the solar cycle, but also to the lunar cycles. Inasmuch as the latter are very precisely established, in contrast to the gross variability of the solar cycle, the lunar periodicities would appear to offer the better prospect for predictive purposes.

R

RADAR, CLIMATIC APPLICATIONS

Radar Detection and Ranging (RADAR) was first developed in the late 1930s by Great Britain, Germany, and the United States for military applications. It was not until 1941 that radar was first used for storm detection and monitoring (Ligda, 1951). Since then weather surveillance radar (WSR) has been an important meteorological tool, particularly in the near real-time operational analysis of storm-scale (meso-γ scale) features. Radar has become a valuable tool in climatological research as well, since, unlike climatological station networks, there are few gaps in coverage between stations where WSR networks exist.

While near real-time satellite imagery is available for most regions of the world, radar provides a number of advantages over satellite remote sensing systems. For example, radar allows a cross-sectional as opposed to “top-down” view, and in some cases a finer temporal resolution. The cross-sectional perspective allows for better determination of internal storm structure, which is valuable when dealing with severe thunderstorms and tornadogenesis.

Radar physics

Radar is a sounding system that transmits radio waves from a rotating parabolic antenna. When each 360° scan is complete, the antenna tilts upward and a subsequent scan is performed. While the specific volume coverage pattern (VCP) applied dictates the number of tilt scans, most scanning strategies employ between five and 14 sweeps at various elevation angles.

Microwave energy emitted by the radar antenna is transmitted in a series of pulses that interact with atmospheric mass, and a portion of that energy is back-scattered to the antenna (known as an echo). The energy received is then amplified and displayed in one of two primary formats: (1) the plan position indicator (PPI), and (2) the range-height indicator (RHI). Distance to the reflecting target is determined by the time elapsed between pulse emission and return, and direction provided according to the azimuth of the radar “beam” when the

target is sensed. The primary atmospheric targets are hydrometeors such as raindrops, snow crystals, and hailstones, although insects and birds may also be detected.

The magnitude of radiation reflected back to the antenna is a function of object density and a refractive index that is dependent upon target diameter relative to the wavelength of the energy transmitted (usually between 3 and 10 cm). The reflectivity factor converted for image display (Figure R1) by the amplifier is equal to the summation of the sixth power of hydrometeor diameters within the volume sampled.

Doppler radar, used to detect sub storm-scale motion, was first used on 27 May 1953 at the Cavendish Laboratory, Cambridge, England (Barratt and Browne, 1953). Doppler radar research and development continued through the 1950s with the most significant advances made by Lhermitte in France. By the 1960s the United States Air Force, Sperry Rand Corporation which had employed the services of Lhermitte, and the National Severe Storms Laboratory (NSSL) in Norman, Oklahoma, began research toward the development of operational Doppler weather radar. The United States Federal Aviation Administration (FAA) was also developing Doppler radar for

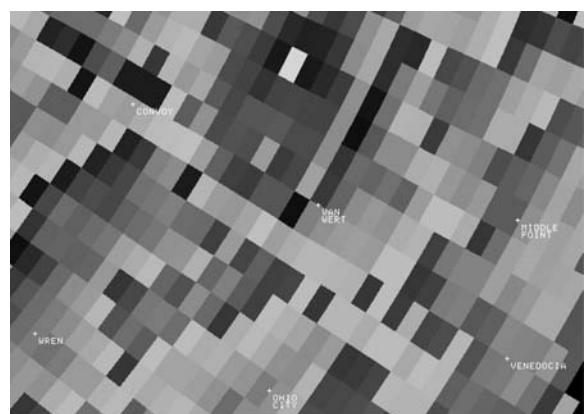

Figure R1 0.5° base reflectivity image at 2030 UTC, 10 November 2002, from WSR-88D KIWX (Northern Indiana) radar.

aviation services, and together with the NSSL, the Joint Doppler Operational Project (JDOP) was begun in 1976 to determine the potential for Doppler radar in operational meteorology (JDOP Staff, 1979). In 1979 the Severe Environmental Storms and Mesoscale Experiment (SESAME) field project (Alberty et al., 1979) was launched by NSSL to investigate the utility of Doppler radar in detecting fine-scale circulations associated with severe convective storms. As a result, by 1988 the United States National Weather Service (NWS) had developed a Doppler radar system (WSR-88D) that has become the cornerstone of the US NEXRAD Doppler radar network.

Doppler radar is based on the principle that the frequency of back-scattered radiation received at a fixed point location changes with time due to target motion. If a target is moving downrange, then the shift is to a lower frequency (red shift); when the target is moving toward the radar the frequency increases (blue shift). When opposite frequency shifts are detected between adjacent image pixels (known as "gates") the possibility of a mesocyclone (parent circulation that may generate a tornado) or microburst (severe "straight-line" winds) exists, depending on whether the rotation detected is cyclonic or anticyclonic.

In many cases a supercell thunderstorm will produce rotation (mesocyclone circulation) several minutes prior to tornadogenesis (Figure R2). Detection of a mesocyclone prior to tornadogenesis allows meteorologists the opportunity to issue timely warnings that help save lives and property. For example, since installation of the NEXRAD Doppler radar network in the United States in the early 1990s, mean tornado warning lead times have improved from 11.4 minutes prior to installation of the WSR-88Ds, to 13.8 minutes within the first 3 years of their operation (Bieringer and Ray, 1996). Probability of Detection (POD) has also improved from 75.4% before commissioning of the first WSR-88Ds in 1991, to 86.4% by 1995.

Radar imagery

Radar imagery is available in two display formats; Plan Position Indicator (PPI) and Range-Height Elevation (RHI). The PPI imagery represents a top-down view of any VCP elevation, while the RHI provides a cross-sectional view through integration of all

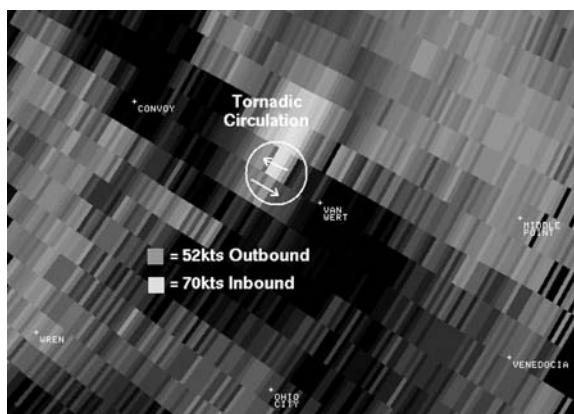

Figure R2 0.5° base reflectivity image at 2030 UTC, 10 November 2002, from WSR-88D KIWX (Northern Indiana) radar indicating a mesocyclone and tornado circulation northwest of Van Wert, Ohio. The WSR-88D radar is upradial northwest of the upper-left portion of the image.

elevation scans. Image products are either based on either reflectivity or radial velocity data.

Reflectivity imagery provides information regarding location and intensity of precipitation, while radial velocity products are used to detect storm scale motion based upon the Doppler principle. Common reflectivity imagery includes base reflectivity, composite layer reflectivity, echo top heights, and vertically integrated liquid products. Radial velocity imagery is provided in both base velocity and storm-relative velocity forms.

Reflectivity products

Reflectivity products depict the magnitude of back-scattered radiation received by the antenna from targets within the radar beam at a given location. The radiation received is amplified and color images generated to indicate strength of the reflected radar signal. With most radar systems warmer hues indicate heavier precipitation and cooler colors lighter precipitation. Radar reflectivity products are useful in determining the location and character of precipitation and meso-γ scale storm structure, which is very valuable in estimating thunderstorm intensity and character.

Base reflectivity

Base reflectivity products are perhaps the most common radar image types available (see Figure R1). While the lowest elevation scan is the most frequently used (generally 0.5°), separate base reflectivity products are available for each tilt-scan angle.

Composite reflectivity

Composite reflectivity is a display of the maximum echo intensity (reflectivity) detected at any elevation angle within a complete volume scan. When compared against base reflectivity, the composite reflectivity can reveal important storm structure and intensity trends. For example, when composite reflectivity is very large for a storm when the lowest level tilt scan reveals much weaker reflectivity, the storm is likely to produce heavy precipitation, and in many cases large hail.

Vertically integrated liquid

The vertically integrated liquid (VIL) product expresses density of water (liquid and solid) within a tropospheric column with a surface area of 1 m². Values of VIL are provided in units of kg m⁻². Since wet hail produces very high reflectivity due to its large diameter, VIL products are commonly used to detect severe thunderstorms.

Echo tops

The echo tops product depicts maximum height in which reflectivity is sensed, which can reach up to 70 000 feet above ground level. Echo top information is valuable in identifying areas of strong updrafts and determining thunderstorm severity. In addition, severe weather events often coincide with the collapse of the echo top.

Precipitation

Accumulated precipitation products involve a summation of radar reflectivity over space to provide estimates of rainfall totals for specified time periods. Common accumulated time periods

are 1 hour, 3 hours, and storm total. Accuracy of estimated precipitation totals derived from radar reflectivity products has improved in recent years, although convective precipitation totals are often both underestimated and overestimated. Legates (2000) has shown that weather radar systems tend to underestimate precipitation when hail is minimal, as is the case of tropical convection. When large hail occurs it is not uncommon for a 2–4 inch overestimation of accumulated liquid precipitation since the reflectivity from wet hail is very large.

Radial velocity products

Radial velocity products (see Figure R2) depict the average radial velocity of targets in the radar beam at a given elevation and range. A single Doppler radar beam (considered a “radial” outward from the radar antenna) can detect motion either directly toward or away from the radar antenna. Rarely is target motion purely radial; rather, most targets exhibit motion that is partially parallel to the radar beam. For example, hydrometeor particle motion may be westerly at 10 m s^{-1} , but if the radar antenna is located to the southwest, then only 50% of motion is considered radial. For this reason radial velocity is not typically related to particle speed. In cases where all of the target motion is perpendicular to the radar beam, radial velocity is zero.

Radial velocity values that depict outbound motion are considered positive and typically assigned warm colors (typically red) to indicate a “red shift” (decrease) in frequency, while inbound radial velocity values are considered negative and usually given cool colors such as blue or green to depict a “blue shift” (increase) in frequency. Gray or white are often used to depict zero radial velocity. Purple coloration is provided for pixels in which the radar cannot determine whether the back-scattered pulse received was from the current emission or a previous pulse. This is referred to as a “second trip” echo, which is also known as “range folding.”

Base velocity

Base velocity data are the default radial velocity information as described above. The disadvantage of using base velocity data is that it is impossible to separate pure particle motion from the motion of the storm that is carrying the particle. In other words, the base radial velocity will only depict true particle motion for those particles within a stationary storm system.

Storm relative velocity

To control for the effects of storm motion, the radial velocity contributed from storm motion is subtracted from the total radial velocity values to depict true particle motion. This would be analogous to moving the radar along with the storm. Storm relative radial velocity, sometimes referred to as storm relative motion (SRM), provides the best estimate of particle motion as a result of micro-γ scale circulations within an individual storm.

Radar limitations

As with any remote sensing system, there are limitations to consider when using radar systems and products. For example, all radar systems exhibit range-height and aspect-ratio problems, and some suffer from significant signal attenuation depending on the wavelength transmitted. Other limitations include ground clutter and anomalous propagation.

Ground clutter

When a radar antenna is sited near objects that extend a significant distance above the Earth’s surface, such as tall trees, buildings, hills, or mountains, a portion of the radar signal at the lower elevation tilt scans ($0.5\text{--}1.5^\circ$) will be returned by those objects to the radar antenna and receiver. While algorithms are used to detect these non-meteorological returns, and filter them out of the image as much as possible, a generally concentric reflectivity ring typically appears around the radar site. This problem is enhanced when the radar is operating in high-power (clear-air) mode.

While this may seem to be a significant limitation when storms pass near the immediate radar site, the “cone of silence” that exists as a result of the upper limit of elevation scans (usually near 15°) usually does not allow the detection of the precipitating system close to the radar site regardless of ground clutter. As a result, use of higher tilt scans (1.5° or higher) to characterize the precipitation as separate from the ground clutter will only yield acceptable results until the storm passes close within the immediate vicinity of the radar site.

Range-height limitations

The range-height problem exists for all surface-based radar systems due to the Earth’s spherical shape. Curvature of the Earth’s surface results in a radar beam reaching greater and greater heights downrange even though its trajectory does not change. An added component of the range-height problem is refraction of the radar beam that results in a natural tendency of the beam to curve slightly upward with distance. In some cases the beam can become either sub- or super-refracted, which either enhances the upward (sub-refraction) curvature or reverses the sense of curvature so that the beam approaches the ground surface (super-refraction). To compound the problem, nearly all radar systems begin their first scan at an elevation angle of 0.5° . These factors limit the useful range of any individual radar system to about 240 nautical miles, and provide a lower elevation scan limit of 8000 feet above ground level just 60 nautical miles from the radar.

Aspect-ratio problems

As the energy is transmitted downrange along the radar beam, the beam itself widens due to the parabolic design of the transmitting antenna. By the time the pulses reach 60 nautical miles downrange the beam width has increased to greater than 1 km. This deteriorating beam width resolution with distance may result in an inability to resolve some of the smaller tropospheric circulations such as mesocyclones that can lead to tornadogenesis.

Signal attenuation

Weather radar systems transmit pulses of energy with wavelengths ranging from 3 to 10 cm, while most hydrometeors exhibit diameters much smaller than this (Rayleigh scattering). When large hail occurs the hailstone diameters the 3–10 cm wavelength range (Mie scattering). As a result shorter wavelength radar systems are more effective in detecting small particles such as cloud droplets and drizzle. However, this shorter wavelength energy is also partially absorbed by these same particles, a process referred to as attenuation. Signal attenuation makes it difficult to accurately measure the intensity of back-scattered energy for more distant small particle targets.

Radar systems that use longer wavelengths are often desired for operational purposes since absorption by the intervening particles is drastically reduced. This means that a distant thunderstorm that lies behind a closer storm will also appear on the radar screen in an accurate manner. Since detecting severe weather is one of the more important missions of weather surveillance radars, such as the US WSR-88D NEXRAD network, these radar systems typically use a greater wavelength such as 10 cm.

Anomalous propagation (AP)

The pulses of energy emitted by a radar antenna normally propagate in a slightly curved upward arch due to the decrease in atmospheric density with height. This enhances the range-height limitations typical with all surface-based radars. When thermal inversions exist, however, the radar beam can arch down toward the ground (super-refraction). In some cases the Earth's surface may reflect the signal back to the radar system, resulting in a very strong return signal at the lowest elevation tilt scans (0.5–1.5°). To the inexperienced observer the resulting image may suggest an intense thunderstorm is occurring, when in fact no storm exists at all. To check the possibility that high-intensity low-level returns are not in fact storms, the radar analyst observes imagery from successively higher tilt scans (1.5° or higher) to determine the depth of the intense reflectivity core. In cases of AP, the high reflectivity area noted at the lower scan angles would not appear at higher levels. A further check may be performed through use of an image loop to determine if the high reflectivity core is moving in a manner expected of a thunderstorm, or if the apparent core remains relatively stationary which suggests an AP echo.

Radar in climatological research

The primary advantage of using radar data in climatological research, compared with data collected from climatological and meteorological stations, is improved spatial and temporal resolution. While climatological and meteorological surface stations are in most cases several tens, if not more than 100 kilometers apart, the resolution of most radar data ranges from about 0.5 km to 2 km, with updated products available every 5–7 minutes.

Although the use of radar data in climatological research has been increasing in recent years, many climatologists have been slow to utilize this valuable resource. A review of the current literature reveals a greater number of radar climatologies being developed by meteorologists in national weather services than by climatologists. A sample of such titles includes: Topographic influences on Amarillo radar echo climatology (Marshall and Peterson, 1980); Relationships between vertically-integrated liquid and thunderstorm severity over central Florida (Kitzmiller et al., 1990); and A radar-based climatology of July convective initiation in Georgia and surrounding area (Outlaw and Murphy, 2000).

For researchers that have been involved with radar climatology, a majority use PPI reflectivity imagery to determine location of precipitation and precipitation intensities from convective systems. One of the primary reasons for this is that precipitation, especially from convective systems, is perhaps the most spatially variable of all climatological elements (Riggs and Truppi, 1957). Examples of such studies are a radar climatology for the state of South Carolina developed by Landers (1969), an investigation of diurnal precipitation patterns in Florida, by Frank and Smith (1968), a radar climatology of

summertime convective clouds in the Black Hills region of the United States (Kuo and Orville, 1973), and a thundertsorm climatology for eastern Colorado (Karr and Wooten, 1976).

RADIATION CLIMATOLOGY

Radiation is the most fundamental energy available to the Earth-atmosphere system (EAS). All significant atmospheric and oceanic circulation systems and critical chemical, material and energy cycles are driven directly or indirectly by the

continuous supply of radiation energy from the sun. The conversion of this energy into biochemical energy provides the foundation for life. In addition, the unequal receipt of this solar energy is primarily responsible for the Earth's climates and the seasons.

Radiation describes both a type of energy and a means of energy exchange. All objects with a temperature above absolute zero (0 Kelvin) will emit electromagnetic radiation that travels at the speed of light as a series of waves. The "quality" of this energy is related to its wavelength (λ), the distance from one crest to the next (usually measured in micrometers, μm). The entire range of potential wavelengths forms the electromagnetic spectrum which extends from gamma and X-rays ($< 0.1 \mu\text{m}$) to radio waves ($> 1000 \mu\text{m}$) and beyond. In climatology we are often interested in specific parts of the spectrum – for example, radiation at wavelengths between 0.4 and 0.7 μm corresponds to the visible spectrum for humans and the energy that vegetation employs in photosynthesis. The amount of energy associated with a radiation transfer (a quantum, Q) is inversely proportional to its wavelength,

$$Q = \frac{hc}{\lambda}$$

where, h is Planck's constant ($6.626 \times 10^{-34} \text{ Js}$) and c is the speed of light, $3.8 \times 10^6 \text{ m s}^{-1}$. The loss (emission) or gain (absorption) of a quantum of radiation is associated with a change in the energy state of a molecule or atom. This change only occurs at specific, often widely separated, wavelengths known as absorption lines. If interactions between molecules occur (as is the case with liquids and solids) these lines broaden to form absorption bands.

At the outset it is worth defining some of the terms used to describe radiation exchange. A complete description of the transfer must include its energy quantity and quality, and directional properties. The radiation flux is the energy emitted per unit time by an object (J s^{-1} or Watts (W)). To compare emitting objects it is common to present the flux per unit area of the emitting surface – this is termed an emittance (irradiance refers to received radiation). More generally, this term is called a flux density (W m^{-2}). The radiation emitted/received toward/from a given direction is described by the intensity, the flux passing through a unit of solid angle, a steradian (W ster^{-1}). A similar term is the radiance, the intensity divided by the area of the emitting surface ($\text{W m}^{-2} \text{ ster}^{-1}$). Initially, it is useful to describe these properties for an ideal object (known as a blackbody) before examining the objects that are of most interest here, that is, the sun, the Earth and the atmosphere.

The emittance of a blackbody at different wavelengths is a function of surface temperature only (Planck's law). A plot of the spectral emittance has a positive skew, with peak energy output occurring at shorter wavelengths (Figure R3). The total emittance is proportional to temperature to the fourth power (the Stefan-Boltzmann law),

$$E = \sigma T^4$$

where σ is the Stefan–Boltzmann constant ($5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$) and T is temperature on the Kelvin scale. The peak of the spectral emittance curve, which establishes the wavelength at which most radiation is emitted, is also a function of temperature (Wien's law),

$$\lambda_{\max} = \alpha/T$$

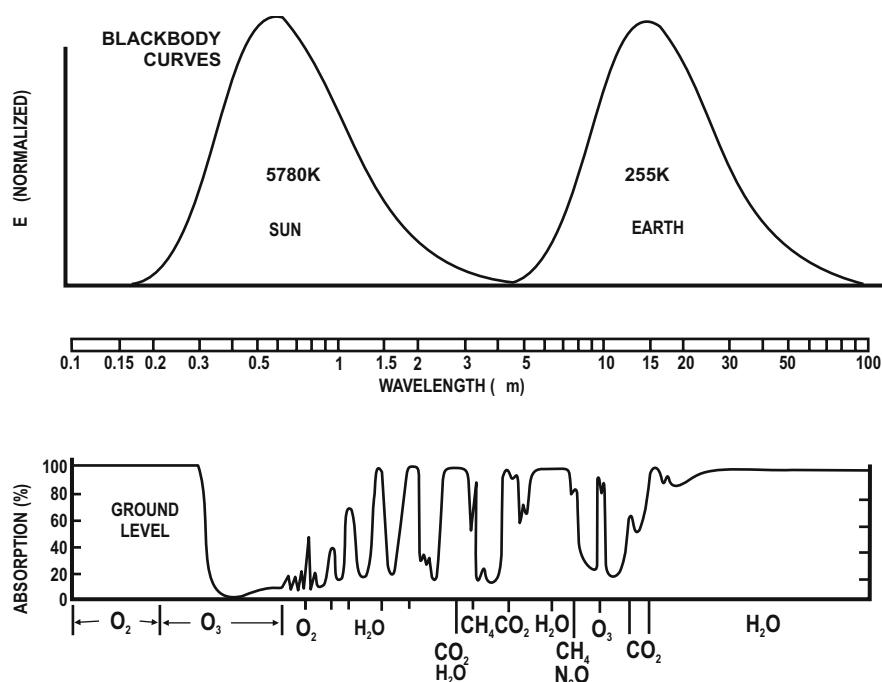

Figure R3 Blackbody spectral emittance (E_λ) in $\text{W m}^{-2} \mu\text{m}^{-1}$ for two objects at the temperature of the Sun (5780 K) and Earth (255 K). The curves have been standardized to demonstrate the difference between the radiation emitted by the Sun (shortwave) and that by the Earth (longwave). The actual area under the curves shown is given by the Stefan-Boltzmann law. The lower diagram illustrates the spectral absorption characteristics of the atmosphere and the gases responsible (modified from Wallace and Hobbs, 1977).

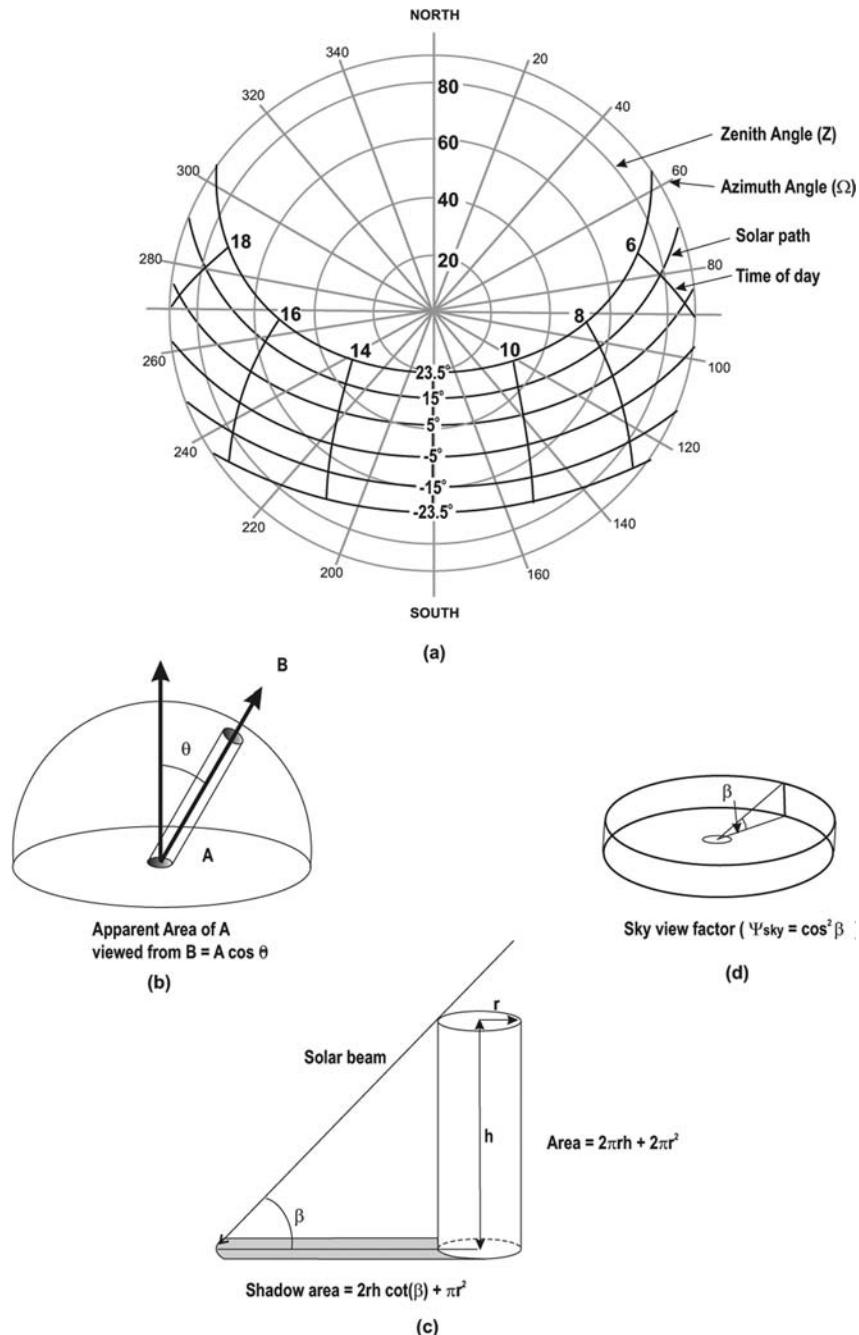

Figure R4 Radiation geometry: (a) The solar path diagram for 45°N illustrating the position of the sun (Z , Ω) for different times of day and times of year (shown by solar declination marked along the center line). (b) For a Lambertian surface the intensity of emitted radiation is equal in all directions. The apparent area of the emitting surface declines with the cosine of the viewing angle (θ) so that the measured emittance is equal in all directions (modified from Oke, 1987). (c) The solar radiation intercepted by a cylinder (used to represent a human, for example) equals its shadow area. To obtain an average irradiance this quantity is divided by the area of the cylinder (after Montieh and Unsworth, 1990). (d) The sky view factor for a simple basin used to represent a forest clearing, for example (after Oke, 1987).

where, a equals 2898 mm K. The emission of a blackbody is isotropic; that is, the intensity of the radiant flux is equal in all directions. However, according to Lambert's cosine law, the apparent area of the emitting surface decreases as the viewing angle increases from the perpendicular (Figure R4b).

A consequence of the laws stated above is that the spectral characteristics of radiation emitted by the Earth and the sun are substantially different (see Figure R3). At an approximate temperature of 6000 K, the sun's radiation profile suggests $E \approx 7.35 \times 10^7 \text{ W m}^{-2}$ and $\lambda_{\max} \approx 0.5 \mu\text{m}$ – by comparison, an approximate value

for the Earth's surface of 300 K yields values of 460 W m^{-2} and $10 \mu\text{m}$. At the top of the atmosphere, the radiation spectra of the sun and the Earth effectively form two non-overlapping curves and are termed shortwave (or solar) and longwave (or terrestrial) radiation, respectively.

The spectral emittance for real objects shows significant deviations from that for a blackbody at the same temperature. Emissivity is a measure of the ability of a surface to emit as a blackbody at a given wavelength (ε_λ). An important corollary is that its absorptivity (a_λ , the ability to absorb at that wavelength) equals its emissivity (that is, $\varepsilon_\lambda = a_\lambda$). This is Kirchhoff's law.

When radiation encounters a medium it may be reflected, absorbed or transmitted. For a given wavelength these fates may be expressed as proportions,

$$r_\lambda + a_\lambda + \tau_\lambda = 1$$

where the symbols represent the spectral reflectivity (r_λ), absorptivity (a_λ) and transmissivity (τ_λ). If the intercepting surface is opaque no transmission occurs, and the radiation is either absorbed or reflected. However, if the medium is transparent some radiation will be transmitted, a proportion that will depend upon the density of absorbing molecules and the distance taken to pass through that medium (termed the path length).

In the EAS, most solid materials and water act as nearly full emitters in the longwave portion of the spectrum. As a result we can effectively use the terms reflectivity (or albedo) and emissivity to refer to the behavior of Earth materials in the shortwave and longwave portions of the spectrum, respectively. On the other hand, the atmosphere has a distinctive absorption profile (see Figure R3), which is highly dependent on wavelength. While much of shortwave radiation is transmitted (particularly at visible wavelengths), most longwave radiation is absorbed. In addition, aerosols and molecules selectively scatter radiation. The nature of this scattering depends on the physical dimensions of the scatterers and the wavelength of radiation. For example, Rayleigh scattering occurs in all directions and is inversely proportional to wavelength – as a result, blue light is preferentially scattered (producing a blue sky). On the other hand, a mixture of larger particles of smoke and dust scatters a wide spectrum of grayish light in a predominantly forward direction known as Mie scattering (Wallace and Hobbs, 1977).

Radiation exchange

The transfer of radiation between objects and surfaces depends on both the magnitude and direction of emissions and their disposition relative to each other. The directional attributes of the exchange can be categorized into parallel (along one path) and diffuse (along many paths) types. Direct solar radiation is treated as parallel (or beam) radiation while scattered solar radiation and emitted and received longwave radiation are treated as diffuse radiation.

The direct solar irradiance (S) on a surface at the base of the atmosphere is a function of atmospheric transmissivity (τ) and the angle formed between the beam and a line perpendicular to the surface. For a horizontal surface,

$$S = 1370 \cos Z \tau^m$$

where Z is the solar zenith angle, m is path length (equal to $1/\cos Z$) and τ is an overall measure of atmospheric transmissivity. Surface irradiance is maximized when the surface is perpendicular to the beam. For complex shapes (such as those of plants or animals), surface irradiance can be estimated by

substituting simpler geometrical shapes for which the irradiance is more easily obtained (Figure R4d).

For diffuse exchanges, geometrical relations control the proportion of radiation exiting one surface (E_A^\uparrow) that impinges on another ($E_{A \rightarrow B}^\downarrow$),

$$E_{A \rightarrow B}^\downarrow = E_A^\uparrow \Psi_{A \rightarrow B}$$

where $\Psi_{A \rightarrow B}$ is the view factor (a value between 0 and 1). If the emittance is perfectly diffuse then the view factor is a function of geometry only. For many common configurations of shapes the view factors are readily available in engineering textbooks. In climatology it is often sufficient to distinguish between radiation derived from the sky and that derived from the terrain – hence, the sky view factor is a useful measure of the nature of exchanges. As with beam exchanges, it may be possible to employ simplified configurations to substitute for real, more complex situations (Figure R4c).

The radiation and energy budgets

In the EAS a statement of the radiation budget of a surface accounts for the nature and direction of these radiation transfers,

$$Q^* = K \downarrow - K \uparrow + L \downarrow - L \uparrow$$

where, the K and L refer to shortwave and longwave radiation, respectively, the arrows refer to receipt (\downarrow) and loss (\uparrow) and Q^* represents net radiation. The radiation budget is itself a part of a more comprehensive statement of all relevant energy exchanges. For a typical land surface,

$$Q^* = Q_H + Q_E + Q_G$$

where, Q^* is said to be partitioned into sensible (Q_H) and latent (Q_E) heat exchanges by convection with the atmosphere and sensible heat exchange by conduction (Q_G) with the substrate. Here, the non-radiative terms are treated as positive when directed away, and negative when direct toward, a surface.

Although the energy balance statement separates the non-radiative and radiation terms, they are intimately linked. For example, modifying surface albedo will directly affect shortwave absorption and the energy available for heating the surface (affecting $L \uparrow$, Q_H and Q_G) and evaporating water (Q_E). Changing these fluxes will, in turn modify near-surface air properties and affect further exchanges.

Measurement and modeling

Radiation instruments are categorized according to the spectral ranges to which they are sensitive. While the surface(s) of a radiometer absorbs radiation from both solar and terrestrial sources, those of a pyranometer and pyrgeometer absorb shortwave ($0.3 \leq \lambda \leq 4.0 \mu\text{m}$) and longwave radiation ($\lambda \geq 4 \mu\text{m}$), respectively. These instruments commonly consist of flat plates that absorb radiation from all directions, and must be positioned carefully to maximize exposure to the desired source of radiation. Net values are obtained by orienting two parallel sensing surfaces in opposite directions. On the other hand, a pyrheliometer is used to obtain measurements of direct (beam) solar radiation and its view must be aligned with the solar beam. Most of these instruments rely on thermometry, whereby the temperature of a spectrally sensitive surface is converted to radiation receipt (DeFelice, 1998).

Surface radiation measurements are usually made at a site that has a substantially unimpeded view of the sky vault; however,

specific projects must consider the view factors of the instrument with regard to radiating surfaces to determine their individual contribution to the measured value. Downward-facing instruments on airborne or satellite platforms will have a wide field of view that incorporates many diverse radiation sources. Moreover, the spectral characteristics of the instrumentation must be such as to separate surface from atmospheric properties. While aircraft-based measurements are usually associated with specific experiments, satellite observations now perform routine observations of the global radiation budget (ERBE Science Team, 1986).

In the absence of actual measurements, models of varying sophistication are employed to determine radiation exchanges at the surface and throughout the depth of atmosphere. The simplest models are based on statistical relations established with existing measurements and use readily available meteorological parameters. For example, $L\downarrow$ from the sky may be estimated from the air temperature near the ground and lower atmosphere emissivity, which can be approximated from knowledge of humidity (Oke, 1987). More complex models simulate the radiative

exchanges at several layers in the atmosphere based on knowledge of the temperature profile and the radiative properties of the layers above and below (Kiehl and Trenberth, 1997).

Earth–sun geometry

The receipt of solar energy by the Earth is governed by its relationship to the sun that changes during the year. The Earth revolves around the sun once every 365 1/4 days and rotates upon its axis once every 24 hours. The orbit is nearly circular with an average Earth–sun distance of 150×10^6 km, and this results in an irradiance on a surface perpendicular to the beam of 1370 W m^{-2} – this value is known as the solar constant. The average irradiance at the top of the atmosphere is one-quarter of this value, 342 W m^{-2} . In reality this value will vary by about 7% during the year owing to the slight eccentricity of the Earth's orbit placing it closest to the sun on 3 January and furthest on 4 July. However, the resulting variation in intercepted radiation is not responsible for the seasons.

As the Earth revolves around the sun on its orbital plane, it rotates around an axis that is tilted at an angle of $23\frac{1}{2}^\circ$ toward a fixed point outside the solar system. During its revolution the orientation of the Earth in relation to the sun is continually changing. At the equinoxes (21 March and 22 September), the shadow line on the Earth bisects both hemispheres (resulting in equal lengths of daylight and darkness at all locations). On these days the solar beam is perpendicular to the equator at noon and the zenith angle of the sun at noon is equal to the latitude of the location – thus, the tilt of the Earth with regard to the solar beam (the solar declination), is 0° . From late March to June the declination increases in latitude reaching a maximum ($23\frac{1}{2}^\circ$) on 21 June (the summer solstice) and the noon sun is now directly overhead at $23\frac{1}{2}^\circ\text{N}$ (Tropic of Cancer). During this transition the illuminated half of the Earth is predominantly in the northern hemisphere where each location experiences more than 12 hours of daylight (Table R2). As the Earth continues on its orbit, the solar declination returns to the equator and then into the southern hemisphere, reaching a minimum declination of $-23\frac{1}{2}^\circ$ (the Topic of Capricorn) on 21 December – the winter solstice.

The effect of these two movements is clearly seen in a solar path diagram that shows the path of the sun across the sky hemisphere at different times of the year (Figure R4a). The position of the sun on this hemisphere can be fixed by its zenith (Z) and

Table R1 Radiative properties of common surface materials (from Oke, 1987)

Surface	Remarks	Albedo (α)	Emissivity (ϵ)
Soil	Dark, wet	0.05 to 0.40	0.98 to 0.98
	Light, dry		
Desert		0.2 to 0.45	0.84 to 0.91
Grass	Long (1 m) Short (0.02 m)	0.16 to 0.26	0.90 to 0.95
Forests, deciduous	Bare Leaved	0.15 to 0.20	0.97 to 0.98
Forests, coniferous		0.05 to 0.15	0.97 to 0.99
Water	Small zenith angle Large zenith angle	0.03 to 0.10 0.10 to 1.00	0.92 to 0.97 0.92 to 0.97
Snow	Old Fresh	0.40 to 0.95	0.82 to 0.99
Ice	Sea	0.30 to 0.45	0.92 to 0.97
	Glacier	0.20 to 0.40	

Table R2 Variation in daylength (DL , hours), solar zenith angle at noon (Z) and daily solar radiation at the top of the atmosphere (K_{EX} , in MJ day^{-1}) at three solar declinations (δ). DL is obtained from the half-daylength angle H where, $\cos(H) = -\tan(\phi) \tan(\delta)$. K_{EX} is obtained from $86\,400/\pi\,1370 [H \sin(\phi) \sin(\delta) + \cos(\phi) \cos(\delta) \sin(H)]$ (Sellers, 1965)

Latitude (ϕ)	Equinox ($\delta = 0^\circ$)			Winter solstice ($\delta = -23\frac{1}{2}^\circ$)			Summer solstice ($\delta = 23\frac{1}{2}^\circ$)		
	DL	Z	K_{EX}	DL	Z	K_{EX}	DL	Z	K_{EX}
0	12.0	0	37.7	12.0	$23\frac{1}{2}$	34.6	12.0	$23\frac{1}{2}$	34.6
15	12.0	15	36.5	11.1	$38\frac{1}{2}$	27.5	12.9	$8\frac{1}{2}$	39.7
30	12.0	30	32.8	10.1	$53\frac{1}{2}$	19.1	13.9	$6\frac{1}{2}$	42.6
45	12.0	45	26.9	8.6	$68\frac{1}{2}$	10.2	15.4	$21\frac{1}{2}$	43.4
60	12.0	60	19.1	5.5	$83\frac{1}{2}$	2.1	18.5	$36\frac{1}{2}$	42.8
75	12.0	75	10.1	0	—	—	24.0	$51\frac{1}{2}$	45.4
90	—	90	0	0	—	—	24.0	$23\frac{1}{2}$	47.0

azimuth angles (Ω), which are obtained from the declination of the sun (δ), latitude (ϕ) and time of day,

$$\cos Z = [\sin(\phi)\sin(\delta) + \cos(\phi)\cos(\delta)\cos(h)]$$

$$\cos \Omega = [\sin(\delta)\cos(\phi) - \cos(\delta)\sin(\phi)\cos(h)]/\sin Z$$

The azimuth (Ω) should be subtracted from 360° if the local time is after noon. In these equations the time of the day is expressed as the hour angle (h), that formed between the longitude of the position and that of the noonday sun (Oke, 1987).

The global radiation budget

Figure R5 depicts the average energy budget of the Earth using an average solar input to the system of 342 W m^{-2} . Of this value just 235 W m^{-2} is absorbed by the EAS and contributes to heating. The remainder, accounting for 30%, is reflected. In the atmosphere, 67 W m^{-2} is absorbed, causing heating in those layers where the chief absorbing gases are concentrated – in the stratosphere (ozone) and near the surface (water vapor). About 58% of the energy at the top of the atmosphere is transmitted to the surface (approximately equal amounts via direct and diffuse paths) of which 168 W m^{-2} is absorbed (Kiehl and Trenberth, 1997).

The EAS maintains thermal equilibrium by emitting 235 W m^{-2} to space as longwave radiation. This would require a blackbody temperature of 254 K . However, the surface emittance is a great deal higher at 390 W m^{-2} – implying a temperature of 287 K . The difference between these temperatures is a result of the selective absorption of the atmosphere, which creates the natural greenhouse effect. In contrast to shortwave radiation, which the atmosphere largely transmits or scatters, the gases in

the atmosphere have exceptional absorption properties in the longwave range. As a result only a small proportion of the radiation emitted by the surface (<10%) is transmitted through the atmosphere directly to space. This “gap” in the absorption capacity of the gases forms the atmospheric window. Outside this narrow range the atmosphere is an excellent absorber (chiefly as a result of water vapor and carbon dioxide) and emitter. It is the “recycling” of longwave energy between the Earth’s surface and the overlying atmosphere that causes the greenhouse effect – 50% of the incident longwave radiation at the surface originates in the lowest 100 m of the atmosphere (Montieth and Unsworth, 1990). The atmosphere is heated chiefly through its energy exchanges with the underlying surface. Thereafter this energy is transferred via radiation and convection through its depth.

In terms of net radiation the Earth’s surface gains heat by radiation. Conversely, the atmosphere cools by radiation and it is the exchange of sensible and latent heat energy (by convection) that allows the budget of the both the Earth and the atmosphere to be balanced. At the top of the atmosphere the energy balance and the radiation balance are equivalent and Q^* is zero. Note that clouds play a very significant role in the Earth’s radiation balance – they are significant reflectors of shortwave and absorbers/emitters of longwave radiation. The net effect of clouds is estimated to warm the EAS by an amount equal to 30 W m^{-2} . Each of these radiation terms shows considerable spatial and temporal variation.

Spatial variations

The broad radiation climate of the Earth can be seen in a meridional plot of Q^* for the Earth’s surface, the atmosphere and the

SHORTWAVE RADIATION		LONGWAVE RADIATION		CONVECTION		BUDGET GAINS AND LOSSES
SPACE	Average irradiance 342	Reflected 107	Surface emission transmitted through atmospheric window 40	Atmosphere emission 235		- $342 + 107 + 40 + 235 = 0$
ATMOSPHERE	Reflected by cloud and scattered by gases & aerosols 77					$67 + 350 - 235 - 324 = -102$
SURFACE	67 Absorbed by atmosphere	Reflected from surface 30	350 Absorbed by Greenhouse gases (CO_2 & H_2O) & clouds	Counter -Radiation	24 Sensible Heat 78 Latent Heat	$24 + 78 = +102$ <hr/> 0
	168 Solar radiation absorbed		390 Emitted	324 Absorbed	24 Direct heating 78 Evapo- transpiration	$168 - 390 + 324 = +102$ $- 24 - 78 = -102$ <hr/> 0

Figure R5 The Earth’s average energy budget showing the radiative and convective fluxes in W m^{-2} (Kiehl and Trenberth, 1997).

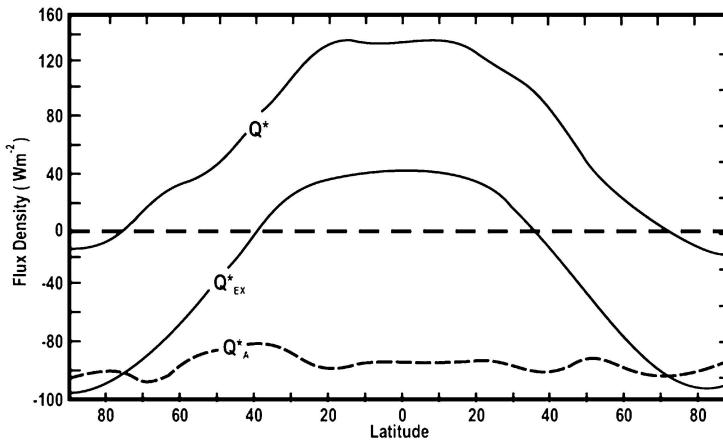

Figure R6 The meridional variation in net radiation at the top of the atmosphere (Q^*_{EX}), the Earth's surface (Q^*) and the atmosphere (Q_A^*). Modified from Sellers, 1969.

entire EAS (Figure R6). At the top of the atmosphere Q^* is positive within 35° of the equator and is negative at higher latitudes. Within the EAS the horizontal movement (advection) of sensible and latent energies by ocean and air currents ensures the long-term stability of climate. At the Earth's surface the pattern of Q^* is much the same but, apart from polar areas, is positive. At these high latitudes the low solar irradiance, coupled with the high albedo of ice, results in little surface absorption and radiative heating – here it is the atmosphere that transfers heat to the surface. For the atmosphere, Q^* is negative and shows little latitudinal variation.

The spatial pattern of Q^* is largely controlled by the net shortwave budget (K^*) at the Earth's surface (Figure R7). The broad pattern of decrease from the equator to poles is disrupted by significant longitudinal variations that result primarily from the different radiative properties of land and water. At any given latitude, K^* is higher over water where the irradiance is greater (low cloudiness) and the albedo is low. Over land surfaces,

unexpectedly low K^* values are found in arid areas where cloud-free skies ensure high solar receipt, but a high albedo (due to lack of vegetation and bright soils) reduces absorption. The net longwave budget may enhance these differences. Cooler ocean surfaces and warmer, more humid, ocean atmospheres will suppress longwave radiation loss; conversely hot and arid land surfaces overlain by warm but dry atmospheres will enhance longwave loss (Breon et al., 1994; Gupta et al., 1999).

Temporal variations

In addition to spatial fluctuations the magnitudes of the radiation terms vary with the passage the sun across the sky hemisphere. This path varies with time of day and time of year (see Figure R4a). The movement of the solar declination (and the latitude of maximum solar irradiance) over the course of the year causes a corresponding shift in the global pattern of

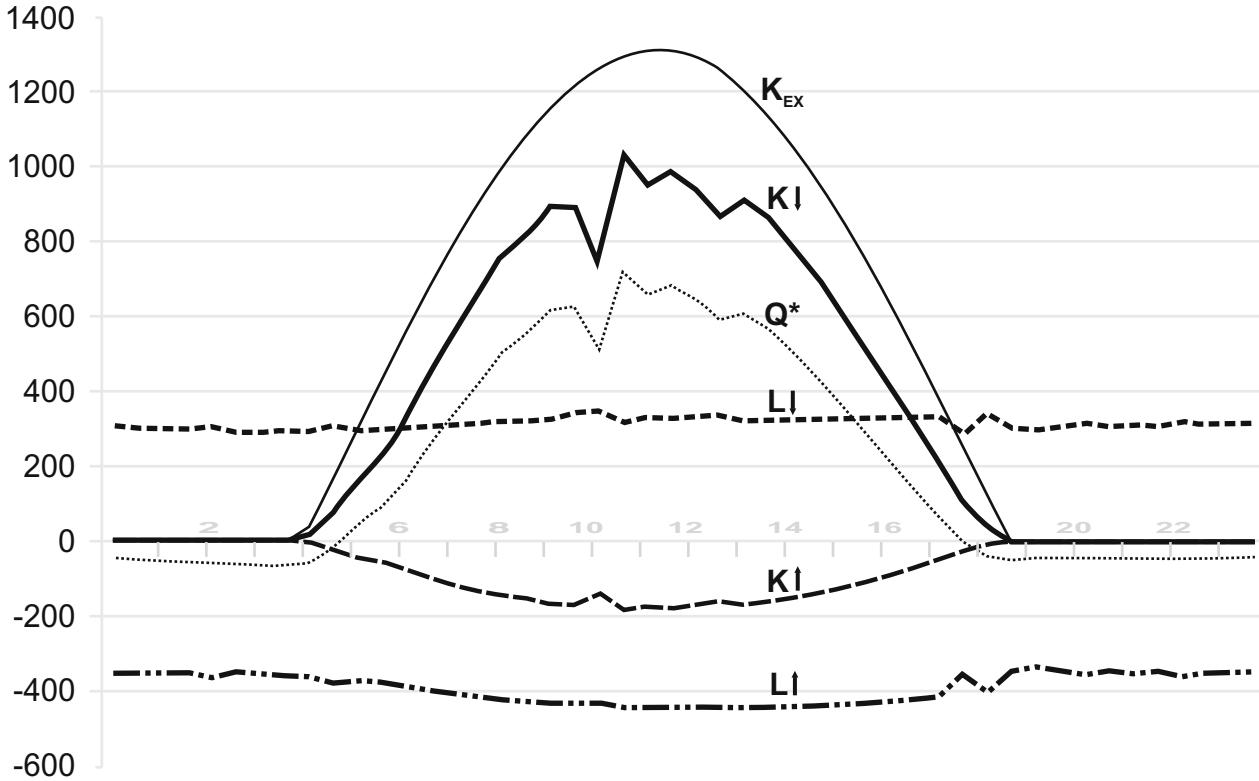

Figure R8 Measured surface radiation budget over recently grazed, fairly dry vegetation in the central US ($39^{\circ}06'N$, $96^{\circ}27'W$) for 4th June, 1987 obtained during the FIFE experiment. The symbols refer to incident shortwave radiation receipt ($K\downarrow$) and reflection ($K\uparrow$) and, to longwave radiation receipt ($L\downarrow$) and emission ($L\uparrow$). K_{EX} describes solar radiation available on a horizontal surface at the top of the atmosphere.

radiation exchange. The effect of these seasonal movements is most apparent outside of the tropics where the noon sun experiences a change in zenith angle of 47° over the year and the length of daylight varies considerably (Table R2).

Superimposed on the seasonal variation is a diurnal pattern that results from the changing zenith angle of the sun during the day. For a flat surface on a clear day, Q^* has a symmetric appearance with the peak receipt occurring at local noon and negative values overnight (see Figure R8). This pattern is largely driven by access to solar energy, which is available during daylight hours and varies inversely with the cosine of the solar zenith angle. By comparison, the net longwave exchange varies little during the day and night, and is negative. The overall result is positive values for Q^* from just after sunrise to just before sunset, and negative values overnight. The effects of cloud on the surface radiation balance will greatly depend upon their character. For example, if the sky is obscured by low-level, thick cloud the solar input to the system is uniformly reduced. On the other hand, the cloud behaves as a full absorber and emitter at longer wavelengths. The net effect will be to reduce the diurnal variation in Q^* and the daily temperature range.

Climates near the ground

Distinctive near-surface climates at all scales can be linked to the radiation budget (Smith et al., 2002). In particular,

distinctive local climates can be generated during calm conditions and clear skies when mixing is reduced and daytime radiation gain and nighttime radiation loss are enhanced. During the daytime such conditions often result in late afternoon convective activity as the convergence of heat in the lower atmosphere produces an unstable vertical temperature profile. At night these conditions result in radiative divergence, cooling and the development of an inversion in a thin layer of air adjacent to the surface. One of the human responses to damaging frost caused by this form of cooling is based explicitly on modifying the radiation exchange by generating a cloud using a fine water spray or smoke particulates. This will have the effect of increasing atmospheric emissivity and reducing the rate of heat loss from the near-surface air volume.

Local variations in land cover and/or topography will enhance the effects of radiation exchanges. At the boundary between land and water the radically different radiative and thermal properties generate land and sea breezes at night and during the day, respectively. Similarly, variations in the slope and aspect of surfaces will result in spatial variations in surface irradiance by creating areas of shade and sunlight in proximity. In valley configurations the surface irradiance/emittance will depend on the topographic geometry and orientation with regard to the sun's path. A slope that presents a near-perpendicular surface to the solar beam will warm and generate shallow up-slope (anabatic) winds as the

adjacent air becomes warm and buoyant. At night, near-surface cooling increases toward the valley ridges (where radiative loss to the sky is enhanced) and a shallow layer of cool air slides downslope (katabatic winds). These locally generated winds may assume particular importance for human affairs, as valleys and coastal areas are preferred areas of occupation – for example, both the sea breeze and katabatic airflow produce low-level inversions that have implications for pollution control.

The climates of all living things are intimately connected to the immediate radiation environment. Over land, the type and magnitude of surface-air exchanges are partly governed by the behavior of the vegetative cover, which can vary their “resistance” to exchanges of mass and energy according to environmental conditions. In the process of photosynthesis, plant leaves absorb light (green is selectively transmitted and reflected) and exchange water and carbon dioxide with the ambient air. If there is insufficient light, or the plant is experiencing water stress, these exchanges do not occur, and an important link between the atmosphere and soil moisture is severed. If the vegetative canopy is elevated, dense and extensive an entirely different climate is created in the canopy layer between the free atmosphere and the Earth’s surface (by analogy, a similar subclimate develops within urban canopy formed by buildings). Within this environment the radiation budget is entirely altered. Shortwave receipt at the soil surface is greatly reduced due to the interception of solar radiation by the canopy. Moreover, net longwave radiation is small in magnitude as the overlying leafy canopy is an excellent absorber/emitter at these wavelengths.

The relationships between radiation and the climates and the behavior of animals are most obvious in hot and arid climates where protection from the intense solar radiation is imperative. For example, cold-blooded creatures (such as lizards and snakes) manage their climates through periods of exposure to, and withdrawal from, the direct solar beam. For other creatures, including humans, survival depends on the construction of shelter that modifies the immediate radiation environment. As an example, ancient Anasazi dwellings at Mesa Verde, New Mexico, suggest a remarkable fit to a semiarid climate. The dwellings are placed in a cliff notch formed at the juncture of two rock types. The overlying rock provides a natural canopy to shade the building group beneath during the hot summer months yet, during the cool winter months (when the solar path is lower), it allows access to the solar beam (Knowles, 1978).

Conclusion

The measurement and modeling of radiative exchanges at all scales will continue to occupy a central role in understanding climate. Many of the globally significant environmental issues of our time (e.g. global warming, stratospheric ozone depletion and urban air pollution) are fundamentally concerned with radiation exchanges. At the grandest scale the global radiation budget is a critical indicator of the state of the EAS. The role of satellites as tools at this scale will increase in importance as they begin to provide long-term records (comparable to surface measurements), improve their spatial and spectral precision and are accompanied by detailed radiation models.

RADIATION LAWS

In the quantitative study of radiation, much use is made of the concept of a *black body* or *full radiator*. This is a theoretical object that absorbs all radiant energy incident on it and that, as a consequence of Kirchoff’s Law (see below), also emits the maximum amount of radiant energy a body can emit at a given temperature. In the natural environment many liquid and solid surfaces approximate black bodies, although gases show large deviations from this type of behavior. Nevertheless, black body radiation provides the starting point for the study of the radiative behavior of all bodies.

Black body radiation

Planck’s Law describes the quantity of radiation emitted at each wavelength (λ) by a black body at temperature T (kelvins):

$$E_{B\lambda} = c_1 \lambda^{-5} / [\exp(c_2/\lambda T) - 1] \quad (1)$$

where $E_{B\lambda}$ is the monochromatic or spectral emittance (i.e. the radiant energy emitted per unit area per unit time within a waveband of unit width centered on λ). The constants of equation (1) are $c_1 = 3.74 \times 10^8 \text{ W m}^{-2} \mu\text{m}^4$ and $c_2 = 1.44 \times 10^4 \text{ K } \mu\text{m}$.

Wien's (Displacement) Law gives the wavelength of maximum monochromatic emittance, $\lambda_{B(\max)}$,

$$\lambda_{B(\max)} = c_3/T$$

where $c_3 = 2897 \mu\text{m K}$.

The Stefan–Boltzmann Law gives the full spectrum emittance E_B ,

$$E_B = \int_0^\infty E_{B\lambda} d\lambda = \sigma T^4 \quad (2)$$

where $\sigma = 5.67 \times 10^{-8} \text{ W m}^{-2} \text{ K}^{-4}$.

Radiation from real bodies

The ratio of monochromatic emittance from a real body at a specific wavelength and temperature to that of a black body at the same wavelength and temperature is termed the monochromatic (spectral) emissivity, $\epsilon_\lambda = E_\lambda/E_{B\lambda}$. Thus, if the behavior of the function $\epsilon_\lambda = f(\lambda)$ is known for the real body, one may compute its monochromatic emittance as

$$E_\lambda = \epsilon_\lambda E_{B\lambda}$$

where $E_{B\lambda}$ is evaluated from equation (1). A body showing $\epsilon_\lambda \neq f(\lambda)$ is a *gray body*. When ϵ_λ varies with wavelength the body is a *discontinuous emitter*.

When a monochromatic irradiance I_λ is incident on a body, the fraction absorbed is the monochromatic (spectral) absorptivity (or absorptance), a_λ . *Kirchoff's Law* states that $\epsilon_\lambda = a_\lambda$. Thus, a body that emits only weakly (or not at all) at a given wavelength absorbs only weakly (or not at all) at that wavelength. For example, both absorption by and emission from the Earth's atmosphere are characterized by rapid changes in absorptive and emissive ability with wavelength between *lines* and *bands* (high ϵ_λ and a_λ) and *windows* (low ϵ_λ and a_λ).

The full spectrum *emissivity* is defined analogously with the monochromatic equivalent, $\epsilon = E/E_B$, where E is the emittance of the real body. Thus, $E = \epsilon E_B$, where E_B is evaluated from equation (2).

There are numerous other physical laws that relate to the angular attributes of radiation (e.g. Lambert's Law), to radiative transfer (e.g. Beer's Law, Schwarzschild's Equation), and to the scattering and reflection of radiation (e.g. Fresnel's formula). Details may be obtained from the bibliography.

RAINFOREST CLIMATES

The tropical rainforest climate is given the name based on several characteristics of temperature and precipitation which result in a broad-leaved evergreen forest biome. The tropical rainforest climate is defined in terms of the high frequency of precipitation and high temperatures throughout the year. The climate is limited to tropical areas as a result of high amounts of radiation evenly distributed through the seasons. Coupled with these temperature characteristics is precipitation distributed through the year. A dense, highly diverse, evergreen forest vegetation has evolved in response to this combination of energy and precipitation.

Geographically, the climate defines a forest region found along the equator in Asia, Oceania, Africa, and South America. The three main areas are in the East Indies, the Congo Valley of Africa, and the Amazon Valley of South America. The climate is generally restricted to some 10° of latitude either side of the equator. The climate is found in small areas as far as the Tropics of Cancer and Capricorn. For example the climate is found on the island of Madagascar and in Brazil at a latitude of 23°S . It has its greatest latitudinal extent on the east sides of the continents due to the prevailing easterly trade winds and warm water along these coasts. In east Africa the trade winds penetrate inland as far as Ngorongoro Crater and the rift valley. The rainforest climate is found in limited areas in these sites. The actual distribution of rainforest climates is much smaller than generally perceived. In Africa, for example, only a relatively small region lying along the equator on the west side of the continent has this type of climate. The same is true of Asia and Oceania. While scattered over a very large area of the Pacific Ocean and the Asian continent, the climate is not found over a large amount of land in one continuous unit.

This type of climate is restricted to low elevations, usually below 1000 m. This also limits the climate to locations where temperatures do not average much below 20°C . At elevations where temperatures drop below this level the rainforest declines and an alpine ecosystem becomes dominant. There is, however, a limited amount of midlatitude rainforests which results from large amounts of precipitation evenly distributed through the year but under cooler but fairly even temperatures. An example of the latter is the rainforest found on the western slopes of the Coast Ranges on the Olympic Peninsula of the United States.

Temperature characteristics

The even distribution in temperature results from the location of these areas within some 10° of latitude either side of the equator. The vertical rays of the sun are thus never more than about $33\frac{1}{2}^\circ$ from the zenith. Resulting insolation varies little as the solar beam stays so close to the zenith. The surface temperatures vary little from month to month. The monthly mean temperatures, as well as daily mean temperatures range from 18°C to 30°C ,

Figure R9 Rainforest canopy in Maui, Hawaii.

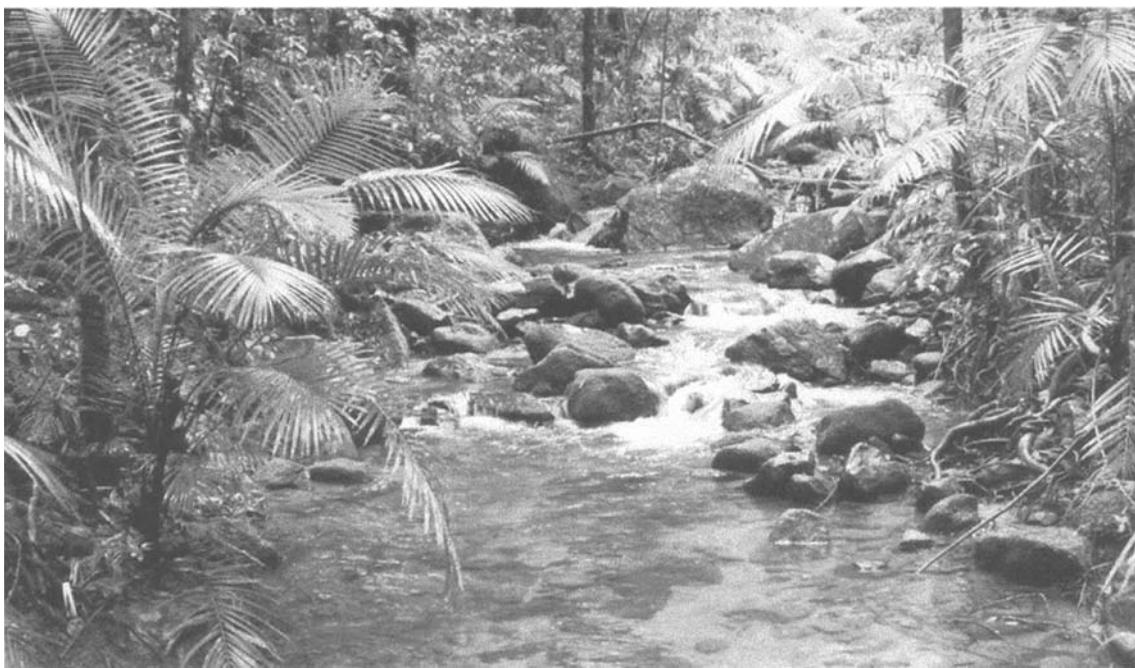

Figure R10 Rainforest in Caribbean National Forest, Puerto Rico.

depending on the actual site. This climate is thus winterless in the sense of having a cold season. It is probably only in terms of sensible temperatures that this climate can be considered hot. Much higher temperatures occur in other climates, including those of the midlatitudes. Because of the location near the equator the

length of daylight, and hence daily insolation, also varies only slightly from day to day. There is an average of 12 h of daylight and 12 h of darkness each day through the year. The annual range in temperature is generally less than 2.8°C . Belem, Brazil, experiences a range from the warmest to the coolest month of only

1.7°C. The combination of nearly even hours of daylight and darkness, the even intensity of radiation through the year, and the high humidity associated with the climate, keeps the diurnal range of temperature very small. Contrary to the rest of the world, diurnal temperature variation is typically greater than the annual range. The typical difference between afternoon and early morning temperatures is less than 10°C.

Precipitation is very frequent and the high frequency is one of the main distinguishing elements of the climate. The intertropical convergence zone (ITC) is present over these regions on a continuing basis. The ITC is the semipermanent low-pressure trough which is located near the equator. This trough of low pressure is consistent through time, but not particularly deep. The pressure is normally slightly below the average sea-level pressure, but the trough is sufficient to bring about convergence most of the year. The ITC shifts location with the seasons, migrating north and south over the equator. In most years it does not shift beyond 15°N or 15°S of the equator. The areas with a rainforest climate lie within the area affected by the ITC in all months. Where the ITC migrates the farthest from the equator, the climate is most restricted in area. The convergence of maritime tropical air into the ITC and the lifting along the ITC produces the precipitation.

Moisture characteristics

Humidity is high and varies between 50% and 100% depending on time of day and season. Partly cloudy skies are the rule and days with clear skies are limited. Cumulus cloud forms are most common building in the daytime hours to altocumulus and cumulonimbus when the air becomes unstable. Precipitation is probable on more than 50% of the days in each month, but there are seasonal differences in frequency in some areas. Duitzenzorg, Java, averages 322 days a year with rain. In the Americas, Cedral, Costa Rica, averages 355 days with rain. In this case the probability of rain on any given day is 97%. Average annual precipitation is quite variable, ranging anywhere from 150 to 300 cm. Belem, Brazil, averages 274 cm per year. Significantly, the variation from year to year in the annual total precipitation is relatively low, being less than 50% in most cases. The seasonal distribution tends to be fairly even in most areas. All areas receive at least 6 cm of precipitation per month and it can run much higher than this. Interestingly enough, the location of the sites which have the highest annual rainfall on each of the continents, are not found in the heart of the rainforest. They are found in other climatic regions where there is a pronounced seasonal distribution of precipitation, and enhanced by orographic lifting. As might be expected from the abundant year-round precipitation, large rivers are a part of the environment. Examples are the Congo of Africa and the Amazon of South America.

The precipitation that occurs is almost entirely rain and occurs mainly as convectional showers with thunderstorms being common. The rainfall can be extremely intense as the moisture content of the air can be very high. Associated with the thunderstorms are immense displays of thunder and lightning. Many of the animist religions found in tropical Africa have among their gods those of thunder and lightning. Among the Yoruba people of west Africa *Shango* is the god of thunder. It is also of note that the highest regional fatality rate due to lightning occurs in Kenya along the eastern escarpment of the rift valley. Tremendous thunderstorms erupt as the maritime air rises along the escarpment. The winds associated with the thunderstorms cause considerable blow-down in the forest, as

well as lightning damage. The typical thunderstorm does not grow to great heights and as a result hail is rare but does occur on occasion. Due to the extremely high moisture content of the trade winds at times, and the nature of the convectional storms, record rainfalls occur in short periods of time. Cilaos, La Reunion, in the Indian Ocean, has experienced as much as 187 cm of rain in one 24-h period.

Morning temperature inversions are quite common as the ground cools slightly. Only a few degrees drop in temperature is often enough to produce the inversion. Since humidity is so high in the daytime, when cooling takes place at night the dewpoint may be reached when temperatures drop into the range of 15–20°C. Early morning fog and heavy dew are both common. Wood is the primary fuel for cooking and heating in most of the rural areas of the rainforest. These inversions tend to trap the smoke from cooking fires and early mornings are often replete with smog. It is of note that tornadoes and hurricanes are rare in these regions. The reason for this is the low rotational element needed to produce these storms.

Weak easterly waves also traverse the ITC. These systems, though weak, tend to lower the pressure and increase convergence. These systems bring prolonged periods of rain that may last for several days. Winds are predominantly from the eastern quadrants; they vary from northeast to southeast depending on actual location and the season. Velocities at standard instrument height tend to be low, as the pressure gradient is low and the rainforest further restricts air flow. Occasionally in winter the harmattan blows from the Sahara Desert bringing dust storms into the fringes of the rainforest in western Africa. These storms can reduce visibility to less than 400 m.

The weather is fairly predictable in most areas of rainforests. Day-to-day changes are relatively small. There is never much question as to how the weather will alter a person's choice of clothing. Afternoon showers are most common, although precipitation can occur during all hours of the day. The afternoon showers are initiated by the surface heating which brings about instability. At some locations the time of onset of the diurnal showers can also be predicted within minutes on most days. This regularity in timing is strong enough for it to be used in timing daily activities.

The rainforest biome

The rainforest climate has favored the evolution of a tremendous variety of plants and animals, including disease organisms. The most widespread indigenous disease today is malaria. Some 40% of the global population lives in regions where malaria persists. While not limited to the rainforest climate it is endemic in all areas where the rainforest climate is found. In parts of Africa it is estimated that nearly every male, by the time he reaches the age of 15 years, is infected by malaria. If the warming of Earth continues, the incidence of malaria is certain to increase as warmer temperatures increase the voracity of malaria-carrying mosquitoes.

Clothing requirements are thus similar throughout the year. Light cotton clothing for daytime wear and a light jacket or other overgarment for evening constitutes a basic wardrobe. Sensible temperatures reach the uncomfortable level for the majority of people when the temperature exceeds 30°C and relative humidity reaches 100%. Since relative humidity is often extremely high, the weather tends to be uncomfortable, particularly in the afternoon hours. It is for this reason that human activity, especially in rural areas without air conditioning, often

ceases or is greatly reduced in the late afternoon hours. For instance, most activities may shut down from 2 to 5 p.m., and resume again after 5:00 p.m.

RAINSHADOW

An area on the leeward (downwind) side of a mountain or mountain range where precipitation is significantly less than that on the windward (upwind) side is considered to lie within the mountain's "rainshadow" (also known as precipitation shadow). The windward side of the mountain or mountain range acts as a wedge where the surface air is forced upward and is cooled adiabatically. Cooling may proceed until saturation is reached, then condensation can begin, and precipitation may result. As the air passes over the summit and begins its descent on the leeward side, it is warmed adiabatically. Descending and warming air causes a loss of saturation, and is conductive to the development of clear skies, thereby resulting in a rainshadow. This process is responsible for the creation of certain desert regions around the world. The Great Basin Desert of the southwestern United States, the Takla Makan of China, and the Patagonia Desert of Argentina are all examples of deserts found on the leeward sides of mountains.

REANALYSIS PROJECTS

Reanalysis projects are the production of retroactive records of global analyses of atmospheric fields. They evolved in the 1990s from the assimilated datasets that were produced in the 1980s as an answer to the problem of providing homogeneous datasets for climatological research. The twentieth century saw a tremendous increase in the amount of climatological data. Four periods can be distinguished: the "surface" period covered the first three decades of the century during which time ever-increasing quantities of surface and some upper air data were collected; the "upper air balloon" period from the 1940s to the International Geophysical Year in 1957 when the upper air networks of both radiosondes and pilot balloons were established; the "modern rawinsonde" period from 1958 to 1978 when radiosondes were tracked by radar to obtain wind observations; and the "satellite" period after 1978. Various international efforts were made to make these diverse data compatible by specifying various standards of instruments, observing times and so on. But it became apparent in the last quarter of the twentieth century that the data could not be objectively used in some climatological analyses, particularly over the vexed question of climate variability. This was because of problems of urbanization, lack of data over the oceans and poles, changes of station site and/or methodological practices, to name but a few. In addition the development of computers and computer models required that data be evenly distributed both on the Earth's surface and vertically through the atmosphere. Consequently two strategies were developed to overcome these problems and both relied on producing "gridded" data; that is data tied to latitude-longitude grid points rather than to individual geographical locations. The first strategy was the "homogenization" of datasets; this occurred in the 1980s and was applied to both station data and gridded data (see Trenberth and Paolino, 1980; Easterling and Peterson, 1995; Jones and Bradley, 1995). The second strategy was the production of assimilated datasets of atmospheric fields (and later incorporating oceanographic fields) in the early 1990s that then evolved into reanalysis projects. This second strategy will now be described.

During the 1970s and 1980s the major operational weather prediction centers developed a variety of global analyses based on atmospheric general circulation models (AGCM). These analyses depended on assimilation systems which quality control, grid and check for and correct inconsistencies in the raw data. The basic outputs of these global analyses have been used in global climate models (see Gates et al., 1996). However, the assimilation systems and the analyses they produced were continually evolving and were consequently not strictly comparable. One answer to this was the production of "control" datasets for a series of years such as the NASA/DAO (National Aeronautics and Space Administration/Data Assimilation Office of the Goddard Laboratory for Atmospheres) assimilated dataset 1985–1989 (Shubert et al., 1993). The second answer was to produce retroactive records of global analyses of atmospheric fields using a frozen state-of-the-art analysis system – reanalysis projects.

The concept of the first reanalysis project (National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) 40-Year Reanalysis) was discussed at a National Meteorological Center (NMC) workshop in April 1991. It arose because there seemed to be some "climate changes" in the NMC climate assimilation system which were really the result of

operational changes. For example the upper air observation times changed in June 1957 from 6-hourly intervals beginning at 0300 UTC to the current 6-hourly intervals beginning 0000 UTC. Similarly the statistical methods used in the assimilation system were continually being improved. The past data include changes in observation systems and a decision had to be made at the outset whether to use all available data at a given time or to select a subset of data that remains stable throughout the period. In the case of the NCEP/NCAR-40 it was decided to adopt the former strategy as this would provide the most accurate analysis (as opposed to the most stable climate) for the period of the reanalysis, which was 1957–1996. The data used in NCEP/NCAR-40 consisted of global rawinsonde data obtained from NCEP (1962 onwards), the US Air Force (1948–1970), China (1954–1962), the former USSR (1961–1978), Japan and several other countries; COADS (Comprehensive Ocean–Atmosphere Data Set, Woodruff et al., 1987); aircraft and constant level balloon data from a variety of sources, mainly post-1962; surface land synoptic data since 1949; satellite sounder data since 1969; satellite cloud drift winds using geostationary meteorological satellites. Once all these data were assimilated the reanalysis output came in two main formats: the binary universal format representation (BUFR) of the World Meteorological Organization (WMO) and the gridded binary format (GRIB). The data output is given for 17 standard pressure levels on a 2.5° latitude \times 2.5° longitude grid at 0000, 0600, 1200 and 1800 UTC each day. In addition a variety of monthly means of atmospheric fields are produced. Full details of NCEP/NCAR-40 are given in Kalnay et al., 1996.

Whilst NCEP/NCAR-40 was being developed it was hoped that the reanalysis could be extended backward in time to incorporate (the mainly northern hemisphere) upper air data for the 1948–1957 decade. This hope became a reality in 2001 when the NCEP-NCAR 50-year reanalysis (1948–1998) was described by Kistler et al. (2001). Information and data for both of these reanalyses can be accessed online at <http://www.cdc.noaa.gov/cdc/reanalysis/reanalysis.shtml>.

The NASA/DAO assimilated dataset mentioned above became the second United States reanalysis project when it was expanded to provide a 17-year reanalysis from 1979 to 1997. It was then redesignated as NCEP/DOE (Department of Energy) AMIP-II Reanalysis (or Reanalysis 2) being an improvement on the NCEP/NCAR reanalysis because it improved the parameterizations of the physical properties and fixed the errors that had been discovered. It has been running in real time since 2001 and now covers the period from 1979 to present. Details may be found on <http://wesley.wwb.noaa.gov/reanalysis2/index.html>.

The European Centre for Medium-Range Weather Forecasts (ECMWF) began a 15-year reanalysis programme (ERA-15) in February 1993 to produce an assimilated dataset for the period 1979–1993. This project used its own archive of observations received from WMO, COADS, the Hadley Centre (UK) sea ice and sea surface temperature (SST) dataset as well as the NCEP SST analyses, data from the First GARP (Global Atmospheric Research Programme) Global Experiment (FGGE) of 1978–1979, the Alpine Experiment (ALPEX) of 1982, Japanese and Australian data, TOGA (Tropical Ocean Global Atmosphere) data, and the vertical sounder data from the TIROS satellites. ECMWF had its own data assimilation system and the project was completed in September 1996. A full description is available online at <http://www.ecmwf.int/research/era/ERA-15/Project/>. In 2000 a new reanalysis was begun by ECMWF, known as ERA-40, which covered the period 1957–2001 and was completed in March 2003. It used the same data sources as ERA-15 but with

the addition of a variety of satellite radiances (from 1972 onwards), cloud photographs and cloud motion winds, particularly those of the European Meteosat geostationary satellite from 1982 to 1988. The output will be 6-hourly analyses on a grid with spacing of about 125 km in the horizontal and with 60 levels in the vertical between the surface and 65 km (Simmons and Gibson, 2000). At the time of writing (February 2003) four sets of data are available and it is hoped that subsets of the data will be supplied through CD-ROMS, finance permitting. The current availability of ERA-40 analyses can be checked online at http://www.ecmwf.int/research/era/Data_Services/section1.html. During the process of validation some deficiencies in the reanalyses have been found, so there will be a rerun covering the latter part of the ERA-40 period. In February 2003 it had not been decided whether these reruns would begin in 1991, 1987 or 1979.

The other major reanalysis is the joint project of the Japanese Meteorological Agency (JMA) and the Japanese Central Research Institute of the Electric Power Industry called the Japanese Re-Analysis 25 years (JRA-25) which will cover the period 1979–2004. This project began in 2001 with data preparation and the assimilation procedures. The JMA will use its own historical archive of observational data as well as the merged database of the NCEP and ECMWF archives. The assimilation system will utilize the latest JMA operational models. The reanalysis began in 2003 and will be completed in 2005. The web page is <http://www.jrap.org/indexe.html>.

International workshops on reanalysis have already occurred. The WMO World Climate Research Programme (WCRP) sponsored one in the USA in October 1997 (WCRP, 1998) and one in the UK in 1999 (WCRP, 2000). The latter consisted of 109 papers covering the development and use of the various reanalysis projects. The third workshop was held under the auspices of ECMWF at Reading, UK, in November 2001 and a printed version of the 34 papers is available at http://www.ecmwf.int/publications/library/ecpublications/proceedings/ERA40-reanalysis_workshop/index.html.

RELATIVE HUMIDITY

Relative humidity (or simply *humidity*) is the ratio of atmospheric vapor pressure to saturation vapor pressure. The World Meteorological Organization prefers to define relative humidity

as the ratio of specific humidity (or mixing ratio) to saturation mixing ratio, expressed in percent. It can be computed from wet-bulb temperature and related psychrometric data.

Relative humidity (U , in percent) is expressed:

$$U = 100 \frac{e'}{e_w'}$$

or

$$U = \frac{\text{Absolute humidity}}{\text{Saturation absolute humidity}} \times 100.$$

where e' is the actual vapor pressure of the air and e_w' the saturation vapor pressure at the same pressure and temperature. Mixing ratio (r) is defined as the ratio of mass of water vapor (m_v) to mass of dry air (m_a), thus $r = m_v/m_a$. Saturation occurs when moist air at pressure p and temperature T may exist in equilibrium with pure water or ice at the same temperature and pressure. In terms of mixing ratio (r) and saturation mixing ratio (r_w), it may be expressed:

$$U = 100 \frac{r}{r_w} \times \frac{0.62197 + r_w}{0.62197 + r}$$

Table R3 Relative humidity (percent) from temperature and temperature-dewpoint depression

30	17	16	14	13	12	11	10	03	08	03	03	06	03	03				

Note: Computed from saturation vapor pressures (with respect to water surface) given in *Smithsonian Meteorological Tables*, (6th rev. (edn), Washington, DC, 1951).

Table R3 provides relative humidity values derived, in this example, from temperature and temperature-dewpoint depression.

Relative humidity generally decreases with height like many other atmospheric characteristics, but it will increase just below clouds since in these the relative humidity is generally 100%. It also has a marked diurnal oscillation opposite in phase to temperature, with a daily maximum at dawn and a minimum in the afternoon. In addition, in certain climatic belts it has an annual variation, also in contrasting phase to temperature. In temperate regions it is generally above 60–80%; in arid regions 20–40%.

In the event of mixing of airmasses of differing relative humidity, a resultant midpoint can be established. If the midpoint falls above the 100% saturation curve, then condensation occurs.

RELIGION AND CLIMATE

Religion, a set of beliefs in one or more gods or supernatural beings, has been defined as humans' attempts to explain the complexities within their milieu and to ensure survival in harsh environments or mental peace in salubrious environments. In times of peace and prosperity, as well as war and tragedy, people have paid homage to who or what they believe is the author and sustainer of life and goodness. One of the premises of many religions was the maintenance of the harmonious relationship between believers and their physical environment, particularly aspects of weather and climate that impacted food production. Three of the largest monotheistic religions, Christianity, Islam, and Judaism, originated within rural agricultural societies in dry climates. All major world religions have specific climate regions of origin, routes of diffusion, and patterns of distribution. Environmental stress invoked, and still invokes, a religious response. Reducing or eliminating critical aspects of environmental stress diminishes traditional organized religious fervor and encourages the proliferation of new religions and cults. All major religions are currently impacted by modern technology, affluence, and urbanization. Secularism has tempered or is replacing mainline religions in highly developed modern societies. The thesis presented for discussion in this item is: if natural

hazards, climatic perturbations, environmental stress, and a need for a stable food supply were factors in the origins of many religions, modern technological creations and the ability to control aspects of human microenvironments could be factors in the decline of universal, mainline religious group adherence. Concomitantly, human technological advancements may induce a modification of religious codes of conduct, replacement of things worshiped, and places revered.

Climate determinism

People and cultural groups react and respond differently, physiologically and psychologically, to climatic regimes. There was, at one time in human history, a very close relationship between the physical environment, specifically climates, in which humans lived and the level of human development, cultural attributes, personality traits, and religion. In some physical environments, and in some climatic regimes, it was easier for humans in that particular stage of socioeconomic and technical development to survive and multiply. Ellsworth Huntington, an American geographer, in his works, *Civilization and Climate* and *Mainsprings of Civilization*, describes at length the role of climate determining religion. In relating religious beliefs to the environment, he suggests that the very nature of the desert environment allows comprehension of a single, omnipotent God. To those who lived in forest climates such a concept had no meaning. In the enclosed environment of the forest, with its distinct flora and fauna, it is much easier to conceive of physical site spirits or animal gods, each of whom rules his own segment of the forest. It follows that animistic beliefs were more likely to be found in the religions of the forest people. Those who lived in tropical or subtropical climates, with forest and grassland biomes (home to a wide diversity of aquatic and zoological creatures) that provided sustenance to humans without the constant threat of starvation, multifaceted deities and philosophical "isms" were recognized as gods or served as gods. Different climate realms became the originating hearths of formal and informal religious systems. The firm relationship between humans and God does not describe all religions and all that is worshiped on Earth. There are "gods of gaps" versus faith as trust in God.

Environmentalism, possibilism, and probabilism

In various works, H.T. Buckle, an English geographer, and more so Friedrich Ratzel, a German geographer, contended that the physical environment determined or molded peoples' culture and religion, as well as governments. Ratzel's carefully crafted theories dominated geographic thought for decades but were eventually rejected as being overly simplistic. Possibilism and probabilism emerged as a way to explain human cultural and religious diversity. Both stressed that the environment put restrictions on human religious expression, but de-emphasized the determining factors in the environment and climate. However, Ellen Churchill Semple, an American geographer influenced by Ratzel, credited the desert climate of the Middle East as the primary reason for the origin and dispersal of Islam. She stressed that the extreme conditions and harsh physical environment cannot help but influence people to be fierce and militant so that they can survive. She also researched aspects of the origins of Judaism and Christianity, focusing upon pastoral images taken from the lives of nomadic herding peoples that

dominate their religious literature. Semple contended that the desert and steppe nomads conceived an orderly, monotheistic deity and religion through their observations of the night skies and other facets of their dry environment. Vidal de la Blanche, a French geographer, credited climate and the physical environment for the type of religion, that developed in a region, and for the diffusion of that religion. In his writings he emphasized the local climate and the physical environment of a place or region and fostered a region-specific culture from which a region-specific religion emerged.

Ellsworth Huntington was a contemporary of both Blanche and Semple. His views of climate and religion differ from theirs. Huntington examined the population decline in the Middle East and related it to a drying climate. Cultural stress created by climatic change and drought made it easier for those who lived in the Middle East to accept a new religion – Islam. Huntington believed that Islam would never have become as accepted as it was, had the weather and climate of the region not changed. Richard Hartshorne, an American geographer, questioned the idea of using climate or the physical environment to explain the development of a religion in his book, *The Nature of Geography*. He wrote that the climate and environment of a place may have led to the development of a “faith system” in primitive societies, but that they have no influence upon religion in mature and advanced cultures. Jan Broek, a Dutch geographer, and John Webb, an English geographer, in the late 1950s and 1960s taught and wrote that “elements of the physical environment have played a significant role in most religions: holy mountains and rivers, sacred caves, groves, and lakes”. In 1961 A.H. Bhattacharya, an Indian geographer, wrote “each religion reflected the geographical spirit of the cradle land from which it disseminated.... Islam is cardinally a desert religion, Christianity a religion of the Mediterranean region, and the Indian religion a product of the prolific Monsoon environment.”

David E. Sopher, an American geographer, wrote in 1967 that most of the world’s monotheistic religions came out of a nomadic pastoral lifestyle within specific climatic regions. He credits exceptions to the actions of small groups of intellectuals in the affluent cultural/administrative center of their society. A review of the literature in the geography of religion reveals a

resilient theme in connection with the type of climate of an area and the development of a distinct religion (Table R4).

Human religious decision making

Humans live in confining physical and socioeconomic environments that vary in personal impact according to population density and stage of scientific and technical development (Figure R11). Within their confines or circles, humans make judgments as to the life system and set of beliefs they will seek, follow, or reject, based upon learned cultural and perceived environmental factors. Initially their actions to ensure survival directed their probe for a set of beliefs until their emotional needs were met within the limits placed by their cultural and physical environments (Table R5). Humanity’s increased numbers have altered the world’s climate through direct or indirect activities or actions. Areas of extreme high population densities, large urban metropolitan areas, represent humanity’s most profound influence upon natural environments, upon the climate of a place, and upon traditional cultural environments. A crude human “Survival Assurance Index” can be postulated that considers those aspects of a cultural group’s mores in altered environments which turn religious zeal to religious deviation, to religion doubting, and into personalized ego-serving, anti-religious philosophies that weaken the bonds and moral glue that hold a society together.

In the past the accepted definition (understanding) of climate was the physical condition of a place or region that synthesized various phenomena of the atmosphere (temperature, wind, moisture, storms, etc.), and it daily affected the lives of humans and animals.

Today the definition of climate has evolved into the holistic physical and social milieu of a place or region that synthesizes all phenomena that affect life on Earth. The natural hazards, and specifically climate perturbations, of the past that led humans to create a set of beliefs to ensure their survival at a place have been tempered by technology and human creativity. Natural hazard fears have been replaced by fears of human actions which threaten an individual’s survival daily. Fears of cultural hazards, not climatic events, have led to a lessening of the personal affinity for a climate-based universal religion and

Table R5 Worship of the Sun: The Source of Heat and Light

1. Allure of the Sun (Sun day)
2. Fear of Darkness (fortnight)
3. Agricultural/Religious Calendars (seasons, Latin for “sowing period”)
4. Sun Festivals (northern hemisphere)
5. “Sun stand” on winter solstice, December 21 (call back the Sun, Yule Log, hope for life after death, Christmas)
6. “Equal day and night” or vernal equinox, March 21 (joy for the return of the Sun, new life, or new beginning, Easter)
7. “Sun stand” on summer solstice, June 21 (bonfires and festivals to increase the Sun’s heat or rekindle its diminishing flame)
8. “Equal day and night” or autumnal equinox, September 21 (lowering or disappearance of the Sun, period of maturity passing to decline, thanksgiving to the Sun that ripened the crops)

Sun worship was a reflection of human dependence upon the mysteries of the Sun's behavior, the Earth's primary source of energy, and observed relationship between the Sun, climate, and food production.

led to the creation of personalized philosophical and new-age religions, i.e. the “gods of gaps” assumption.

Jewish religious festivals and climate as a case study

An example of the influence climate has had upon the development of religion is the calendar of Jewish religious festivals and rituals. When the Hebrews brought to the Promised Land their lunar calendars and lunar festivals, characteristics of nomadic

shepherds who depended upon the light of the moon for convenient movement of the flocks, they merged their festivals with ancient Canaanite agricultural festivals whose dates were determined by the position of the sun. The Hebrews had their own concept of the universe, of climate and of their world (Figure R12). The times fixed for the observances were arranged in accordance with the climate/weather and in order not to interfere with agricultural tasks or agricultural labor needs. During religious festivals, rituals were followed to invoke the cooperation and

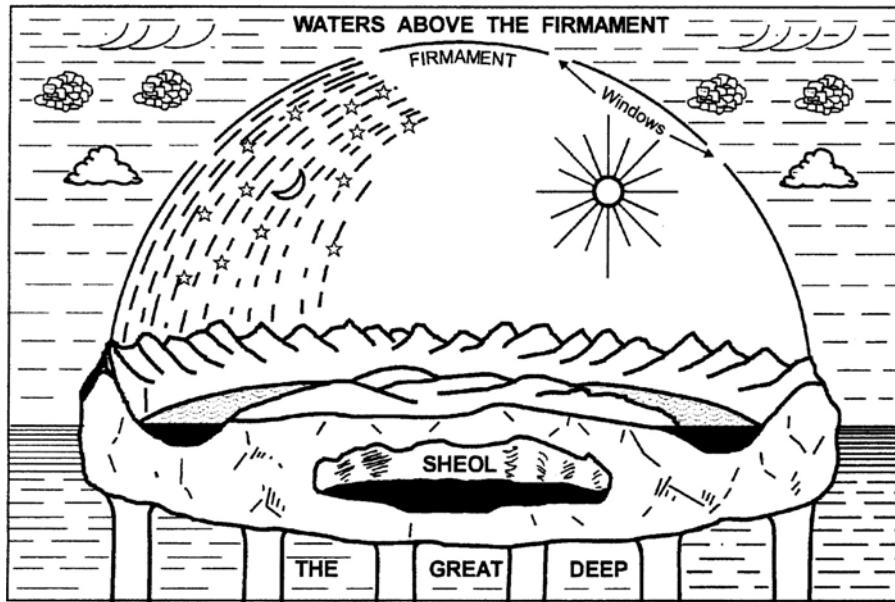

Figure R12 Climate and the Hebrew world. This diagram represents a cross-section of the Hebrew world as they imagined it and as they described it in their sacred literature. Rain came through windows in the firmament, and climate was created by interactions of elements within the domed firmament. Source: modified from Miller, M.S., and Miller, J.L., *Harper's Bible Dictionary*. London: Harper & Rowe, 1961, p. 193.

blessings of God in all aspects of weather, agricultural life, and food production. Not only did the festivals provide a welcomed respite for those who were tilling fields or tending flocks, they knit together the developing religious soul of the Hebrews/Israelites and promoted a sense of union with God. Besides daily worship, there were weekly, monthly, and yearly festivals to be observed. Festivals in ancient Israel included the activities shown in Table R6. Jewish religious festivals had an agroclimatic base. Today, these festivals are retained despite the occupational evolution of most Jews from rural shepherds thousands of years ago into modern urban professionals.

Climate, environmental and social stress and modern religious thought

Religious climatic inertia and historic precedence are evident also in the spatial dynamics of major religions. The current world distribution of major religions remains primarily in accord with the basic climate regions in which they originated (Figure R13). Islam is found in the Middle East and North Africa (BWH and BWK climates) plus Indonesia (Af Climate); Buddhism, Confucianism, Taoism, and Shintoism are found in eastern Asia (Ca climates) while animism remains in a few primal cultures located in northern Siberia, northern North America (Dd and ET climates), portions of the Amazon Basin of South America, southern Africa, New Guinea, and northern Australia (Af and Aw climates). Christianity is the dominant world religion found in all continents. It originated in ancient Israel (Cs and Ca climates) and spread northward into Europe and Eurasia (Cs, Cb, BS, BW, Da, Db, and Dc climates), then to similar climatic regions in North America, South America, and Australia. Only in the continent of Africa has the pattern of religions

changed radically in the past 100 years. African religious groups are multifarious, having been impacted by colonial rulers, and changeable. Depictions of any religious patterns are of limited value. Christians are still a minority in Africa while animism is the dominant religious force. In many instances Christian doctrine is wedded to traditional beliefs.

In most Western societies, secularism has tempered the growth and development of mainline Christian denominations. Climatic stress has been replaced by social stress. Social stress, found in almost all technologically and economically developed nations, produces great strain in an individual, in a family, and in a relationship. Excessive demands by society placed upon an individual create great personal and interpersonal tension, produce a debilitating and wearing effect, and at times deform an individual's physical body and mental health. Also, militant atheism, as manifested in the anti-religious commitment and ideology of communism, has proven to be a deadly foe of religion in general and Christianity in particular. The demise of the communist dictatorship and the break-up of the Soviet Union, the emancipation of Eastern Europe, and the relaxation of some political control in China have lessened somewhat the impact of militant atheism. As militant atheism waned, traditional universal religions were revived and new religious cults emerged. The New Age Movement, for one, is based upon Eastern mysticism, Hinduism, and paganism. Devoid of an environmental or climatic-linked base, there is no one specific holy book, beliefs vary according to the individual, and God is an impersonal force or principle, not a person. Adherents believe that people have inner power but need to discover it, and that followers can contact supernatural beings through meditation, self-awareness, and "spirit guides". A cycle of reincarnations may occur. These beliefs

Table R6

- I. Septenary (cycles of Sabbaths)
- Weekly Sabbath – to restore the human body's energy lost in the manual labor required of farmers in a dry, summer subtropical climate.
 - Feast of the Trumpets or Seventh New Moon – a break from labor involved in sowing grain.
 - Sabbatical Year or every seventh year – a fallow year when the land was to have a complete rest from cultivation.
 - Year of the Jubilee or every forty-nine years – a complete year of rest from all agricultural or economic activity, reversion of property, and remission of slaves.
- II. Yearly
- Passover – the lambing season and just before barley harvest.
 - Pentecost or First Fruits – conclusion of the grain harvest and prior to the grape harvest.
 - Day of Atonement – after the fruits of the ground were harvested and before plowing of the land.
 - Tabernacles or Books – plowing and sowing time begin.
- III. Jewish Religious Calendar and Agroclimatic Events

Month	Festival	Agricultural activity	Weather
1. Abib or Nisan (March–April)	Passover	Prior to barley harvest; lambing season	Warm/humid cloudy/latter or spring rains
2. Iyyar Ziv (April–May)	Little Passover	Barley harvest	Warm/low humidity/cloudy/dry
3. Sivan (May–June)	Pentecost/Feast of Weeks	Wheat harvest/lambing season	Hot/very dry/low humidity/few clouds
4. Tammuz (June–July)	—	—	Hot/very dry/low humidity/no clouds
5. Ab (July–August)	—	Grapes, figs, olives ripen and harvest	Hot/very very dry/few clouds/low humidity
6. Elul (August–September)	—	Vintage begins/pomegranates ripen	Warm/very very dry/few clouds/low humidity
7. Tishri or Ethanim (September–October)	Day of Atonement/Feast of the Tabernacles/Feast of Booths	Harvest of the fruits of the ground/ ploughing of fields	Cool/early or beginning of fall rains/some cloudiness/humid
8. Marchesvan or Bul (October–November)	Feast of the Trumpets	Sowing of barley and wheat	Cool/intermittent rain/moist-to-dry/ cloudy/humid
9. Chislev (November–December)	Hanakkah/Feast of Dedication	Trees and plants growing	Cloudy/humid
10. Tebeth (December–January)	—	Trees and plants growing	Cloudy/high humid
11. Sebat (January–February)	Arbor Day	Blossoming of fruit trees	Cold/heavy rain/very cloudy/high humidity
12. Adar (February–March)	Purim	Blossoming of nut trees	Moist-to-dry/cloudy/humid
13. Veadar or Second Adar (Intercalary Month)	—	—	—

are not linked to agroclimatic events, and there is no heaven or hell. In general, cults of modern religious thought are separated from the physical environment and employ meditation, crystals, and psychic powers. They strive for world peace and holistic health. The new religious cults and movements have had less effect upon universal religious systems than modern secularism. They are found in Climatic Realms C, D, A, and B.

Secularism and environmental change

There are many religious and semireligious movements emerging to help individuals cope with problems they face in the socioeconomic and political environments of our times. These, in most part, rely upon human reason, experiences, science, or technology, and not upon supernatural deities or revelations. Modern urban societies engender a global view of

life issues devoid of old mystical, faith-based elements. Scientific achievements, social institutions, and rational thoughts have replaced religious institutions, religious beliefs, and religious values in the minds of New Age and new cult believers. Organized, mainline religions are being separated from the core institutions of society, specifically the family, education, business, and the state. Modernity, science, and urbanization have created a new environment for new religions – that of an urban climate. In these climatic regions humans, political structures, and corporations determine whether a person is successful or unsuccessful, whether a person eats or does not have food, and whether a person survives walking down a sidewalk or is harmed. Nature almost has been eliminated as a factor in choices that must be made in an urban society for human survival. Society, those who make up society, and society's idols, are the new gods that must be appeased in the world's urban centers.

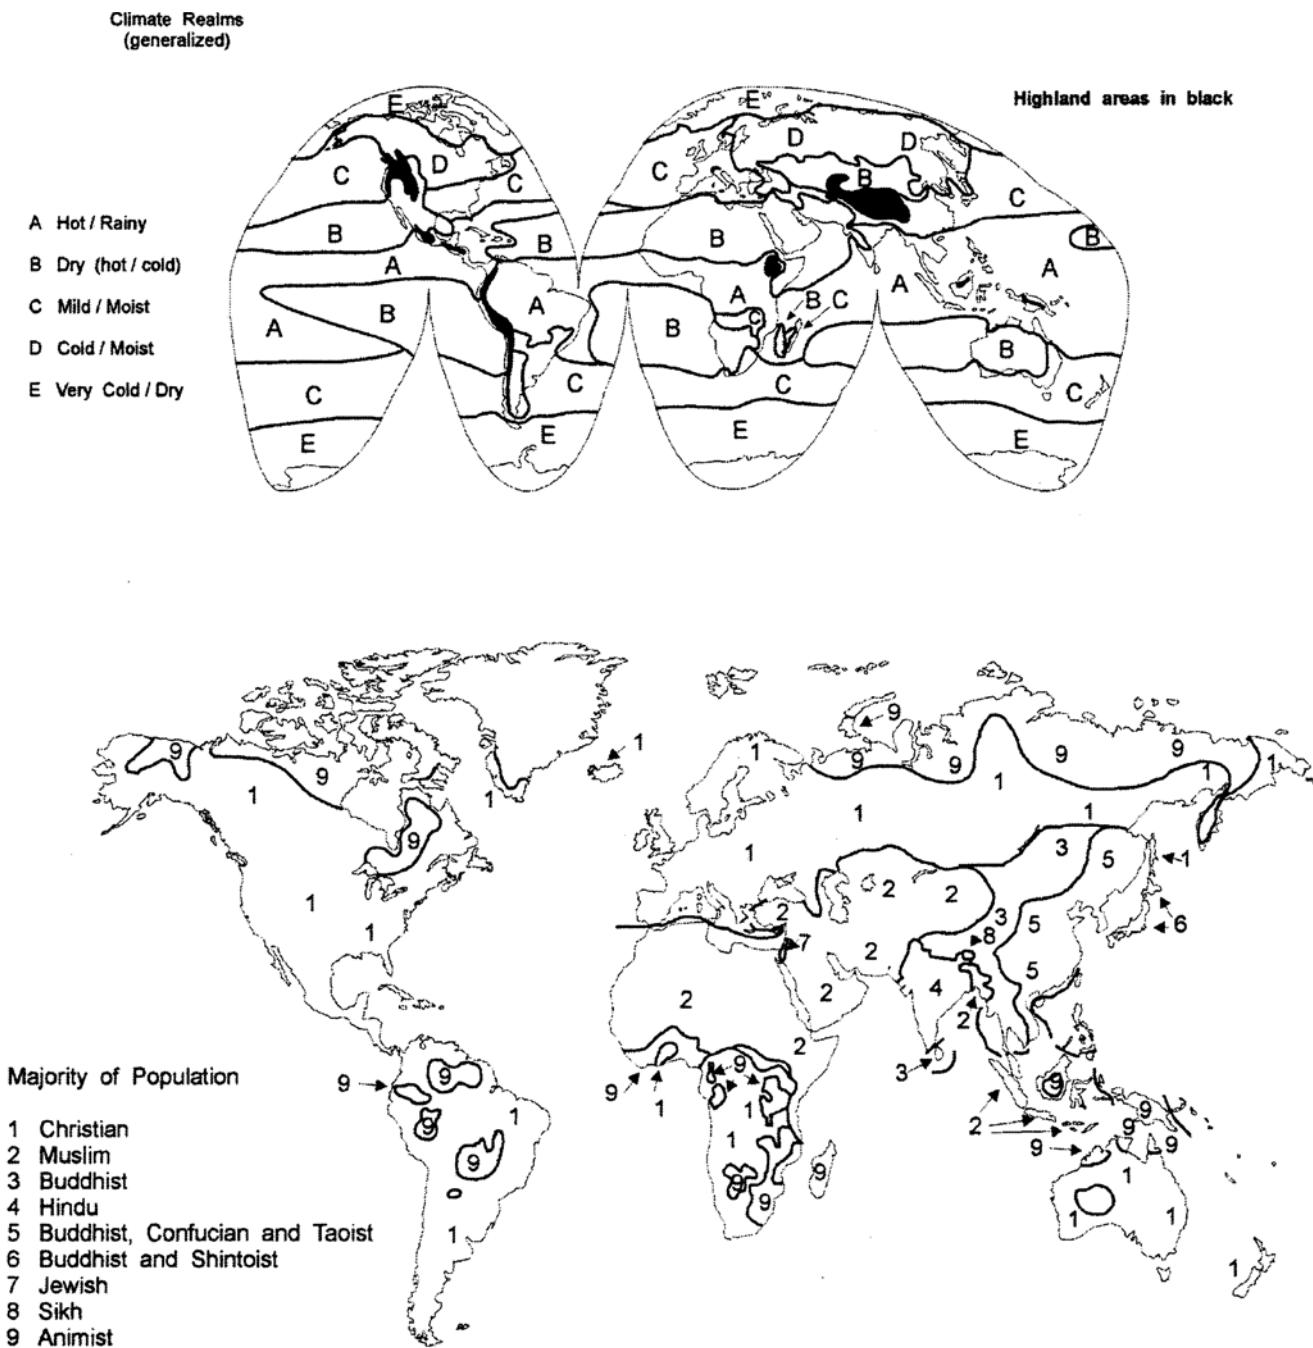

Figure R13 Climate and religious affiliation.

Religion and human-made urban and socioeconomic climates

Concerned urban area leaders are struggling to provide economic and cultural amenities for urban inhabitants as well as to create a pleasant place to live. The bulk of all urbanized land is used for human residences, not for food production or economic activities, together with extensive transportation networks needed for access to the city's economic and social

functions. Migration of people and wealth to urban areas has caused much anxiety about the future of rural life in society. The shift of population from rural to urban has been too recent and too rapid to fully understand its total ramifications. Urban expansion cannot continue indefinitely. Large cities have spread and coalesced with other large cities into a formless mass in which the very function of a city has been lost. The urban habitat is where humans now live, not the area in which

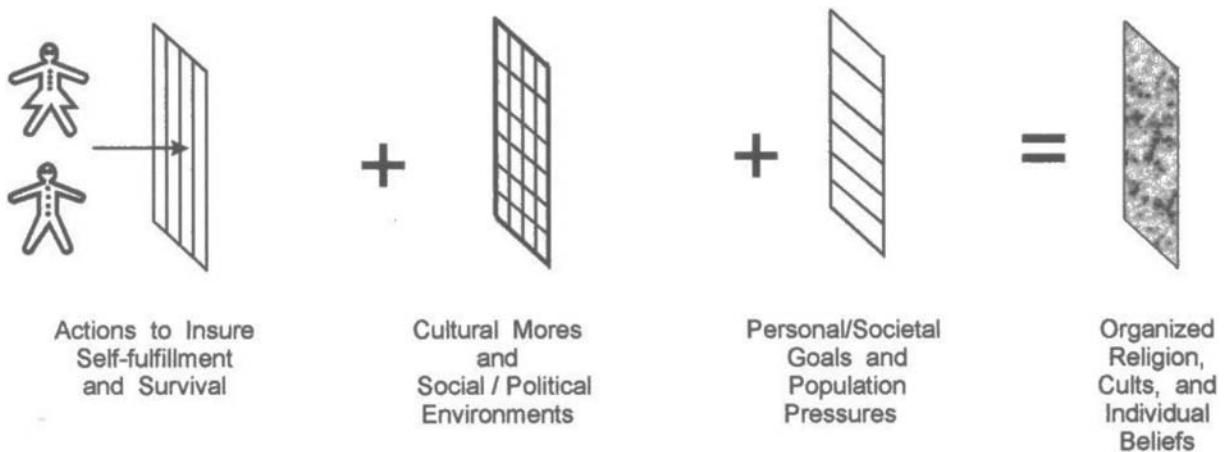

Figure R14 Human religious decision making: post-modern.

humans are biologically and socially best suited to live. Humans need space for complex biological and psychological reasons. Great distortions in human behavior occur when population density reaches certain excess thresholds. Planless urban development, accumulating refuse and scrap, and increasing pollution and crime affect people and their outlook on life. Modification of the natural environment and construction of a brick-and-cement urban habitat have created a physical environment, in most part, not conducive to human happiness and well-being. Also, it has created a new type of climate – an urban climate.

The issues and concerns facing a modern urban dweller daily are not the same issues and concerns of those who resided in the site of a religious system's origin. For the major universal religions the inhabitants of the site of origin were agriculturalists dependent upon the physical environment, particularly weather and climate, for survival. Drought, food shortages, and famine were common occurrences in the primitive societies based upon dry-land agricultural systems. Organized methods and objects of worship were contrived or revealed to temper those elements that impacted food production in many cultures of the world. In contemporary society the same fears and concerns are not manifested in urban complexes. Science and technology, along with human ingenuity and creativeness, have enabled humans to separate themselves, in part, from nature and place themselves in the hands of other humans (Figure R14).

Cultural hazards, not natural hazards, confront modern urban dwellers today. Organized universal religions are now facing new challenges in an urbanized world plagued by urban terrorism, ethnic strife, economic uncertainty, and religious leaders' indiscretions. Still, the religious impulse is extremely strong and vital in America. Two out of three Americans claim religion is very important to them and their families. One out of every two Americans attends weekly worship services. All surveys, whether professional or casual, report that a belief in a supreme being and devotion to prayer is very important to a majority of Americans. There is a deep desire for spiritual support and a hunger for a benevolent supreme being. Americans strive for and want spiritual reassurance and gain spiritual sustenance in personal experiences and private meditative practices. The Bible Geography Specialty Group of the Association of

American Geographers contends that the United States is the most religiously diverse and most religiously tolerant of all highly developed nations in the world. Humans live in a mosaic of environments. In the past the physical environment, particularly climate, and now the cultural environment, serve as a catalyst for religious evaluation. In modern urban societies, where multilayered economic and complex social stratifications are the rule, microevaluation of religious thought is favored. Here, environmental change and cultural change are inextricably interwoven. Culture serves to mediate between environment and society. It also serves as the catalyst for religious innovation. Adaptation to new environments, specifically urban environments, involves concomitant cultural innovation and religious diversity. Environmental changes trigger macro cultural responses and micro or personalized religious commitments (Figure R15).

New religions, new cults, and new philosophies of life are created by humans in response to the perceived new threats to their happiness, success, and survival. The new urban environments, these human-made urban climates, are presenting issues to urban dwellers that the universal religions are not addressing or are incapable of addressing. As it was thousands of years ago, new environments and new climates (both physical and social) are engendering new religions. The old religions, the mainline religions, the universal religions are being challenged, membership captured, and resources taken by new religions, cults, and philosophies. The decline in membership of many religious systems in the world is, in part, a result of the change in human habitats and changes in human concerns. Yet physical environment-induced stress or calamities (droughts, floods, tornadoes, hurricanes) and cultural environment-induced stress (terrorism, war, loss of a job, bankruptcy) still evoke traditional religious responses and increase worship service attendance. Viability and sustainability of religious systems will depend upon their capability to adapt to the rapid changes in the climate of where people live – specifically the physical climate and the socioeconomic climate. In modern climate-controlled or climate-tempered society, people's loyalty, beliefs, and hearts are where their fears and riches are.

ROSSBY WAVE/ROSSBY NUMBER

The configuration of the higher atmospheric flow, particularly in the westerlies, tends to revert to a wavelike pattern, a situation confirmed by both observation and hydrodynamic experiments (Fultz, 1949). Although these waves in the westerlies, within the middle or upper troposphere, exist in a continuum of lengths, they tend to be of either short (<50° longitude) or long (50–120° longitude) wavelength. Frequently, the situation is one of rapidly moving shortwaves

superimposed on a field of slowly progressing or quasistationary longwaves.

Named after the late C.G. Rossby, a meteorologist who contributed much to their theoretical understanding, Rossby waves are the features of the greatest length within the westerlies (Rossby, 1939). Characterized by cold troughs and warm ridges, and best developed between about 700 and 200 mb, they may be quasistationary or progress slowly, depending on their thermal structure. In either case they are usually not responsible for generating the synoptic-scale systems associated with the daily weather changes so typical in the midlatitude westerlies. Rather, their primary impact is to function as steering influences on these systems.

Possible origin

Important vorticity relationships help account for the development and maintenance of longwaves (Rossby) in the westerlies. One such relationship exists between the horizontal area of airstreams in the troposphere and their absolute vorticity. For example, as the westerlies ascend a mountain barrier, such as the Rocky Mountains, the airstream is vertically compressed between the rising terrain and the tropopause; vertical compression is compensated by lateral expansion (not detectable on airflow maps). Lateral expansion necessitates a decrease of absolute vorticity (somewhat analogous to the outstretching arms of the spinning ice skater, a motion that then slows the spin rate), which is achieved by a turn to the right in the northern hemisphere, transporting the air to lower latitudes and values of earth vorticity (Figure R16). On the downslope side of the barrier, however, vertical stretching between the tropopause and the lowering terrain leads to horizontal contraction, and absolute vorticity may again increase. This increase is achieved by lessening the right-hand turning initiated earlier, and, at the base of the barrier, where the lateral area of the airstreams is similar to the initial state, the degree and direction of trajectory turning (vorticity) are similar to the original state (in the theoretical absence of other perturbations).

In this fashion, interaction with the Earth may generate torques in the atmosphere and force certain features in the tropospheric flow (Reiter, 1963). Accordingly, mean longwave patterns display geographic preferences. Other more complex forcing may be associated with less conspicuous Earth features (Namias, 1980; Walsh and Richman, 1981).

Establishment of a train of waves

Once a meridional trajectory is initiated, a second important vorticity relationship helps ensure establishment of a downstream wave pattern. Above the friction layer in the middle or upper troposphere, airstreams tend to follow trajectories of constant absolute vorticity (Petterssen, 1956). In longwaves particularly, this absolute vorticity is maintained through a seesaw of the value of the terms representing curvature vorticity and Earth vorticity. Earth vorticity (f) must be considered because the size of longwaves is such that latitude changes are of significance in the equation; shear vorticity can be ignored at this large scale, so curvature vorticity becomes the dominant relative vorticity term. Thus, in this situation, the absolute vorticity of the air particles is the sum of vorticity due to curvature and f . For example, a turn to lower latitudes where the value of f decreases will necessitate cyclonic curvature (increasing the value of x) if the sum of these turns is to remain constant (Figure R17). This cyclonic curvature then redirects the particle to higher latitudes and values of f , so the trajectory then must bend increasingly to the right (decreasing the value of x) in order for constant absolute vorticity to remain constant. Such a sustained equilibrium between the value of these two terms in the equation theoretically leads to a train of longwaves around the hemisphere that may have been originally stimulated by only one perturbation arising from Earth–atmosphere interaction. In reality, however, these interactions are continuously occurring as the westerlies circle the Earth and the observed wave train may differ substantially from the theoretical plan.

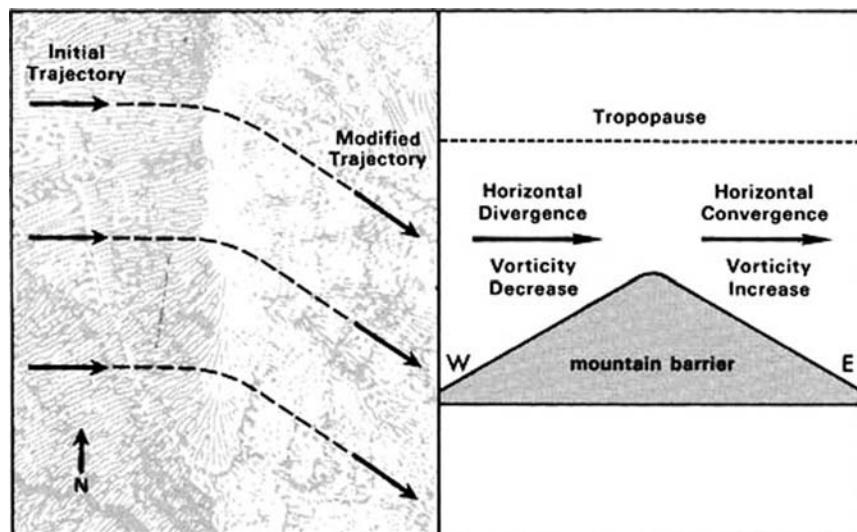

Figure R16 Schematic diagram summarizing the process in which the trajectory of an airstream in the northern hemisphere westerlies can be altered by passage over a mountain barrier.

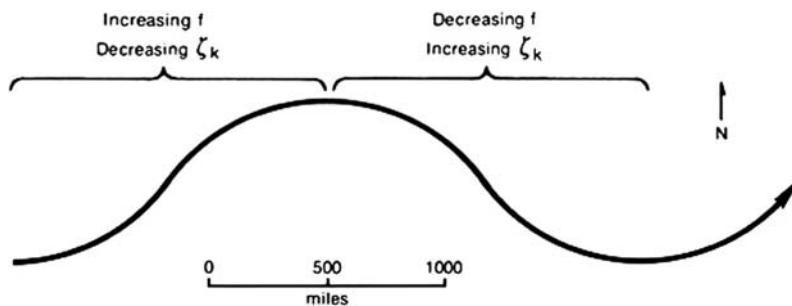

Figure R17 Diagrammatic summary of the changes of relative and Earth vorticity in the upper troposphere as air passes through a quasistationary wave in the northern hemisphere westerlies.

Figure R18 Illustration of the effect that increasing the amplitude of an initial wave (from A to B) might have on the downstream wave train in the northern hemisphere westerlies.

Teleconnection

Once established, waves within a longwave train are teleconnected because of the tendency of the air to follow constant absolute vorticity trajectories. For example, a perturbation in one wave may, by consequence, increase the amplitude of that wave. A trajectory issuing from that now-amplified feature would retain at least some of that amplitude downstream and might result in the entire wave train acquiring greater amplification (Figure R18). In this way weather events in remote corners of the hemisphere may have ramifications far downstream in less time than is needed for the events themselves to reach the affected area.

Impact of Rossby waves on weather

The impact of Rossby waves on surface weather is primarily in their function as steering influences on the path taken by mid-latitude cyclones and anticyclones. This influence operates because cyclone and anticyclone paths correspond closely to jet stream positions, where vertical atmospheric motions supporting these systems are strongest. Jet streams follow the general configuration of the upper tropospheric circulation, which normally features a number of quasistationary Rossby waves. The number of such waves around the hemisphere averages three or four in winter but increases to five to seven in summer when the circulation is weaker and stationary waves are shorter.

The configuration of the upper tropospheric westerly flow is one of the most important factors contributing to the weather of specific regions (for a general discussion, see Reiter, 1963). As noted, mean troughs and ridges often have geographic preferences; by guiding airmasses into a region or diverting storm sys-

tems, these features also can lend specific character to a region's climate. Beneath a stationary ridge, for example, storminess is suppressed by subsidence or the presence of warm air aloft and the weather, perhaps for long periods, would be stable. Where ridges are often forced (perhaps by Earth interaction), such weather would recur so often as to characterize the region's climate. The weather associated with stationary troughs, on the other hand, is often cloudy and wet. Here, cold airmasses brought equatorward by the upper air flow would produce lower mean temperatures than would be expected beneath ridges at the same location. Within a given region, alternation between dominance by slowly progressive Rossby waves would produce periods of different weather, each lasting a week or two.

Importance of Rossby waves in the general circulation

Rossby waves are an integral part of the meridional heat transfer in the westerlies. By ushering cold surface air equatorward and warm tropical air poleward, they help offset the heat imbalance arising from the nonuniform distribution of solar energy between the equator and the poles. Furthermore, the weak upward vertical motions east of longwave troughs help promote cyclonic formation, moving generally northeastward as they develop. These eddy circulations further contribute to the meridional exchange of heat, moisture, and momentum necessary in the middle latitudes to maintain the global energy budget.

The Rossby number

This is a nondimensional number (Ro) that defines the ratio of inertial force to the *Coriolis force* for a given flow in a rotating

fluid. With U as a characteristic velocity, f the Coriolis parameter, and L a characteristic length,

$$\text{Ro} = \frac{U}{fL}$$

In experiments of the dishpan type system, which is cylindrical rather than spherical, the Rossby number will still be a basic relationship provided the Coriolis parameter is replaced by a cylindrical value that is simply twice the rotation rate of the system. An analogous but distinctive nondimensional number is the *thermal rossby number* (Ro_T), which is the inertial force due to the thermal wind (U_T) and the Coriolis force (f) in the flow of a fluid heated at the center and cooled at the rim. With L as a characteristic length,

$$\text{Ro}_T = \frac{U_T}{fL}.$$

The thermal wind (U_T) is given by

$$U_T = g\epsilon \frac{(\Delta r\theta)\delta}{f\Delta r},$$

where g is the acceleration of gravity, ϵ is the coefficient of thermal expansion, $\Delta\theta_r/\Delta r$, a characteristic radial temperature gradient, and δ the depth of the fluid.

SATELLITE OBSERVATIONS OF THE EARTH'S CLIMATE SYSTEM

The Earth's climate is established via a complex set of interactions between and within its major subsystems. Predicting the evolution of the Earth's climate is difficult as the processes that govern these interactions are connected over vast ranges of time and space. Credible climate prediction requires a deep level of understanding which in turn requires observations that are able to link processes that take place on the smaller-faster scales, such as those affecting the evolution of clouds, precipitation and other aspects of the hydrological cycle, to the global scale. Climate also requires that these observations be made over sufficiently extended time periods. The almost regular-in-time and global-in-space nature of satellite observations makes them particularly attractive for this purpose and the use of satellite data in the study of Earth's climate has grown significantly over the last two decades.

Selected examples of climate studies that use satellite data are introduced below to highlight the general issues involved in constructing climate information from such data. Other examples of programs that focus on developing satellite climate data, such as the Earth radiation budget and solar irradiance programs, are not discussed.¹ It will become apparent that a satellite observing system is much more than the instrument on a satellite and thus its accuracy is defined by more than the instrument calibration. Rather satellite observing systems are complex systems defined by mixtures of properties including the properties of the sensors, the platform including its orbit, and the properties of all sorts of other extraneous information associated with the inverse process. As such, proper characterization of these observing systems is complicated.

¹More can be found on the radiation budget and total solar irradiance satellite programs, <http://asd-www.larc.nasa.gov/ceres/ASDCeres.html>, http://daac.gsfc.nasa.gov/CAMPAIGN_DOCS/FTP_SITE/INT_DIS/readmes/sol_irrad.html

Terminologies

Asynchronous sampling. This refers to the way sensors on polar orbiting satellites, in particular, observe the Earth. Because these satellites move with respect to Earth, the observations made from them mix space and time variations of properties.

Brightness temperature. An alternative way of expressing spectral radiances. It is a measure of the equivalent blackbody temperature of a hypothetical body emitting that same amount of radiation as detected by the sensor. This is not equivalent to the (true) thermodynamic temperature of the medium.

Calibration. The process by which raw instrument data (e.g. voltages) are converted to physical quantities (e.g. radiance units). Radiometric calibration ideally requires the conversion be connected in some way to a reference standard.

Climate subsystems. Atmosphere, the lithosphere, hydrosphere, cryosphere and biosphere (Pielke and Oort, 1992).

Data inversion. The process of extracting geophysical information from sensor data. Most sensor data are in the form of (spectral) radiances.

Geostationary satellites. These satellites are high above the Earth, nominally at about 36 000 km in an orbit that lies in the equatorial plane. As a result the satellite remains stationary with respect to a fixed point on the equator. Sensors on these satellites are thus able to stare at the Earth watching the atmosphere evolve below it.

Observatory. The sum of the spacecraft, entire instrument payload and the orbit characteristics that define how the Earth below is sampled in space and time.

Observing system. The sum of the observatory, model systems used in data inversion and all other components of the inversion process including observing networks used in vicarious calibration.

Polar orbiting satellites. Satellites in low-altitude orbits, often between about 400 and 1000 km above the Earth's surface. These satellites view the Earth in a swath with a periodicity that is related to orbit altitude. The angle of inclination of the orbit dictates whether or not the swath extends over the polar regions.

Radiances. The detected amount of radiant energy over some defined spectral region confined to some acceptance angle characteristic of a radiometer.

Radiometers. Instruments for measuring the amount of energy of EM radiation integrated over a spectral region of nominal width $\Delta\lambda$ typically in a few selected spectral regions. These regions are referred to as channels as defined by the width and a nominal central wavelength λ .

Representativeness. The space–time properties of a measurement in relation to the true space–time properties of a given climate parameter.

Resolving power. The ratio $\lambda/\Delta\lambda$. Most satellite visible and infrared radiometers as used in climate research have resolving powers of order 1–10, but spectrometer systems such as being planned for the next-generation sounders have powers that are orders of magnitudes greater.

Satellite platforms. The spacecraft.

Sensor. A particular instrument flown on a satellite. By far the majority of sensors are spectral radiometers.

Vicarious calibration. The process of calibration using non-traceable and often indirect methods.

Selected traits of a climate satellite observing system

Figure S1 depicts a few characteristics of satellite observing systems that might be considered desirable for many types of climate problems. The figure is in the form of a 2×2 matrix with one dimension representing measurement accuracy and the other measurement precision. Accuracy is especially important for many studies that delve into detailed study of processes requiring quantitative information about parameters and relationships between parameters. Precision is critical for monitoring the types of climate change expected under global warming. Detection in and of itself requires precision but not necessarily accuracy. Understanding the nature of such change and attributing cause to such change requires both precision and accuracy to quantify changes to processes. The dilemma confronting the climate community is that only the operational satellite observing systems have the long-term commitments necessary to sustain observations over time-scales of interest to climate. These operational systems generally do not have a precision adequate for climate trend analysis; nor do they possess sufficient accuracy to quantify the typically small changes to processes responsible for the observed changes. In partial response to these shortcomings, concepts for dedicated satellite monitoring missions have been proposed (e.g. Goody et al., 2003).

Factors affecting both accuracy and precision of satellite observing systems are many and complex and include: (a) the platform, (b) the space–time representativeness, (c) the inversion process responsible for extracting information, (d) sensor properties and calibration.

Platforms

The most elementary factor that governs the overall statistical properties of the measurements is the type of orbit the satellite is placed into. Earth orbiting satellites are typically launched in one of two orbits – the Low Earth Orbits of polar orbiting satellites (LEO) and the geostationary orbit (GEO). LEO satellites vary most in size from microsatellites carrying payloads of just a few kilograms to large observatories with payloads exceeding thousands of kilograms. LEO also typically carry one of two types of payloads – experimental one-of-a-kind sensors or prototype operational sensors and operational payloads designed with versions of the same instrument flown over many years on multiple satellites. Examples of the experimental class of missions are

NASA's Earth Observing System missions (EOS) and Earth System Science Pathfinder (ESSP) missions, Japan's ADEOS missions and ESA's Earth missions.² The basis for these missions is typically rationalized in terms of fulfilling climate observational needs, usually in the context of studying climate processes over finite periods of time. Further discussion of experimental satellites, including a historical perspective, can be found in Kidder and VonderHaar (1995), among other references.

Operational satellite programs of the USA include satellites in both LEO and GEO, whereas those of Europe and Japan, at present, are based solely on GEO, although the launch of the ESA-EUMETSAT Polar System (MetOp, <http://www.esa.int/export/esaME/index.html>) is imminent. The convergence of the US military and civil polar satellite programs has occurred forming the NPOESS program (<http://www.ipo.noaa.gov/index2.html>). The first launch of NPOESS is expected around 2008 and, when combined with MetOp, an internationally coordinated system of polar satellites will be established.

The GEO platforms are larger (thousands of kilograms) than most polar orbiters, and their ability to observe the same region of Earth almost continuously makes them ideal for observing the evolution of severe weather and other short-term phenomena. To date, the payloads of geostationary satellites consist of rudimentary imaging and sounding radiometers, although more advanced sensors are being planned beginning with the new imager of Eumetsat's MSG1.

Representativeness

The time–space sampling properties inherent to different satellites are fundamentally dictated by its orbit and the type and number of satellites that compose the observing system.

Geostationary satellites provide a more synoptic-like method of observing Earth; that is sensors on GEO effectively produce a snapshot of information observing large regions of Earth at the same time. Unlike the LEO polar orbiters, they do not provide information at higher latitudes. Despite the sampling limitation and the lack of advanced sensors, GEO data continue to play an important role in climate research. The International Satellite Cloud Climatology Project (ISCCP, Rossow and Schiffer, 1991; <http://isccp.giss.nasa.gov>), for example, collects and analyzes observations from the imager radiometers flown on operational GEO. ISCCP pieces together these GEO observations, augmenting them with data from polar orbiting satellites to produce a global distribution of cloud properties. ISCCP is one of the first climate projects to integrate multiple satellite observations of this type.

Polar orbiting satellites sample the Earth in a very different manner. These satellites observe Earth “asynoptically” such that different portions of Earth are observed at different times. Global fields are then created in such a way that the space–time properties of quantities are mixed. This creates problems when observing processes that vary irregularly on small space and short time scales, or when observing processes that possess diurnal variability. The latter model of variability is particularly troublesome given that key elements of the Earth's hydrological cycle possess pronounced diurnal variability. Under-sampling of such behavior introduces aliasing on the longer time-scales of primary interest to climate studies.

²More information about NASA's EOS, ESA's Earth observations and Japan's ADEOS programs can be found under the respective home pages of each program, <http://eospso.gsfc.nasa.gov/>, <http://www.eorc.jaxa.jp/ADEOS/>, <http://www.esa.int/esaSA/earth.html>

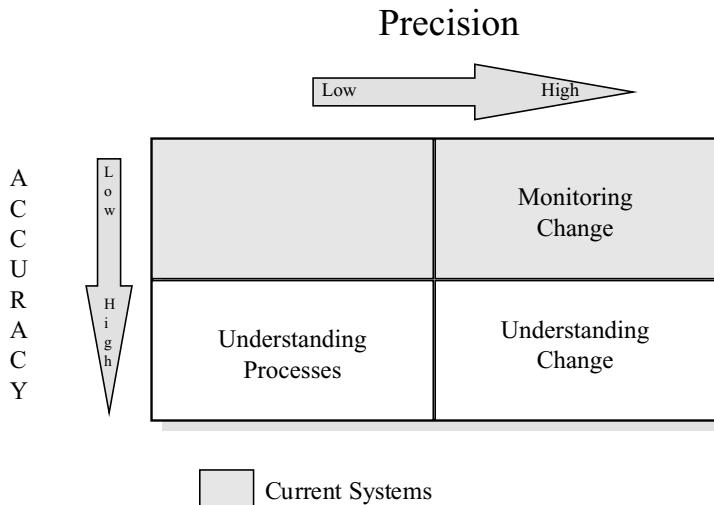

Figure S1 The climate measurement problem – understanding climate processes requires accuracy, monitoring climate change requires high precision and detection, and understanding climate change requires both.

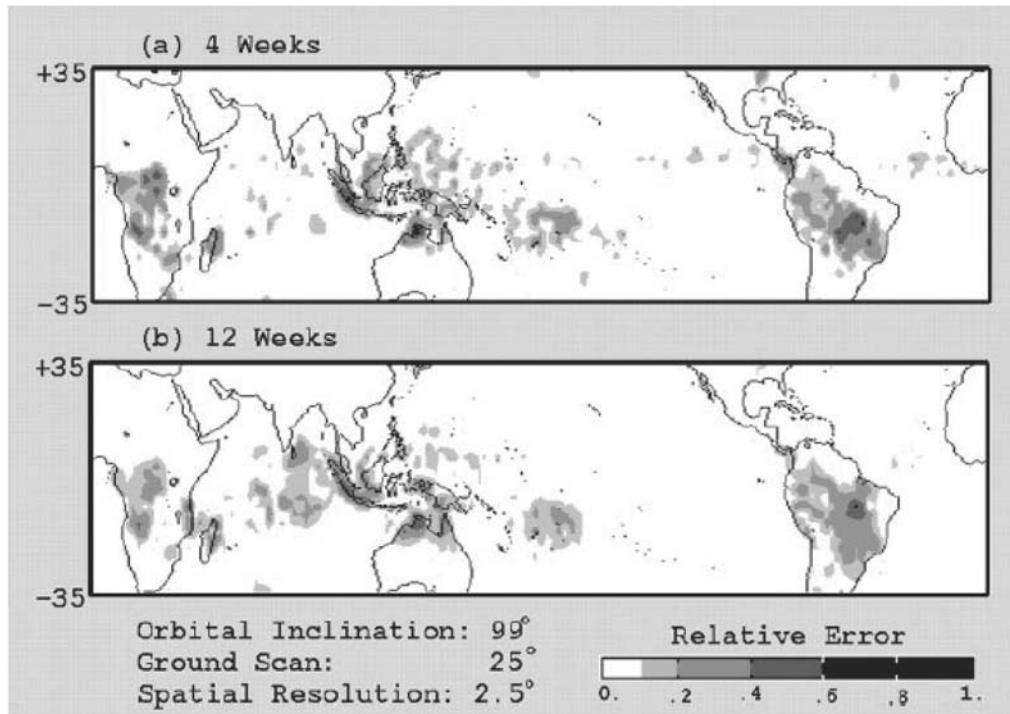

Figure S2 Illustration of the effects of asynchronous sampling on a proxy for convective precipitation. Shown is the sampling error in monthly and seasonal mean precipitation when observations from only a single polar orbiting satellite are used to sample precipitation. Large biases in excess of 20% arise because of aliasing of errors associated with the under-sampled diurnal cycle on the longer-term means (Salby and Callaghan, 1996).

The inversion process

An essential part of any remote sensing observing system is that part of the system that takes measurements and inverts them into geophysical parameters, such as temperature, moisture, and cloudiness, among others. This inversion process is

complex and almost always requires other sources of data. One example of such data is the *a-priori* information often needed to constrain the inversion process. *A-priori* data typically derive from some climatological database which inescapably enters the final product. Therefore the accuracy and stability of the

final product depend in part on the quality of the direct measurements and in part on *a-priori* and other data used in the inversion process. The observing system is thus more than the instrument on a satellite, being now defined as a complex system involving the satellite and its platform properties, the sensors on the satellite, the inversion process and all related data required for this process. Consequently, assessing the real quality of the observing system is difficult. An example of how these other factors associated with the inversion process affect climatological distributions of water vapor is described in Engelen and Stephens (1999). The problems faced in interpreting satellite data without proper understanding of the inversion process are also highlighted below in the discussion of trends in microwave brightness radiances.

Calibration

The suitability of space-based data for studying climate ultimately hinges on how well the sensor is calibrated. The purpose of calibration is to convert raw instrument output to appropriate physical units using known standard references in the translation. Calibration therefore establishes the absolute accuracy of the measurement. While some sensors are calibrated prior to launch, in-orbit instrument changes require that this calibration be carried out routinely on orbit. Such a requirement adds significant costs to instrument design, so often sensors are only partially calibrated in orbit, calibrated only prior to launch or not at all. Indirect methods of calibration, referred to as vicarious calibration, are needed. The approach to vicarious calibration varies from application to application and often involves comparison of a measurement to some model simulation of the measurement. We learn from the examples below that vicarious calibration is generally less accurate than direct calibration, and that it is often difficult to assign errors to the process. Despite these shortcomings, vicarious calibration, when conducted routinely and with care, serves a vital role in the use of satellite observations in climate research.

Calibration of the AVHRR

Satellite sensors degrade in orbit, initially because of the outgassing from the radiometer components and subsequently

because of continuous exposure to the space environment. Thus it is generally insufficient merely to calibrate sensors before launch. Issues associated with instrument degradation are illustrated in the example of channel 1 of the Advanced Very High Resolution Radiometer (AVHRR, <http://noaasis.noaa.gov/NOAASIS/ml/avhrr.html>). This channel, uncalibrated on orbit, is used with channel 2 to monitor land cover and vegetation. Post-launch calibration of these channels has been carried out using the vicarious calibration approach. One approach builds on the method developed for ISCCP and is based on: (a) the use of terrestrial targets that are radiometrically stable in time, (b) model simulations and (c) matching the performance of the AVHRR sensor to a known, calibrated sensor. The terrestrial target typically used to calibrate the visible channel 1 is a portion of the Libyan Desert which is taken to be stable. The absolute calibration scale is based on congruent aircraft/satellite radiance measurements over White Sands, New Mexico. Figure S3 shows the effects of how this vicarious calibration removes the significant and spurious downward trends of channel 1 solar radiances. The absolute accuracy of this vicarious calibration procedure is between 5% and 10%. Measure of precision, on the other hand, suggested by the rms deviation of the albedo, is significantly smaller than absolute accuracy.

WV channel calibration on Meteosat

Routine onboard calibration of operational-like sensors is carried out more as an exception than as a rule. Furthermore, the inflated size of the optics of imagers on GEO and the associated costs of calibration usually prevents direct calibration in orbit. Vicarious calibration has become a common procedure for calibrating operational GEO sensors.³ An example of this type of calibration for the Meteosat (<http://www.eumetsat.de>) water vapor channel is described at length by van de Berg et al. (1995). The procedure developed is to match in time satellite radiances to radiosonde data at selected locations where the quality of these data is maintained. A radiative transfer model converts these sounding data into synthetic radiances which are

³ Although the IR sensors of the GEO satellites are operationally calibrated in orbit, vicarious calibration is required to correct for unwanted effects.

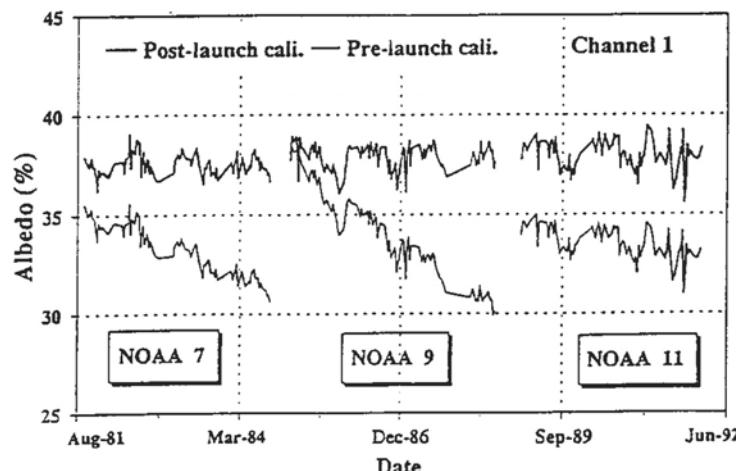

Figure S3 Albedo derived from AVHRR channel 1 over the southeastern portion of the Libyan desert (Rao, 1997).

then used to convert raw radiance counts to radiance. The absolute accuracy of this approach is difficult to estimate and requires some calibration of the model. The precision might be deduced from the variability of the calibration which is claimed to be at the 2% level or even slightly less (Schmetz, 1989; van de Berg et al., 1995).

The TOMS experience

The two examples described above refer to calibration of sensors that are either otherwise uncalibrated, and include no means of onboard calibration or whose calibration for one reason or another is incomplete. As noted in the above example, the intrinsic accuracy of this vicarious calibration is one issue, but the precision of the calibration is another. Unfortunately, the precision of the AVHRR calibration cannot be addressed when calibration scales are referenced to a single (or even limited number) of matched aircraft flights. High precision generally requires accurate description of an instrument time-dependent characteristics. Characterizing instrument stability must therefore be a major consideration in the design of monitoring systems.

Experience has shown that routine vicarious calibration has to be an essential ingredient of any monitoring system. A clear illustration of its value was provided in the example of detection of decadal ozone climate trends using TOMS data (Hilsenrath et al., 1997). The gradual degradation of optical components (chiefly the solar diffuser that served as part of the on-orbit calibration procedure) prompted the development of an *ad-hoc* vicarious calibration approach to account for instrument drifts. Like the case of water vapor radiances, the TOMS approach relied heavily on a surface observing network of Dobson spectrometers.

Constructing climate records from multiple satellites

The ISCCP, which began in 1983, was the first internationally coordinated project for integrating satellite radiance data from multiple platforms. This program involved routine collection of operational polar and GEO satellite data merged to produce homogeneous global radiances and climatological cloud information from these radiances. One of the key lessons learned from this activity concerned the difficulty associated with the maintenance of an observing network of multiple satellites for an extended period. The ISCCP notionally planned to make use of data from five geostationary satellites as well as data from a single polar orbiter in an effort to fill in the data voids over polar regions. Actual availability of data, however, fell below this hypothetical combination and the amount of data varied over the course of the project. The extent to which this has affected trends in ISCCP data is under investigation. The long-term trends evident in ISCCP data are not reproduced in other satellite cloud climatologies, such as the one PATMOS produced, based on AVHRR (Jacobowitz et al., 2003).

In addition to PATMOS, there are other examples of studies that combine data obtained from multiple versions of the same instrument flown on a series of NOAA polar orbiting spacecraft. Data from the TIROS Operational Vertical Sounder (TOVS, www2.ncdc.noaa.gov/docs/podug/html/c4/sec4-0.htm) accumulated over more than 20 years provide an important climate resource. The issues associated with combining these data concern the removal of sampling biases from the

data (representativeness errors) and the need to correct for different response characteristics of the different versions of the same instrument. The NOAA spacecraft carrying the TOVS are placed in a nominal sun-synchronous orbit, which means the time at which any particular location is fixed. Unfortunately these orbits drift at a disturbing rate (Figure S4), creating time-dependent representativeness errors and thus spurious trends in climate parameters extracted from the measurements.

TOVS channel 12 water vapor radiances

Bates et al. (1996) describe an empirical method to correct for sampling biases introduced by both satellite drift and lack of resolution of the diurnal cycle in a 20-year record of the TOVS channel 12 water vapor radiances. They also examine biases that arise through differences between the particular versions of TOVS flown on the different satellites. In a crude sense the satellite-to-satellite differences can be thought of as an indication of the precision of the data. For monthly mean data this difference is about 0.25 K, except for the NOAA-9 satellite which differs from the other satellites by 0.4–0.45 K. Assigning an absolute accuracy to the brightness temperature data is more difficult, requiring post-launch vicarious calibration procedures.

MSU temperature trends

Microwave radiance data, converted to brightness temperatures, obtained from the microwave sounding unit (MSU, see <http://orbitnet.nesdis.noaa.gov/crad/st/amsuclimate/amsu.html>) of TOVS have been interpreted as a direct measure of atmospheric temperature. The apparent lack of any trend in the time-series of these brightness temperatures have been much debated over the past decade since they appear to be contrary to arguments for global warming. MSU data have been combined by different investigators to produce extended time-series. The details of the temperature trends, however, depend on the nature of assumption made in correcting for instrument, sampling biases, and inter-satellite sensor differences. Two notable efforts are those at the university of Alabama Huntsville (UAH, e.g. Christy et al., 1995) and those by the Remote Sensing

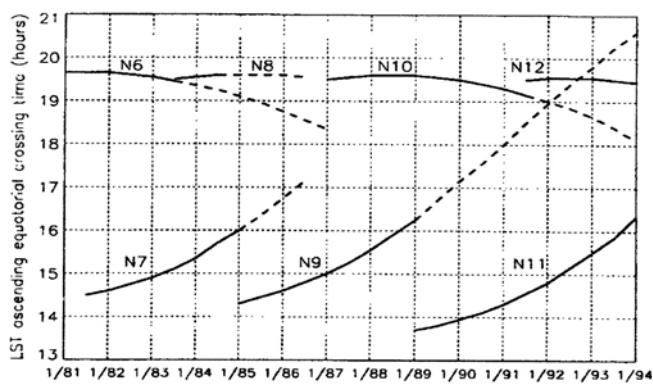

Figure S4 Ascending node equatorial crossing times for the NOAA series satellites up to 1994. The solid line is the period of operational coverage (from Bates et al., 1996).

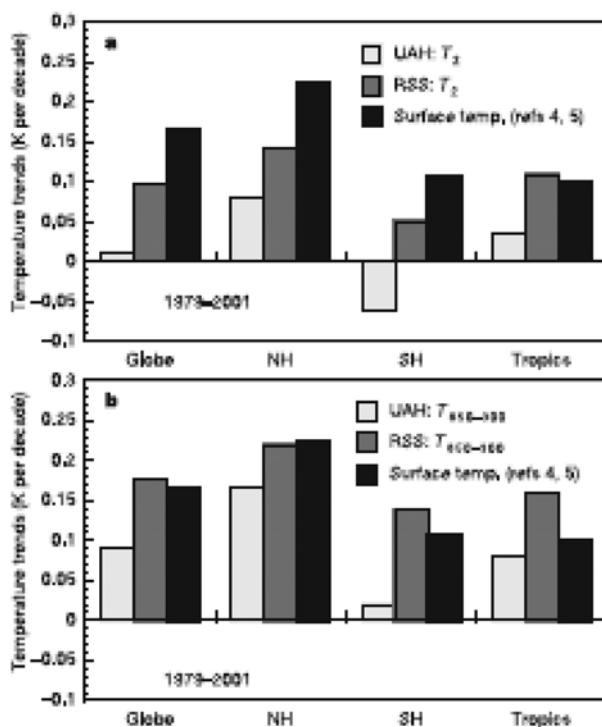

Figure S5 Trends in monthly mean temperature anomalies. (a) MSU channel 2 brightness temperature trend and (b), MSU-derived 850–300-hPa layer temperature trend for the globe, northern hemisphere (NH), southern hemisphere (SH) and tropics (30°N–30°S). The results using both UAH (version 5) and RSS data sets are shown (from Fu et al., 2004).

Systems (RSS, Wentz and Schabel, 2000), each producing different MSU temperature trends.

What tends to be lost in the debate on MSU trends is that most of the uncertainty and thus source of debate stems from the interpretation of the observations more so than the details of the MSU observations themselves. The inversion processes applied in studies that analyze these data are inappropriately primitive. The radiance data of channel 2, or simple combinations of channel data, are mostly used in trend analysis and are interpreted simply as a direct measure of the atmospheric temperature. The different channels of the MSU, however, measure emission from different portions of the atmospheric column. The problem is that this emission is smeared over almost the entire troposphere, including contributions from the surface and even portions of the stratosphere. Any trend or lack of trend in the brightness temperatures cannot be simply interpreted as a trend in actual temperature as changes to surface properties (soil moisture over land, wind over ocean and atmosphere properties, e.g. lapse rates, precipitation, among other factors) affect the interpretation of the data (e.g. Hansen et al., 1995; O'Brien, 2001). In a recent study Fu et al. (2004) develop a simple correction for the effects of changes in stratospheric temperatures on the MSU temperature trends. They difference between MSU channels 2 and 4 brightness temperatures which they empirically relate to the mean 850–300 hPa temperature.

Figure S5 shows the MSU channel 2 trends (T2, Figure S5a) and MSU-inferred T850-300 (Figure S5b) for the globe, northern hemisphere, southern hemisphere, and tropics (30°N–30°S) using both the UAH and RSS MSU datasets, as well as surface temperature trends based on *in-situ* observations. The trends of 0.01 K per decade (UAH) and 0.1 K per decade (RSS) for global mean are substantially smaller than the surface temperature trend of 0.17 K per decade. In the southern hemisphere the trend from UAH is actually negative. However, as shown in Figure S5b, the global trends of T850-300 are 0.09 K per decade (UAH) and 0.18 K per decade (RSS), which are about 0.08 K per decade larger than the corresponding channel 2 trends alone.

SAVANNA CLIMATE

The savanna climate is named for the mixed grassland and tree vegetation which is characteristic of the climate. On the margins with the rainforest, trees dominate the landscape but open areas of grass and shrubs are interspersed. In the drier areas grasses predominate with some trees scattered throughout. The distinguishing characteristics of the climate are the year-round high temperatures and pronounced wet and dry seasons. The climate is found marginal to the tropical rainforest climate and in most cases poleward from the rainforest. The climate occupies much of the area from the boundary with the rainforest climate to the Tropics of Cancer and Capricorn. Large areas of the tropics experience this climate. Most of Africa south of the Sahara Desert has a savanna climate, contrary to secular perception of Africa as a tropical jungle. Similarly, much of Southeast Asia and northern Australia has this climate.

The location of the savanna climate with respect to the general circulation is such that the area is subject to the seasonal migration of the equatorial convergence zone (ITCZ) and the subtropical high. The migration of the Hadley cell in the tropics is both pronounced and unpredictable. The ITCZ found between the northern and southern cells migrates as much as 40° in some areas. The migration is influenced by the extent of the landmasses in each hemisphere. Since the landmasses are more extensive north of the equator, the ITCZ tends to migrate farther in the northern hemisphere than in the southern. Therefore the savanna climate is generally found at higher latitudes in the northern hemisphere. In the southern hemisphere

the ITCZ and the accompanying precipitation does not go much beyond 15°S. In the northern hemisphere the system moves as far as 30°N.

Temperature characteristics

The temperature is controlled by latitude and the shift of the semipermanent pressure belts. The variation in the length of the day through the year is not too significant as the photoperiod varies from 11 to 13 hours. There is substantial variation in the angle of incidence. On the poleward margins the elevation of the sun varies as much as 45° from summer to winter solstice. Annual average temperature in this climate averages very nearly that of the rainforest climate, ranging from 18°C to 21°C. Monthly averages vary from high sun to low sun season, primarily as a result of the variation in insolation. The range in temperature from month to month averages between 2.8°C and 8.3°C. Sites on the margins of the rainforest have the least variation and those sites on the poleward margins the greatest variation. The greater variation on the poleward margins is due to the incursion of dry continental air which allows greater radiation heating and cooling. There is no winter as we know it in terms of temperature. The frost-free season is continuous, although temperatures as low as the teens have been recorded on the dry margins of the climatic region.

During the rainy season diurnal temperatures vary little as a result of the high humidity and even hours of daylight and darkness. In the dry season there is a greater exchange of radiant energy between the surface and atmosphere and so the diurnal range is greater. During this part of the year the diurnal range averages between 11°C and 17°C. As in other tropical climates the change in temperature from day to night is greater than the change from month to month.

Moisture characteristics

The most significant feature of the savanna climate is the pronounced seasonal moisture pattern. The wet and dry seasons are the result of the migration of the ITCZ. In the northern

Figure S6 Savanna with mixed woodland and grass as is found on the wetter margins of the climate, Chobe National Park, Zimbabwe.

Figure S7 Dry savanna dominated by grasses, Botswana.

hemisphere the ITCZ moves north of the equator in the months of May through September. The rainy season north of the equator occurs during these months. Atmospheric humidity is high when the ITCZ brings in moisture during the high sun season. During the low sun season dry air from the subtropical high replaces the more humid air. The change in humidity is visible in terms of cloud cover. When tropical maritime air is present clouds exist much of the time and clear days are infrequent. Low and middle forms of cumulus clouds are most prevalent. At this time of year dewpoints will range from 16°C to 22°C. In the dry season clear days are common and dewpoints range from 0°C to 7°C.

Average annual precipitation totals vary a great deal, and are not used to define the region. On the dry margins annual totals may diminish to as little as 25 cm. On the wet margins of the rainforest, especially where orographic lifting occurs, totals reach over 10 m. It is probable that the greatest annual average rainfalls occur in this climate. Variability from year to year is very high. The reason is that the total precipitation in a given year is subject to the extent of the migration of the ITCZ and the length of time the migration persists. The farther a site is from the mean location of the ITCZ the lower the mean annual precipitation tends to be, and the greater the relative variability. There are exceptions to the generalization that totals decrease with distance from the ITCZ, such as in the Assam Hills of India where some of the highest totals on the planet occur.

Seasonality of weather increases poleward, as might be expected. In a traverse away from the equator, the low sun precipitation begins to decrease first. The high sun precipitation remains as high as in the rainforest climate. Midway between the ITCZ and the tropical desert the low sun precipitation drops to near zero. Continuing poleward, the high sun precipitation declines until it is no longer sufficient to support woodland growth. The tropical steppe emerges at this point.

Grasses dwindle as high sun precipitation decreases. In the zone where precipitation becomes too little for grasses to grow, true desert appears. The rainy season is concurrent with the high sun and presence of the ITCZ overhead. The heating of the lower atmosphere favors the formation of thunderstorms, with the greatest frequency of thunderstorms in the afternoon hours. Occasional incursions of low-pressure systems bring more

widespread precipitation. Near coastal areas remnants of tropical cyclones can produce extensive precipitation. These storms do not penetrate very far inland. The dry season is a product of rather stable desert air originating from the subsidence and divergence in the semipermanent subtropical high-pressure zone. Extremely dry and dusty winds frequently move into and through these climatic areas. These go by a variety of names, but the Harmattan is perhaps the best known.

Seasonal variation

This climate has the most pronounced seasonality of precipitation of any of the climatic types. An example of the extremes that are reached is found in Asia. Rangoon Burma has a winter 3-month average precipitation of only 2.5 cm. In contrast there is a 3-month summer average of 190 cm. The seasonality increases northward along the coast of Burma where the seasonal averages are 3.8 cm and 432 cm. The maximum in Asia is reached at Cherrapunji, India, where in 2 winter months they receive an average of 2.5 cm and in 2 summer months 536 cm. Cherrapunji has recorded a 5-day total of 381 cm of rain, a 1-month total of 930 cm and a yearly total of 2647 cm.

Migration of the ITCZ north and south of the equator is highly variable from year to year. As a result the amount of precipitation received also varies a great deal. In addition to the marked seasonal variation in precipitation so there is great year-to-year variation in rainfall. In some years an area may receive much-above-average precipitation, and the next year practically none. Most of the inhabitants of this climate region are agriculturalists. The variability of rainfall, whether too much or too little, often causes serious social, political, and economic problems. When too much rain falls, crops are often washed out, or are subject to mold and mildew. Too little rain frequently results in drought.

Severe drought in turn results in famine. All regions of savanna climate have experienced drought and famine. Perhaps the greatest human struggles with drought-induced famine in the savanna climate have occurred in Asia and Africa.

SCALES OF CLIMATE

The types of climate that prevail over a region are determined by quantifying the prevailing weather elements whose periods of observation extend over a length of time. The longer the observation period the better the representation of the existing climate. The observed weather phenomena range over a broad spectrum of scales, but in reality none of the weather features is discrete, being part of a continuum. As a result, attempts to divide weather phenomena into distinct scales have resulted in disagreement with regard to the scale limits. The characteristics of the climatic spectrum depend on the nature of the exchange of heat, moisture, and momentum between the Earth's surface and the atmosphere. The physical laws that control the exchange processes between the Earth's surface and the atmosphere are the same everywhere. However, as with the problem of meteorological scale, so there is disagreement on areal scale in climatology. To illustrate this, two common approaches are outlined here. The first is a three-part division, the second includes a further category often identified in regional climatic studies.

The basic scales

The subdivision of the climatic phenomena provides a basis for dividing the climatology into micro-, meso-, and macroclimatology, and these features are revealed by having a network of

observing stations spaced at intervals of a few square kilometers, about 1 km, and 20 km or so respectively (Munn, 1966). The schemes of classification use horizontal and vertical characteristics as criteria as shown in Table S1 and Figure S8.

Microclimatology

Geiger (1966) emphasized the importance of the air layer below the agreed level of about 2 m of the atmosphere dealing with the "climate near the ground". In this level the horizontal extent of the circulation could be of the order of tens of kilometers or less. The magnitude of all the meteorological elements in this air layer is subject to vertical and horizontal changes. The vertical variations are due to the nearness of the ground, whereas the horizontal differences are due to changes in the nature and moisture of the soil, differences in surface slopes, and by the type and height of vegetation cover on it. Terms such as position climate, miniature climate, and spot-climate also can be adopted for microclimate but are somewhat ambiguous. Huschke (1959) viewed the microclimate as a fine climatic structure of the air space which extends from the Earth's surface to a height where the effects of the immediate character of the underlying surface cannot be distinguished from the general local climate. Munn (1966) was of the opinion that microclimatology is restricted in depth to the lowest hundred meters of the atmosphere, the surface boundary layer.

Mesoclimatology

In mesoclimatology the configuration of the ground, type of soil, and its vegetation cover are considered as features of the locality, which are subject to only slow changes over time, and determine the climate that prevails in a particular place and can be called local climate. The horizontal extent of this type of phenomena (mesoscale feature) is of the order of hundreds of kilometers. The concept of topoclimate proposed by Thornthwaite (1953) serves as an intermediate position between macro- and micro-climates; but Scaetta (1935) argued that the word topoclimate should be changed to mesoclimate, and Utaaker (1974) felt that the term topoclimate is more appropriate for local or mesoclimates since the topography of the land is the main causal factor responsible for local climatic peculiarities. In the opinion of Konstantinov et al. (1974), the formation of microclimate and local climate occurs under the influence of the underlying surface. Barrett (1974, p. 9) described the mesoscale phenomena as "local embroideries upon a larger, more generalized climatic picture".

Table S1 Scales of meteorological motion systems

Motion system	Approximate characteristic dimensions			
	Horizontal scale (km)	Vertical scale (km)	Time scale (n)	Total energy ^a
Macroscale				
Planetary waves	5×10^3	10	2×10^2 to 4×10^2	—
Synoptic perturbations	5×10^2 to 2×10^3	10	10^2	Average depression 10^{-3}
Mesoscale phenomena	1 to 10^2	1 to 10	1 to 10	Average thunderton 10^{-8}
Microscale phenomena	$< 10^{-1}$	$< 10^{-2}$	10^{-2} to 10^{-1}	Average windgust 10^{-17}

^a Base 1 = daily solar energy intercepted by the Earth.

Table S2 Scale of climate and its corresponding meteorological phenomena

Climate	Horizontal distribution (m)	Vertical distribution (m)	Example of climatic phenomena	Lifetime of corresponding meteorological phenomena(s)
Microclimate	10^{-2} – 10^2	10^{-2} – 10^1	Climate of greenhouse	10^1 – 10^4
Local climate	10^2 – 10^4	10^{-1} – 10^1	Thermal belt of slope	10^1 – 10^4
Mesoclimate	10^3 –(2×10^5)	10^0 –(6×10^3)	Climate of basin	10^4 – 10^5
Macroclimate	(2×10^5)–(5×10^7)	10^0 – 10^5	Climate zone, monsoon region	10^5 – 10^6

Source: From Yoshino (1975), p. 3.

Macroclimatology

This is concerned with broad features of the climates of substantial parts of the globe or most of a continent that are governed by the large-scale atmospheric circulation systems. It involves consideration of mean weather belts on a global basis. Large-scale disturbances of the order of thousands of kilometers, including the moving cyclones and anticyclones, define macroclimatic features of a continent. Regional macroclimatology deals not only with the variations in the amount, intensity, and seasonal distribution of the climatic elements but also the general tendency of synoptic weather features.

The high relief partly produces changes in the geographical distribution of a meteorological phenomenon.

Scale and local climates

A knowledge of the interrelationships between the climatic patterns and Earth surface, together with the influence of major atmospheric systems on even lower levels of the atmosphere, is of vital importance in understanding the nature of the macroclimatology of a continent.

In a review of climatic scale, Yoshino (1975) suggests that the term local climate is intermediate between microscales and

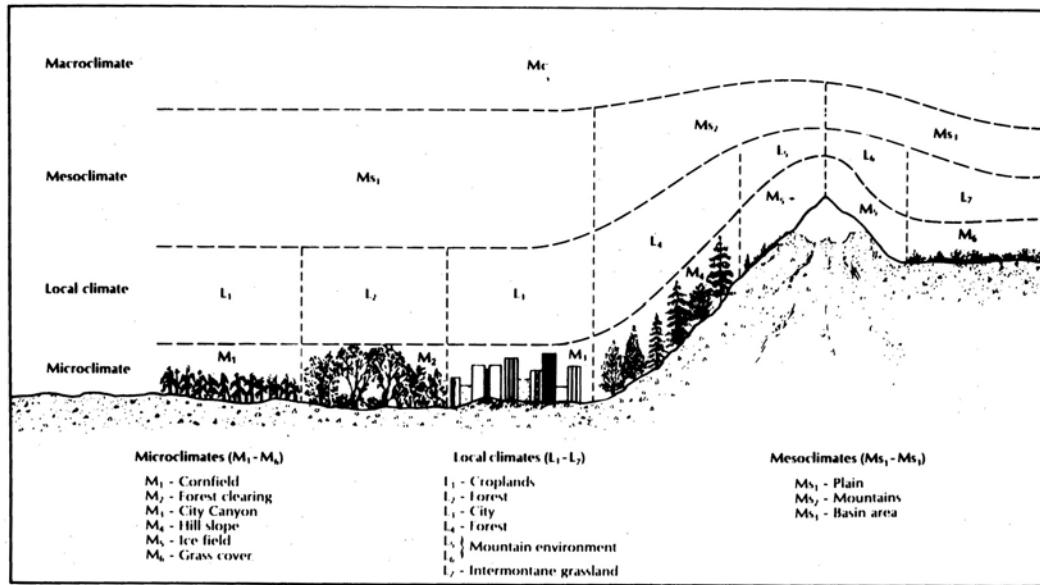

Figure S9 Area scales of climatic investigation.

mesoscales (Table S2). He suggests that the determining climatic factors in local climate are mesorelief, vegetation masses, etc. The characteristics of local climate are manifested in a layer of air observed at places tens and even hundreds of meters high. Further, mesoclimatic phenomena have been defined as those limited to the size of objects representing single independent units in geographical taxonomy, so that they are independent types of local climate. In the USSR there are two different views on scale; the first view is that local climate is a subclass between microclimate and macroclimate, and the second that local climate is nothing but a subclass of a microclimate in a broader sense in which local climate and microclimate are combined.

A graphic representation of the Yoshino scales is given in Figure S9.

SEA ICE AND CLIMATE

Sea ice forms in those portions of the high-latitude oceans where the water temperature falls below the freezing point (approximately 271.2 K). Once it has formed, a sea ice cover generally fractures into floes with typical dimensions of 10–1000 m. The fracturing is a response to stresses imposed by the oceans and the winds, which also cause the ice to drift at speeds of up to 10 km day^{-1} .

In the Antarctic, the area covered by sea ice varies seasonally from $2.5 \times 10^6 \text{ km}^2$ to $2.0 \times 10^6 \text{ km}^2$. Only slightly more than 10% of the ice survives the summer melt. The average thickness

is 1.5 m, and recent satellite observations indicate that typical concentrations are 60–85%. Because the ice is unconstrained by land at its equatorward boundary, it is free to interact with the open ocean. In contrast, much of the Arctic ice cover is constrained by land areas. The seasonal range is much less ($7.0 \times 10^6 \text{ km}^2$ to $14.1 \times 10^6 \text{ km}^2$) than in the Antarctic, and much of the ice has survived at least one summer melt season. The mean thickness of Arctic sea ice is 3–4 m, and concentrations are typically 90–100%.

Thus, there are fundamental differences between sea ice in the north polar and south polar regions. Obviously, the seasonal maximum is reversed because of hemispheric location. In the north polar regions the sea ice area doubles and ice extends to middle latitudes while in the south sea ice enlarges to four or five times the summer area but remains in polar regions. Southern hemisphere sea ice is restricted to the high latitudes by the Antarctic Circumpolar Current. This ocean current circles the pole, creating an even latitudinal distribution of heat in the southern ocean. The north polar area sea ice appears to be decreasing more rapidly than that of the south polar area although it is an older, thicker and more persistent covering.

Physical characteristics of sea ice

Expectations concerning a climatic role of sea ice are based on the profound surface changes associated with the formation or disappearance of an ice cover. First, the formation of sea ice increases the surface albedo (reflectivity of solar radiation) from 0.10 to 0.15 over open water to approximately 0.60 in the case of snow-free ice and values of 0.70–0.90 are typical of snow-covered ice. Second, the low thermal conductivity of sea ice results in an effective reduction of the vertical fluxes of moisture and heat at the surface, thereby insulating the atmosphere from the ocean. Third, because of the latent heat associated with melting and freezing, sea ice acts as a thermal reservoir that delays the normal seasonal temperature cycle. Finally, sea ice alters the salinity distribution and hence the density stratification of the ocean, both by the expulsion of brine during freezing and by the large-scale advective transport of low-salinity ice. Results of sea ice model studies show that the wintertime heat input to the atmosphere is one to two orders of magnitude larger over thin ice ($\leq 0.5 \text{ m}$) than over perennial ice.

Air-sea-ice interactions

Local effects

There is abundant evidence that fluctuations of sea ice extent are associated with *local* anomalies of air temperature. For example, annual air temperatures at the Antarctic island station, Orcadas, are highly correlated ($r = -0.77$) with the duration of ice cover at nearby Scotia Bay (Schwerdtfeger, 1970). Ice fluctuations at a single longitude generally are not, however, representative of those at other longitudes. There are also statistically significant correlations between ice extent and air temperatures observed several months later at stations near the ice edge. Sea ice may therefore be of modest predictive value at some locations.

Regional and interannual effects

In both the Arctic and the Antarctic, year-to-year fluctuations of ice extent have been shown to be associated with shifts of

cyclone trajectories and frequencies. The data suggest that cyclone development is aided by anomalously large areas of open water within the ice pack. However, the associations between storm tracks and ice fluctuations are not indicative of simple causal relationships. Feedbacks undoubtedly complicate the directionality, and other factors such as remote atmospheric forcing and oceanic processes are most likely involved. In fact, statistical studies of ice–atmosphere associations on the monthly and interannual time-scales indicate that the associations are often manifestations of atmospheric effects on the ice, i.e. equatorward winds and below-normal temperatures increase the areal extent of sea ice.

The effects of sea ice on the atmosphere can be isolated in controlled experiments with three-dimensional mathematical models of the atmosphere. One such experiment, based on parallel simulations in which the prescribed Arctic ice extremes differed by approximately 10° latitude, produced statistically significant differences of atmospheric sea level pressure (up to 8 mb), 700 mb geopotential height (up to 100 gpm), and tropospheric temperature (up to 8°C at low levels). Although the largest differences occurred in the general vicinity of the ice margin, substantial effects were found over Europe and the subtropical Atlantic and Pacific. The model results therefore suggest that a general advance or retreat of the ice edge by 500–1000 km could have a significant atmospheric impact over large portions of the northern hemisphere.

Long-term changes

Satellite detection of sea ice

Polar latitudes have historically made sea ice a difficult subject for scientific study. Prior to the 1970s the extent and variability of sea ice distribution was not well understood and it remained for successful remote sensing of the polar regions by satellites to provide meaningful answers.

Sea ice, prior to the advent of passive microwave imagery, was observed by satellites detecting visible and infrared radiation. Visible and infrared radiation from sea ice was often obstructed by cloud cover and visible signals were dependent upon daylight. This produced frequent and regular gaps in the data accumulation. Microwave detection is possible during all hours of the day, and is not hampered by non-precipitating clouds (Parkinson and Gloersen, 1993). There is also greater contrast between the microwave signals of ice and open water. These properties allow microwave radiometry to detect the large-scale characteristics of polar sea ice.

Changes in sea ice

Since the late 1970s there has been a well-documented decline in Arctic sea ice, and this may be related to global warming trends. However, some studies have shown that the decline is periodically reversed with several reversals occurring about the time of a maximum North Atlantic Oscillation (NAO) index. Parkinson (2000) reports that several studies show connections with the NAO and the spatially broader Arctic Oscillation. Accordingly, the possibility of close connections between the sea ice cover and major oscillatory patterns in the atmosphere and oceans requires more research to establish the real cause of changes in the areal coverage of sea ice.

Importance of sea ice changes

Two major changes occur during the transformation of seawater into ice: salt is rejected from the ice and heat is released. Salt rejection increases the salinity and density of surface waters, which can cause them to sink. Salt rejection during the formation of sea ice is a distillation process, allowing only a fraction of the initial salt content to become captured within the ice. Because evaporation and precipitation rates in the polar regions are low, the formation and redistribution of sea ice is the only effective way that freshwater is created and distributed in the polar regions (Aagard and Carmack, 1994).

As water changes its state from liquid to solid, the energy requirements necessary to maintain the new solid form are decreased. The extra energy is then released. Conversely, sea ice absorbs heat as it melts. The release and absorption of heat results in a moderation of temperature extremes. At present it is not possible to verify the effect of this on long-term climatic changes, yet it is on the longer time-scales that sea ice is most likely one of the key climatic variables.

Oscillations

SEA LEVEL RISE

Sea level is a fundamental climatological parameter that integrates diverse physical phenomena of the ocean–atmosphere system. The ocean surface adjusts to diurnal, seasonal, and interannual variations in atmospheric pressure, geostrophic currents, and coastal upwelling. Long-term changes in sea level derive from deformation of the Earth's crust as well as from eustatic and steric changes associated with climate change. At present, sea level is rising at around 1–2 mm/yr (Church et al., 2001). However, rates of sea level rise (SLR) are anticipated to increase by factors of 3–5 during this century, due to greenhouse gas-induced climate warming. Future SLR arouses concern because of potentially adverse consequences to coastal populations. These include land loss due to inundation and erosion, as well as increased frequency of coastal floods, with a rising water level. A knowledge of current sea level trends is essential in establishing an accurate baseline for future projections and for coastal zone management.

Causes of sea level change

Over the last few million years, changes in the extent of polar ice sheets and glaciers have periodically removed or added water to the world's oceans, affecting global sea level. *Glacial eustatic* changes in sea level are those caused by variations in ocean water volume from growth or melting of continental ice. At the peak of the last ice age, around 20 000 years ago, global sea level was 120 m below the present level (Bard et al., 1996). As the glaciers receded, sea level rose continuously for over 10 000 years, punctuated by at least three major meltwater pulses, around 13 800, 11 300, and 7800 years ago, when rates of SLR increased by factors up to 15–20 times present values (Cronin et al., 2002; Bard et al., 1996; Blanchon and Shaw, 1995). Although most ice melting ended by 6000 years ago, some minor melting of the Antarctic ice sheet may have persisted into the late Holocene. In many areas, sea levels fell since the mid-Holocene, caused by "siphoning", due to displacement of ocean water toward coastal regions subsiding at the periphery of former ice sheets and also weighted down by added meltwater (Peltier, 2001). However, the rate of SLR over the last few millennia has been rather low: ≤ 0.3 mm/yr (Table S3).

Although the ice contained in mountain glaciers represents only ~0.5 m of global sea level, they are highly sensitive to climate change. A worldwide compilation of data from glaciers suggests that the retreat of glaciers has added 0.2–0.4 mm/yr to observed SLR during the twentieth century (Table S3). Recent rates may be increasing. Shrinkage of Alaskan glaciers alone may have added the equivalent of 0.14 ± 0.04 mm/yr SLR, between the mid-1950s and the mid-1990s, and 0.27 ± 0.10 mm/yr SLR from the mid-1990s to 2000–2001 (Arendt et al., 2002).

The Antarctic and Greenland ice sheets contain enough water to elevate global sea level by ~70 m, so that even a small change in volume could create a significant effect. The behavior of ice sheets is determined by calculation of the mass budget (i.e. net losses via melting and discharge of icebergs vs snow accumulation), measurement of elevation changes over time by satellite altimeters, and modeling studies. During the 1990s, coastal glaciers in Greenland have been thinning rapidly, in contrast to gains at higher elevations, resulting in a net loss equivalent to

a sea level rise of ~ 0.13 mm/yr. In Antarctica, the West Antarctic Ice Sheet, especially around the Amundsen Sea, has been shrinking, adding ~ 0.1 mm/yr to SLR (Rignot and Thomas, 2002). In contrast, large sectors of East Antarctica are either stable or gaining mass, although the overall mass balance is still poorly constrained.

As oceans warm, water density decreases and, even if no meltwater were added from ice sheets or glaciers, the volume would increase, causing a *steric* change. Thermal expansion is a major contributor to modern SLR, adding an estimated 0.5 ± 0.2 mm/yr during the second half of the twentieth century (Table S3). (Changes in ocean salinity have a negligible effect on global sea level at present.) Because of the high heat capacity of the ocean, a considerable time lag may exist before surface warming has penetrated to depths. Thus, global sea level will continue to rise long after greenhouse gas concentrations have stabilized.

Crustal deformation introduces a major source of geographic variability into tide-gauge records. Although deglaciation ended over 6000 years ago, sea level has continued to change due to the Earth's delayed viscoelastic response to the redistribution of mass on its surface (*glacial isostasy*). The effects of these glacial isostatic adjustments (GIA) extend for thousands of kilometers from the centers of the former ice sheets (Peltier, 2001). Differential vertical motions over shorter distances are associated with tectonic deformation and fault displacements, particularly at convergent plate margins. More localized

crustal motions include land subsidence due to sediment loading by major rivers, such as the Mississippi or the Ganges–Brahmaputra, compaction of peat in coastal salt marshes, and overpumping of water, oil, or natural gas.

Changes in the amount of water stored in lakes and reservoirs, groundwater, and modification in land-use patterns that alter evapotranspiration and river runoff rates may also influence sea level. These human activities may have reduced river runoff by approximately $328 \text{ km}^3/\text{yr}$, equivalent to 0.9 ± 0.5 mm/yr of SLR (Gornitz, 2001). Alternatively, water sequestered behind dams may largely counteract other anthropogenic effects (Sahagian, 2000). These estimates carry significant uncertainties, due to limited historical data and simplifying assumptions. In the near future, satellite radar altimetry and gravity measurements will help quantify the global water mass budget and the extent of such anthropogenic transformations.

Recent sea level trends (last 100–200 years)

Variations in sea level are measured using a tide gauge, which is usually placed on piers. The tide gauge consists of a graduated staff to measure the rise and fall of water with the tides. Older gauges use a float operating in a stilling well, to dampen the effects of waves. More modern, automated systems employ acoustical signals to record the ever-changing water levels at 6-minute intervals (Figure S10). The tide gauge measurements are linked geodetically to a local fixed benchmark on stable

Table S3 Estimated sea level rise

Source	Minimum (mm/yr)	Mid-value (mm/yr)	Maximum (mm/yr)
Thermal expansion	0.3	0.5	0.7
Mountain glaciers	0.2	0.3	0.4
Greenland	0.0	0.05	0.1
Antarctica	-0.2	-0.1	0.0
Long-term glacial eustatic	0.0	0.25	0.5
Land water storage	-1.1	-0.35	0.4
Miscellaneous	0.0	0.05	0.10
Total	-0.8	0.7	2.2
Observed	1.0	1.5	2.0

ground. Global sea level data are compiled by the Permanent Service for Mean Sea Level (Spencer and Woodworth, 1993; <http://www.pol.ac.uk/psmsl/>). However, most records are too short or are too broken to be useful for climate studies. A time-series of at least 50 years, and preferably longer, is recommended in order to minimize effects of interdecadal fluctuations and to derive a meaningful long-term sea level trend (Douglas, 2001). Only 175 stations have nearly continuous series of ≥ 50 years. Furthermore, most usable stations are located in the northern hemisphere, particularly in Europe and North America. Thus, selection of an optimal record length becomes a trade-off between the number of sufficiently long records and geographical coverage.

Tide gauges measure *relative* sea level change, which includes shifts in the land relative to the sea surface, in addition to the recent climate-related signal. These vertical land motions introduce considerable spatial variability in tide-gauge records. Late Holocene sea level proxies (e.g. peats, corals, wood, mollusks, etc.) have been used to construct long-term sea level curves which include glacial isostatic and other geologic trends (Gornitz, 1995). Differencing the recent and late Holocene sea level trends provides a measure of the climate-related *absolute* sea level change. Geophysical models filter the glacial isostatic component from raw sea level data by computing gravitational changes induced by the global redistribution of mass, including both ice and water, caused by deglaciation (Peltier, 2001; Lambeck and Johnston, 1998). These models are calibrated by means of radiocarbon-dated geological proxies. The geophysical method is sensitive to assumptions of viscoelastic properties of the Earth's mantle as well as the thicknesses and melting histories of the former ice sheets. Neither methodology eliminates other sources of land motion, such as neo-tectonic displacements. Continuously-operating global positioning satellite (GPS) stations at or near tide gauges will measure vertical crustal changes. Nearly a decade of observations may be required to achieve the ~ 1 mm/yr accuracy for absolute sea level measurements.

Radar altimeters, such as those on board the ERS-1, Geosat, and TOPEX/POSEIDON satellites, measure ocean surface heights. By precisely tracking the satellite's orbit, the satellite's distance relative to the Earth's center can be established. A difference of these two measurements yields the absolute sea level. Satellite altimetry, especially since the launch of TOPEX/POSEIDON in 1992, has become a major tool for investigating interannual ocean basin variability, such as the El Niño-Southern Oscillation (ENSO) and sea level change (Nerem and Mitchum, 2001).

Mean global sea level, determined from tide gauges, and more recently from satellite altimeters, has been increasing by 1–2 mm/yr over the last 100 years (see Table S3). Recent measurements suggest a global trend close to 1.8 mm/year (Church et al., 2004). The observed rates are significantly higher than those of the past few thousand years, derived from geological data (Gornitz, 1995; Shennan and Woodworth, 1992; Varekamp and Thomas, 1998). Precisely dating the onset of this accelerated phase is difficult because of limited instrumental data prior to 1850 and proxy sea level data for the last 1000 years.

The disparity between observed sea level trends and the sum of individual contributing sources still needs to be explained (Table S3). The sea level trend of 2.5 ± 0.7 mm/yr detected by the TOPEX/POSEIDON altimeter is largely related to ocean thermal expansion during a period (1993–1998) strongly influenced by major ENSO events, and may therefore be unrepresentative

of longer-term sea level changes (Nerem and Mitchum, 2001). The longer-term (1955–1996) thermal expansion has been 0.5 ± 0.05 mm/yr (Cabanes et al., 2001). Along with mountain glacier retreat supplying close to 0.3 mm/yr during most of the twentieth century (Table S3), this accounts for less than 1 mm/yr SLR. The thermal expansion may be strongly enhanced at shallow coastal stations, which are therefore not truly representative of the world's oceans, leading to an overestimate in global sea level trends derived from tidal data (Cabanes et al., 2001). On the other hand, the eustatic contribution from small glaciers and the Greenland ice sheet may have been growing in recent years (Meier and Wahr, 2002; Rignot and Thomas, 2002).

Future sea level rise

Rates of SLR are anticipated to accelerate as future climate warms, due to increasing concentrations of atmospheric greenhouse gases. Diverse scenarios of greenhouse gas and aerosol emissions have been input into a suite of coupled Atmospheric–Oceanic General Circulation Models (AOGCM) by the Intergovernmental Panel on Climate Change (Houghton et al., 2001). The global mean sea level by 2100 is projected to rise by 9–88 cm over 1990 values, with a central value of 48 cm (for all scenarios). These values are slightly below those published previously by the IPCC, due to model improvements that show a smaller contribution from glaciers and ice sheets. However, recent observations suggest that these models may have underestimated the role of the cryosphere (Arendt et al., 2002; Meier and Wahr, 2002; Rignot and Thomas, 2002). Even after eventual stabilization of greenhouse gas concentrations, sea level will continue to rise, because of the time lag in ocean warming.

SEASONAL AFFECTIVE DISORDER

The decreasing daylight that heralds the coming of winter means for some people the onset of unpleasant and sometimes even debilitating symptoms. Some people experience mood swings and changes in level of activities that coincide with shifts in the seasons. In its most extreme form these changes constitute seasonal affective disorder (SAD). The most widely recognized form of SAD is the winter type (w-SAD) whose symptoms first appear in fall, gradually intensify into winter and then usually abate during spring. In addition to exhibiting the characteristic symptoms of non-seasonal anxiety and depression (hostility, anger, irritability), people with w-SAD also demonstrate atypical conditions. These different symptoms include increased rather than decreased sleep and increased rather than decreased appetite, which is often accompanied by a craving for carbohydrates. The latter behavior typically leads to weight gain. Another seasonal pattern of activity level and mood begins in late spring, intensifies in early summer and then remits in fall. In contrast to victims of w-SAD, people experiencing the summer form of SAD (s-SAD) tend to demonstrate

the typical symptoms of non-seasonal depression including a lack of sleep and poor appetite, leading to weight loss. The summer form of SAD typically occurs at lower latitudes whereas the winter form prevails at middle and higher latitudes.

Since the first documentation of SAD in the early 1980s, most research on this syndrome has focused on w-SAD. The considerably greater prevalence of w-SAD and the early identification of an effective treatment have stimulated greater research interest in w-SAD than in s-SAD. In marked contrast, knowledge of the less common s-SAD, which lacks a specific treatment, has advanced little since its discovery in the late 1980s. Consequently the remainder of this item will center on w-SAD.

Epidemiological surveys suggest that 1–4% of the general population of Europe and North America experience w-SAD, while as many as 20% exhibit subsyndromal symptoms (Wehr, 2001). Seasonal changes in this latter group are not severe enough to meet all clinical criteria for w-SAD (American Psychiatric Association, 1994). Studies consistently find a strong relationship with gender. Women with w-SAD outnumber men with w-SAD by four to one. Furthermore, women experience greater increases in overeating, weight gain, and increased sleep than their male counterparts. The winter form of SAD is more prevalent among young adults than adolescents and older adults. This age-related pattern of w-SAD contrasts with that of non-seasonal depression that is most common in the early 60s.

A number of studies have sought to identify the factors that influence the occurrence of SAD. Given the considerable seasonal changes in photoperiod at mid and high latitudes, logic suggests that the prevalence of w-SAD should increase with latitude. Recent literature reviews suggest, however, that this relationship is weak. Studies of the influence of climate and social-cultural factors on patterns of prevalence also have failed to demonstrate significant linkages. This inability to find consistent epidemiological relationships may be the consequence of the relatively small number of studies, limited sample sizes, and the reliability and heterogeneous nature of the methodology used in studies of prevalence (Haggarty et al., 2001; Mersch et al., 1999). Furthermore, the relatively mild symptoms exhibited by many SAD patients may obscure identification of causative factors.

Explanations

Scientists have proposed several explanations for the onset of SAD. An early hypothesis proposed that seasonal changes in photoperiod disrupted one or more of the body's rhythmic behaviors such as the daily pattern of change in blood pressure, body temperature, and activity level (sleep/wake cycle). Such endogenous rhythms of about 24 hours are called circadian (about a day) rhythms and are driven by an internal biological clock. The human biological clock has a period of about 25 hours, but varies considerably from person to person. In the absence of external clues, circadian rhythms increasingly go out of phase with the outside world. In the case of the activity/sleep cycle, for example, people awaken later each day. When persons who have been living in isolation for an extended period are then exposed to the day/night cycle, their biological clock and their circadian rhythms soon are back in phase.

The primary biological clock in humans resides in the suprachiasmatic nucleus (SCN), a small mass of tissue located

in the hypothalamus of the brain. The most potent synchronizer of this clock is bright light. A dedicated neural pathway (termed the retinohypothalamic tract) leads directly from the retina of the eye to the SCN. This tract, including the light-absorbing cells in the retina, differs from the pathway that mediates vision. The retinohypothalamic tract synchronizes the activities of the SCN with the natural cycles of day and night. In response to that cycle, the SCN coordinates via neurons the release of melatonin from the pineal gland, a pea-sized mass of nerve tissue located deep between the cerebral hemispheres. Melatonin plays a major role in the activity/sleep cycle. Darkness stimulates the release of this hormone whereas both dim and bright light inhibit its release. Melatonin levels, therefore, follow a circadian pattern, peaking around midnight and dropping to their lowest level around noon. Furthermore, the duration of nocturnal secretion of melatonin follows a distinct seasonal pattern with the period becoming longer in winter and shorter in summer. Sites that respond to the melatonin signal induce changes in physiology and behavior that vary with the duration of the signal; that is, the seasons.

Understanding of circadian rhythms led to the phase-delayed hypothesis for w-SAD. The theory proposes that w-SAD develops when circadian rhythms are phase delayed relative to the external clock or to other rhythms. Studies utilizing the most reliable measures of circadian rhythm phase change have shown evidence of a phase advance in w-SAD patients when they are exposed to light. Subsequently the atypical symptoms of w-SAD remit. There remains, however, a subset of SAD patients who do not have demonstrable phase-delayed circadian rhythms, do not require a phase shift for a response to light, or both. Therefore, other mechanisms must be playing a role.

Additional mechanisms

Another avenue of research on the cause(s) of w-SAD has focused on neurotransmitters, particularly serotonin, that are implicated in mood disorders. Like melatonin, serotonin levels exhibit a marked seasonality, albeit it in the opposite direction. Serotonin reaches its lowest levels during midwinter and its highest during midsummer. Given the role of serotonin in regulating hunger, low levels in midwinter could explain the typical tendency of patients with w-SAD to crave carbohydrates and gain weight during winter. Various lines of research, including the use of medications that enhance serotonin function in the brain, demonstrate a major role of the serotonin system in the clinical symptoms of w-SAD. Other research suggests that norepinephrine and dopamine (neurotransmitters in the same family as serotonin and implicated in mood disorders) also play some role in w-SAD.

Although preliminary in nature, emerging evidence suggests that genetic factors influence vulnerability to or protection from SAD. Studies of twins, for example, have found that the "atypical" symptoms of SAD are inheritable. A related line of study has focused on Icelanders, descendants of a population that was essentially isolated for much of the past 1000 years. Despite living at high latitudes, modern-day Icelanders have a significantly lower prevalence of SAD than populations residing at lower latitudes along the US coastline. A recent follow-up study conducted in Winnipeg, Canada, of two adult populations – one of wholly Icelandic descent and the other of non-Icelandic descent – found that the rate of SAD among the people of Icelandic descent was about half the rate of the non-Icelandic population. The authors of these studies suggest that

genetic adaptation to the long winter season occurred within the native Icelandic population. Other genetic studies have begun to find associations between patients with SAD and certain alleles of genes that are associated with the functioning of the biological clock and the brain's neurotransmitters such as serotonin.

Although substantial evidence continues to accumulate for the circadian phase shift and the serotogenic hypothesis of SAD, conflicting results suggest that SAD is a complex and diverse condition. Recent progress on determining the molecular mechanisms of the human biological clock and how it regulates circadian rhythms should provide important insights into the etiology of pathophysiology of SAD (Lam and Levitan, 2000).

Bright-light therapy is the first-line option for the treatment of patients with SAD. Patients typically are exposed for 2 hours to light-boxes emitting at least 2500 lx (one lux equals one lumen/meter). Administering treatments between 6 a.m. and 10 a.m. is recommended. If treatment during that period is not feasible, however, some patients benefit from early evening exposure. (With regard to the phase-delay hypothesis, the efficacy of evening exposure, although typically less than that of morning exposure, has been surprising.) Continuing treatment throughout the winter season prevents relapses. Responses to bright-light therapy are good to excellent. When properly administered light therapy has few adverse side-effects (eye irritation, headache, and nausea), all of which are typically mild and reversible. Usually a patient will respond to bright-light therapy within only 2–4 days. A full remission, however, may require several weeks. If a patient does not respond to bright light, prescription of an antidepressant drug is an alternative. Given current research, the best choice at this time is medication that influences serotonin activity. For persons seeking a more natural treatment, simply being outdoors an hour or two can make a significant difference, particularly in combination with exercise such as walking, jogging, or skiing. When indoors, persons with SAD should opt for a room with a window or bright artificial lighting. As a point of reference, indoor lighting should be typically 100 lx at home and 300 to 500 lx at work.

Although individuals who experience seasonally related changes in activity level and mood have been known since ancient times, the first systematic description of SAD and its treatment was not published until 1984 (Rosenthal et al., 1984). Since that milestone the number of studies has grown rapidly, and the field of study now encompasses contributions from epidemiology to molecular biology. Although we continue to learn more about the characteristics of the syndrome, its patterns of prevalence, and its causes, we now know that SAD is much more complex than originally thought. Such factors as improved design of epidemiological surveys of larger populations, advanced brain-imaging techniques, and further applications of molecular biology to the workings of the biological clock and its mediation of circadian rhythms will continue to lead to a greater understanding of the SAD syndrome and consequently its diagnosis and treatment.

Climate Comfort Indices
Seasons

SEASONAL CLIMATE PREDICTION

Seasonal climate is generally defined as the mean temperature and precipitation and other statistics of weather over a region for a 3-month period. Seasonal climate prediction aims to predict the climate anomalies (departures from normal) of coming seasons based on current conditions of the atmosphere, ocean and land surfaces. Seasonal climate prediction is of great societal interest. For example, if the major droughts around the world could be predicted in advance, it would lead to substantial savings for the economy of the countries affected by the droughts.

Climate prediction approaches have been evolving over hundreds of years. Earlier approaches were to identify some environmental indicators which could suggest likely abnormal climate in the next season. In the early twentieth century, as more and more meteorological data became available, scientists started to construct empirical models for seasonal climate predictions. Before the 1980s, however, these empirical models were mostly

based on statistical techniques, providing little understanding of the physical mechanisms responsible for relationships between current conditions and the future climate. In recent years, owing to the advances in numerical modeling and climate diagnostics in last two decades, numerical climate prediction models have emerged and statistical models have become more physically based, leading to improvement in prediction skill.

Predictability of seasonal climate

Since the equations controlling atmospheric motion are nonlinear and sensitive to initial conditions, errors in initial conditions, no matter how small, will inevitably grow and eventually lead to unskillful deterministic forecasts. All studies have led to a conclusion that the day-to-day weather fluctuation is not predictable beyond 1–2 weeks. While the predictability of the day-to-day weather is limited to such a short period, seasonal climate anomalies are found to be predictable for a much longer period in some circumstances and for some regions.

The predictability of seasonal climate comes from the slowly evolving upper oceans and land surfaces. The atmosphere is coupled with oceans and land surfaces by exchange of heat, water (liquid water or water vapor) and momentum. For example, the surface wind drives oceanic circulations, precipitation provides fresh water to oceans and land surfaces, and oceans and land surfaces in turn release water vapor and heat to the atmosphere. Because of the air-sea and air-land interactions, anomalies in oceans and land surfaces may cause anomalies in the atmosphere, and vice-versa. Since the thermal inertia of the upper oceans and land surfaces is much larger than that of the atmosphere, the fluctuations in upper oceans and land surfaces are much slower than the day-to-day weather process. The slower fluctuations can lead to longer-range predictions, hence providing a physical basis for seasonal climate predictability.

The most predictable seasonal climate anomaly is that associated with the El Niño and Southern Oscillation (ENSO). ENSO is a coupled ocean–atmosphere phenomenon. Its sea surface temperature (SST) manifestation is the episodic warming and cooling in the equatorial central and eastern Pacific at seasonal to inter-annual timescales (see Figure S11). These slowly evolving SST exert an influence on the tropical atmosphere by redistributing the surface heating, low-level wind fields, tropical convection and mid/upper troposphere heating. The atmospheric heating anomalies in tropics then force a planetary wave train of climate anomalies to a large area of the globe, in particular the Pacific/North America (PNA) region. Figure S12 shows the linear correlation between the tropical SST shown in Figure S11 and the global 500 hPa height for the January–February–March season, indicating the global climate impact of the ENSO phenomenon. Current researches have shown that ENSO is predictable several seasons in advance, and therefore the associated climate anomalies are also predictable to some degree with that time lead.

SST anomalies in other ocean basins are also found to be important in seasonal climate prediction. For instance, the tropical Atlantic Ocean is important for Brazil and western Africa, and the Indian Ocean is influential for eastern Africa, Southern Asia, and Australia.

As an example of the seasonal climate predictability resulting from the land surface feedbacks, the variability of the Asian summer monsoon is related to the winter snow cover over the Eurasia continent. In addition, a portion of the temperature and precipitation anomalies over the North American continent in the summer is caused by the soil moisture conditions in the spring.

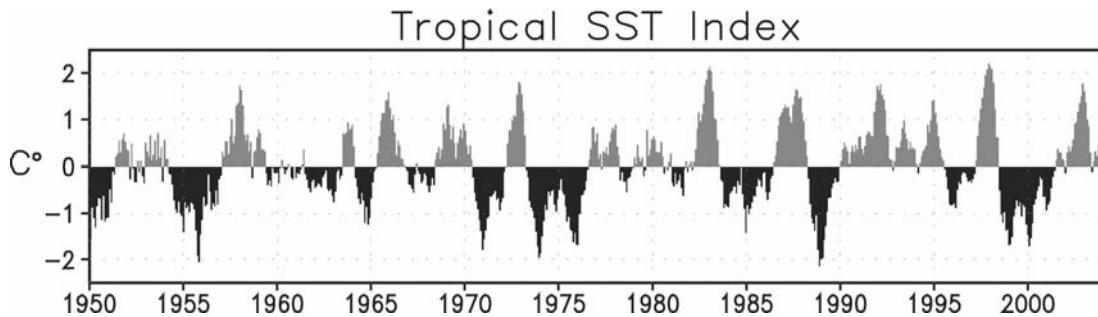

Figure S11 The time-series of monthly sea surface temperature (SST) anomalies averaged over the area ($180\text{--}130^{\circ}\text{W}$, $5^{\circ}\text{S}\text{--}5^{\circ}\text{N}$) for the period 1950–2003. Unit is degree Celsius. The large positive (negative) departures correspond to El Niño (La Niña).

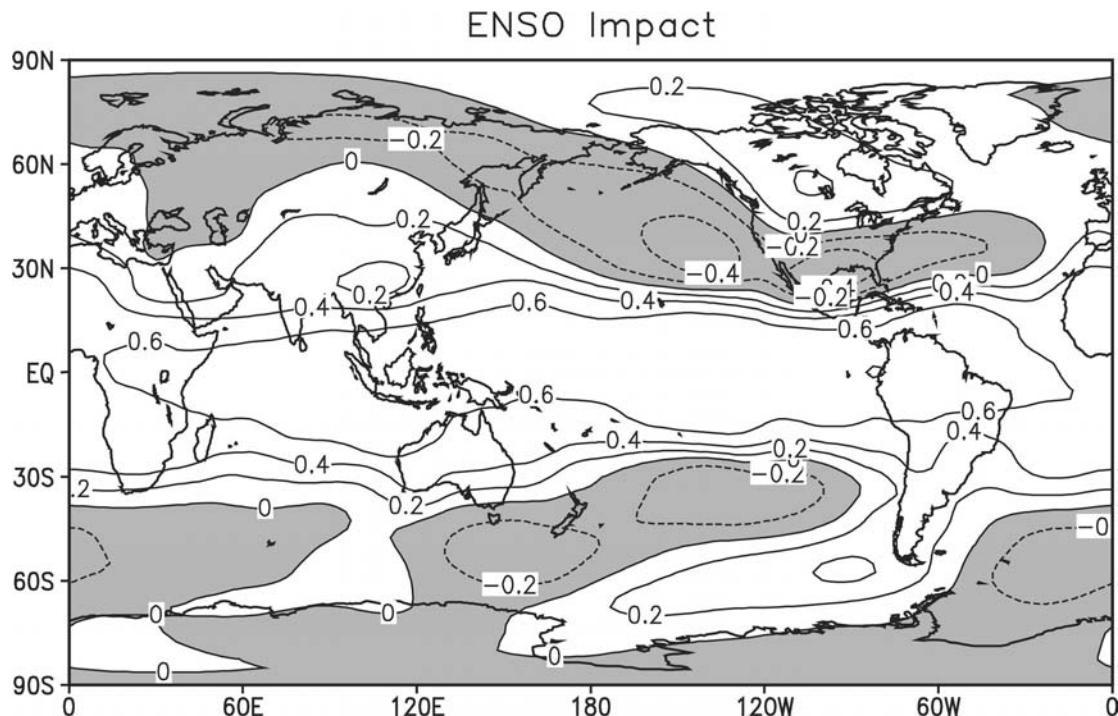

Figure S12 Linear correlation coefficient of 500 hPa height anomalies with the tropical Pacific sea surface temperature (SST) index shown in Figure S11 for the January–February–March seasons of the period 1950–2003.

Prediction methods

All the forecast models currently in practice can be grouped into two categories: statistical (or empirical) models and dynamical models.

Statistical models

Statistical forecast is based on the principle that the future state of a predictand can be predicted from antecedent and current values of predictor variables. Predictors should be selected based upon the understanding of the mechanisms of climate variability. Formulations of predictor–predictand relationships are ascertained by appropriate statistical techniques, including

testing on independent data or cross-validation. The statistical techniques widely used for this purpose include canonical correlation analysis, multiple linear regression, constructed analog, Markov process, singular spectrum analysis, singular value decomposition, linear discriminant analysis, and neural networks. The quantitative predictor–predictand relationship, representing the statistical model, is then used to calculate predictand values in real-time situations.

In most cases predictors for seasonal climate predictions are boundary forcing, such as SST, soil moisture and snow cover. Although sometimes atmospheric predictors are included, these predictors, except the quasi-biennial oscillation (QBO) in the tropical stratosphere, generally are boundary forced signals,

and thus do not mean that the atmosphere itself has sufficient memory to provide predictability at seasonal time-scales.

Dynamical models

There are two types of dynamical models currently used for climate prediction. One is atmosphere-only general circulation models (AGCM), the other one is coupled ocean-atmosphere general circulation models (CGCM). Both are based on the full set of the physical equations of motion. A two-tier climate prediction approach is used with AGCM, in which the SST are predicted first with statistical models or coupled dynamical models and then used to force the overlying atmosphere. In CGCM, similar to nature, both atmosphere and oceans evolve freely and influence each other. Being initialized appropriately, forward integrations of the coupled model directly result in seasonal climate predictions, in a more straightforward way than the two-tier approach.

Nevertheless, AGCM are still widely used in operational forecasting. The reason is that, in the current CGCM, SST tend to drift away from their realistic values as the integration proceeds, thus yielding unrealistic patterns of atmospheric anomalies. This problem is expected to be alleviated, and eventually solved, by continuing efforts in model development.

In both AGCM and CGCM, land surfaces are coupled with the atmosphere through land-surface process models, which determine soil moisture, surface temperature, snow cover and vegetation. Initialization of the land surface, however, remains a challenging problem because observations of soil moisture and evaporation, for example, are scarce.

Format and expressing uncertainty

Because the precise state of the atmosphere is unpredictable beyond 1–2 weeks, climate prediction is inherently probabilistic. For this reason seasonal climate predictions are usually issued in the format of a probability distribution, which indicates the chances that the temperature and precipitation will be *above*, *near* or *below* their long-term averages (climatology). For statistical forecasts, the probability distribution is estimated based on conditional probabilities indicating the relative frequency with which a particular climate pattern was observed under certain boundary forcing, such as El Niño or La Niña SST. For dynamical forecast the probability distribution is estimated by counting the ensemble members falling into the three categories. Calibration procedure as a post-process is usually applied here for reducing the influence of model biases.

Summary

Seasonal climate is potentially predictable in many regions of the world, especially the tropics. Its predictability comes from the slowly evolving underlying boundary conditions that force the atmosphere, such as SST and land surface characteristics. Skillful seasonal climate predictions, therefore, depend on the extent to which the relevant boundary conditions and their climate impact are predictable. Since the atmospheric motion is inherently chaotic, climate predictions need to be expressed probabilistically, indicating the likelihood of the climate shifting from its unconditional climatology. Currently, both statistical (empirical) and dynamical models are used in operational forecasts. These two types of model are compensatory for their different characteristics. The improvement of prediction skill in

the future will depend on the enhancement of the observing system and model development, in particular the improvement of the fully coupled ocean-land-atmosphere model.

SEASONALITY: ASTRONOMIC FORCING

The basic concepts of *season* are treated under that heading. However, in decadal or century-length time-series, distinctive alternations of seasonal characteristics are apparent, and seem to relate to astronomical forcing. The whole question is

controversial, however, being bound up with prejudice, politics and even religion, so it must be approached with care.

The best-established systematic variables are connected with the atmospheric pressure *oscillations*, which have long been recognized on the basis of two “nodes”, usually employing the data from two weather centers that have long been in operation. The usual parameters employed are mean pressure records, but closely related also are sea-level data (the “inverted barometer effect”).

As established by David Thomson (1995), analysis of instrumental records since AD 1659 shows that the dominant frequency of the seasons is one cycle per *anomalistic year*; that is, perihelion to perihelion (365.25964 days), which also controls the annual temperature cycle. Fluctuations of that temperature are “probably of solar origin”, but are partly by albedo feedback. False readings of seasonality are partially based on using the equinox-to-equinox standard, the *tropical year* (365.24220 days).

As customarily taken, “seasonality” is a response to the different attitudes of the Earth’s surface in the reception of the solar constant, approximately $1.95 \text{ cal/cm}^2/\text{min}$ (or $1.4 \times 10 \text{ ergs/cm}^2/\text{s}$). It should be remembered, however, that the sun’s spin rate is somewhat variable and this affects its radiation characteristics. Furthermore its emissions fall into two broad categories: (a) electromagnetic radiation, which travels at the speed of light in direct rays, so that its impact on the Earth’s surface (its “perpendicularity”) is limited to the equatorial belt and the boundaries of the tropics of Cancer and Capricorn (roughly 23.5°N and S). And (b) its particle or corpuscular radiation that reaches the Earth in the plasma of the solar wind, the particles being magnetized so that they are funneled in to the north magnetic pole and the auroral oval, following a spiral trajectory and with greatly variable energetic attributes (corresponding to the violence of the solar eruptions).

Another customary assumption is the alleged “11-yr” solar cycle, which is often grossly in error. Its long-term periodicity has a mean of 11.1212 yr, over some intervals being 11.17 yr, but over century intervals it has a ± 6 yr variability. No climatic time-series should ever be statistically locked in to an “11-yr” standard.

A second aspect of “seasonality” is the lunar factor. Whereas the solar year is closely related to the calendar year of 365 days, or the leap year mean of 365.25 d, further corrections have to have been made over centuries. In contrast, the lunar year may be $28 \text{ d} \times 336 \text{ d}$, or $28 \text{ d} \times 13$, thus 364 d, or $28 \text{ d} \times 14$, thus 393 d, with further computations relating to various religious calendars. For climatic purposes several lunar cycles, beyond the 28 d standard, are helpful:

1. *Perigee-syzygy cycle* (PSC, approx. 3 or 6 yr). During the twentieth century, phases fell near the vernal equinox on 19–28 September. The ascending node and perigee (closest approach in the 8.849-yr apsidal cycle) coincide in 1910, 1916, 1922, 1934...1982, 1988, 1994. They are antiphase in 1913, 1919...1985, 1991, 1997. In successive cycles they may be up to 1 week apart. Sanders (1995) remarked on the rough parallelism of the PSC with rainfall. The 6-yr period appears in many climate spectra, perhaps relating to the *ca.* 438 d. Chandler Wobble, and thus with the high-latitude atmospheric angular momentum.
2. *Quasi-biennial oscillation* (QBO, average 2.172 yr), the well-known weather cycle (Schove, 1983), but also a less

well-known periodicity of solar emissions. To create a seasonality, one looks to a 13.03-yr return ($\times 6$), which is also important in climatic time-series, including ENSO events. The QBO ($\times 96$) is also in a planetary alignment (Uranus–Jupiter–Venus synod) which resonates at 208.5227-yr intervals, and which is seen in tree-ring ^{14}C flux rates (Thomson, 1990). It is linked to innumerable other planetary geometries.

3. *Lunar nutation and declination cycle* (NDC, approx. 18.605 yr, $\times 5 = 93.025$ yr). Coincides with tidal maximum in AD 1912 and with climatic spectra (Pettersson, 1930; Currie, 1995). Declination brings lunar zenith to more than 1100 km farther north (or south), accelerating geostrophic currents such as the Gulf Stream (Lamb, 1977).

Tidal cycles and others are strongly seasonal, so that if the astronomical periodicity is an uneven number, such as 18.605 yr, its effect is less than is the case when its multiple epoch returns at the same season. In this case the fifth return (93.025 yr) brings the “seasonality” factor into more emphatic relief. Solar cycle warming, at times in phase with the lunar forcing, is a supplementary factor (see also below, item 4). Pettersson (1930), using tax returns from the Hanseatic League ports reflecting the herring fishery which is tidally responsive, was able to trace this 93-yr seasonal return through more than eight centuries, a truly remarkable use of economic proxies for climatic purposes.

4. *Arctic tidal/temperature resonance* (approx. 11–22–45–179–359 yr). First observed in Greenland ice core 0–18 temperature proxies, later this series was seen as beat frequency of lunar nodal/apsides (L_N/L_A) tide cycles and as a lunar–solar resonance in Hudson Bay temperature proxies (Guiot, 1987). A 185 “staircase” of isostatically uplifted beachridges on Hudson Bay, spanning about 8300 yr, was provisionally identified by Fairbridge and Hillaire-Marcel (1977) as a 44.5-yr solar cycle, but evidently a lunar resonance is also involved. A period of about 74.4 yr ($4 \times 18.6/7 \times 10.6$ yr) spans both lunar and (high-energy) SSC. Similar raised beaches are seen throughout the polar and subpolar regions (Fletcher et al., 1993; Müller et al., 2002).

All these high Arctic data are seasonally constrained by the universal presence of sea ice in winter, which inhibits wave action and evaporation, and reduces tidal effects. Care should be taken with “annual” statistics because of the seasonality asymmetry in the sub-Arctic, where a Jan.–Feb.–Mar.–Apr.–May interval is typical “winter”, whereas in the midlatitudes the seasons are more closely expressed as quarter-year units (NH): Dec.–Jan.–Feb. (winter); Mar.–Apr.–May (spring); June–July–Aug. (summer); Sept.–Oct.–Nov. (fall). In equatorial and monsoon lands the seasons are best identified with rainfall (in Australia “the Wet”). The “year” of an ENSO is particularly deceptive because its precursors appear in one statistical year while its full expression usually follows the “Christ-child” anniversary and falls in January.

Global aspects

Extreme asymmetry of land and sea on planet Earth renders the northern hemisphere to be more continental in climate and the southern to be more oceanic. Because of the present axial tilt and the state of the precession, the southern hemisphere receives

higher insolation at perihelion in early January, and the northern hemisphere has a milder seasonality on a 10⁵-yr time scale. Thus its continentality is moderated in both summer and winter.

Over long-term intervals one may note the seasonality controls of three fundamental resonance periods involving the astronomic beat frequencies and the mean sunspot cycle (SSC). The key beat frequency is a “lap” of the two largest planets, Saturn and Jupiter (SJL: 19.8593 yr), which has been described as the “heartbeat of the solar system” (Fairbridge and Sanders, 1987). Also involved is the mean beat frequency of the inner planets (IPC), 46.3383 yr, and the mean SSC, 11.1212 yr. The three resonance events are also exact, whole number multiples of the QBO, 2.1721 yr. The three resonances are:

1. 556.06 yr, “Stacey Cycle”: SJL × 28; SSC × 50; QBO × 256.
2. 278.03 yr, “Stacey Hemicycle”: SJL × 14; SSC × 25; QBO × 128.
3. 139.015 yr: SJL × 7; IPC × 3; QBO × 64.

Those three resonance intervals return at close to the Earth’s perihelion, at the present time in earliest January, but this date shifts over long periods. Thus the season shifts but the “seasonality” remains constant.

The ¹⁴C flux variance recorded in tree rings, inversely to the global temperature patterns, was about 4–5 times greater in the early Holocene (about 8000–9000 years ago) than today. The ¹⁴C maximum (temperature minimum) in 7590 BC was 8897 yr before the AD 1307 start of the Little Ice Age. Then, within one decade of 1307, the climate of Britain and western Europe swung from a medieval “medieval climatic optimum”, 2–3°C warmer than today, to one that much colder. Documentary evidence shows that, even in Britain, crops were devastated, and in central Europe monastic records indicated that in places half the population died of starvation. Comparable events occurred about a dozen times during the Holocene, but require more study.

The interval 8897 yr corresponds to 16 × 5560 yr (the basic planetary quadrature unit). The 556-yr alignment corresponds to 2 × 278 yr ($64^2 \times 0.0678784$ yr, the ISSR, inner sun spin rate); and 278 yr is the basic resonance period of the two largest planets, Jupiter and Saturn (14 SJL) and the mean sunspot period (25 SSC). Over the long term of 8897 yr, other synodic pairs are involved, e.g. NUL × 52, the 317-yr double synods (USL/SJL) × 28, the 12.783-yr NJL × 697, and exactly 2 × 4448.485 yr, the planetary quadrature cycle. This period is also exactly 800 × 11.1212 yr, the mean SSC. Therefore, sunspot periodicity relates both to planetary cycles and long-term climatic change.

From the evidence of the ¹⁴C flux oscillations, those of glaciogenic sediments in deep-sea cores in the North Atlantic and ¹⁸O fluctuations in Greenland ice cores, the swing from one climate-forcing extreme to the other was achieved in less than one century; probably much less. Sampling problems prevent a more precise evaluation. Even in terms of mean temperatures, the swing from one extreme to the other was in the order of 5°C.

In summary, “seasonality” is characteristically expressed by cycles of both solar and lunar causes. Worldwide time-series analyses of all sorts of meteorological and geophysical data disclose them both (Currie, 1995; and his lifelong bibliography). While the lunar cycles, mainly expressed in oceanic tidal data

and in their related atmospheric derivatives, are very regular, those dependent on solar activity are highly irregular.

Acknowledgments

Appreciation is expressed for many decades of scientific help from Clyde Stacey, John Sanders, Göran Windelius, Fergus Wood (all regrettably deceased), and others, as well as logistic help from Dr James Hansen (Goddard Institute for Space Studies, NASA).

SEASONS

Season is term for a period of time during the calendar year characterized by or associated with a set of coherent climatic activities or weather phenomena. Traditionally, there are four seasons of three months each winter, spring, summer, and autumn (fall), which are reversed in each hemisphere. The seasons are terrestrial responses to solar heating inequities that are governed by the dynamic relationship that exists between the Earth and the sun at various times during the year. The single most important heat source on the surface of the Earth is the sun. Endogenic heat flow from the earth's interior is three orders of magnitude less than solar energy. The amount of solar heat intercepted by the Earth can be expressed as a fixed value referred to as the solar constant, which is approximately 1.95 cal/cm²/min. Seasonality is a response to the different attitudes in the reception of the solar constant at locations on the Earth's spherical surface. Variations in the reception of the solar constant lead to terrestrial heating imbalances that are largely a latitudinal phenomenon. The amount of terrestrial heating accomplished by the sun depends on (1) the intensity of the sun's rays; and (2) the duration of time to which the land is exposed to the sun's rays. These two variables are regulated partly by the fact that the Earth is a sphere but mainly by the fact that the Earth is in orbit around the sun. Of greatest import are the orbital characteristics of the Earth, i.e., revolution, inclination, and parallelism.

Revolution

The Earth revolves around the sun in a slightly elliptical orbit (Figure S13). On or about 3 January the Earth is as close as 147 million km (91.5 million miles) to the sun. This closest position of the Earth to the sun is referred to as perihelion (Greek for

around the Sun) and occurs during the winter season of the northern hemisphere. On or about 4 July the Earth is as far away as 152 million km (94.5 million miles) from the sun. This most distant position of the Earth from the sun is called aphelion (Greek for *away from the Sun*) and occurs during the summer season of the northern hemisphere. This 3% disparity in the proximity of the Earth to the sun is responsible for approximately 7% more intense insolation (incoming solar radiation) in January than in July. This is evidently not the cause of the natural seasons.

Perpendicularity

Far more important than closeness to the Sun is another factor governing the intensity of insolation received at the surface of the Earth: the directness (perpendicularity) with which the rays of the sun strike the surface of the Earth. The more direct the solar beam, the greater its potential for heating. Because the Earth is a sphere, only one point on its surface can receive perpendicular (90°) rays from the sun at any one time. Stated differently, only one latitude on the Earth receives perpendicular rays from the sun on any one day of the year. When the sun has reached its zenith (highest altitude in the sky), the latitude on which perpendicular rays from the sun are received on a horizontal portion of the Earth's surface is called the declination of the sun. Figure S14 is a curiously shaped graph called an analemma that shows the declination of the sun for any day of the year. Only locations between 23.5°N and 23.5°S ever receive direct rays from the sun. The most effective solar heating is accomplished at the declination of the sun due to the directness of the solar beam there. The equator receives perpendicular rays twice a year (at the time of the crossover on the analemma) and is never farther than 23.5° of latitude from the location of perpendicular solar rays. Due to the relative directness of the solar rays at low latitudes, effective heating is accomplished annually and only slight seasonality is expressed there. On the other hand, at polar areas where the most indirect rays of the sun are received throughout the year, large seasonality is expressed. Not only a function of revolution and sphericity, perpendicularity of the sun's rays is also a function of the Earth's orbital characteristics, referred to as inclination and parallelism.

Inclination and parallelism

As the Earth revolves around the sun it describes a geometrical plane referred to as the plane of the ecliptic (Figure S15). While orbiting, the Earth rotates about its axis, which is inclined 23.5° from a vertical to the plane of the ecliptic. This tilt of the Earth's rotational axis is called inclination. The orientation of the rotational axis remains fixed in the direction of Polaris, the North Star, throughout revolution so that the Earth's axis is always parallel to itself at any moment in time (Figure S16). This orbital characteristic is called parallelism. The angle of inclination (presently 23.5° from the vertical to the plane of the ecliptic) is often referred to as the obliquity of the ecliptic. The Earth can be thought of as a gyroscope tilted 23.5° from a position normal to the plane described by its orbital path around the sun. Due to inclination and parallelism during revolution, the northern hemisphere (NH) is tilted some increment toward the sun for 6 months of the year, whereas the southern hemisphere (SH) is directed away from the sun. During the other 6 months of the year the NH is tilted away from the sun, and the SH is directed towards the sun. The hemisphere that is tilted in the direction of the sun receives more direct rays and is heated more effectively, resulting in the warm season of that

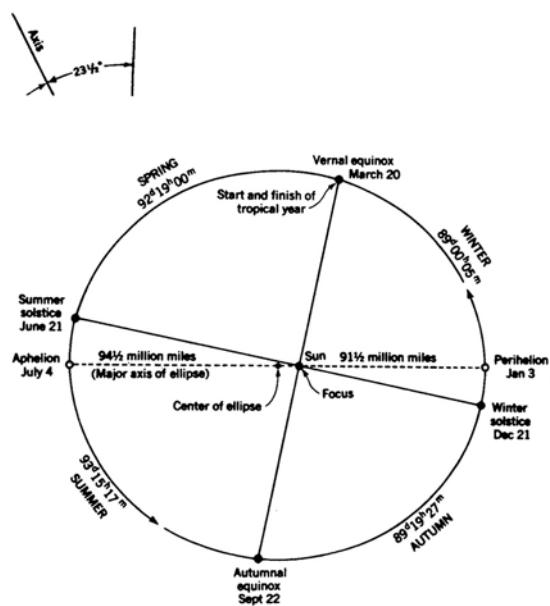

Figure S13 Dates of equinox and solstice: duration of seasons for the northern hemisphere.

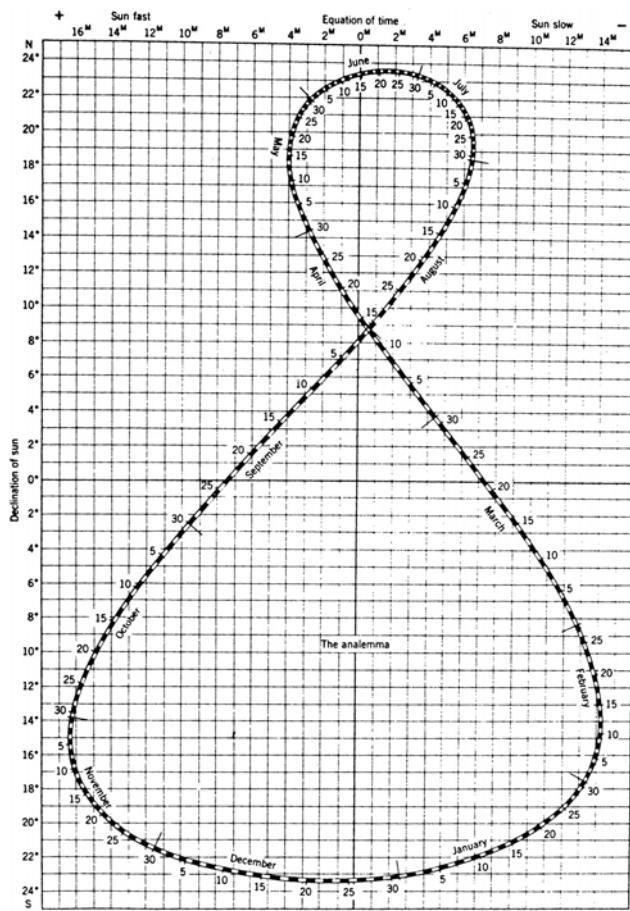

Figure S14 The analemma allows both the sun's declination and the equation of time to be estimated for any date in the year.

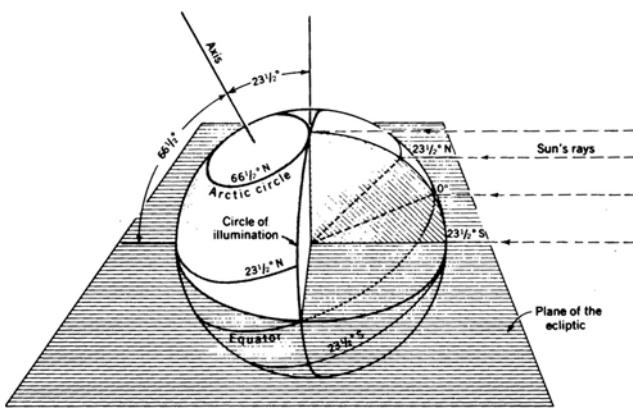

Figure S15 At winter solstice the sun's rays at noon are perpendicular at 23.5°S, the Tropic of Capricorn. All the region lying poleward of the Arctic Circle experiences night for the full 24 hours.

hemisphere. The hemisphere that is tilted away from the sun receives less direct rays and is heated less effectively, resulting in the cool season of that hemisphere. Thus, at the same period of time that the warm season occurs in the NH, the cool season occurs in the SH and vice-versa.

Duration of exposure

While a hemisphere is tilted toward the sun, the surface of the Earth in that hemisphere not only receives more direct rays from the sun but also lengthened time of exposure. Figure S17 contains sunset–sunrise diagrams from which estimates can be made of the number of daylight hours at any latitude during various times of the year. During the month of June when the NH is tilted toward the sun, sunrise occurs before 6:00 a.m. at all northern latitudes and after 6:00 a.m. at all southern latitudes. Similarly, during the month of June, sunset occurs after 6:00 p.m. at all northern latitudes and before 6:00 p.m. at all southern latitudes. During the month of December, when the NH is directed away from the sun, sunrise occurs after 6:00 a.m. at all northern latitudes and before 6:00 a.m. at all southern latitudes, whereas sunset occurs before 6:00 p.m. at all northern latitudes and after 6:00 p.m. at all southern latitudes. Earlier sunrises and later sunsets of the hemisphere that is tilted in the direction of the sun result in longer daylight hours. These lengthened time exposures, coupled with more direct rays of the sun, lead to the terrestrial heating imbalance that causes the seasons across the globe.

The march of the seasons

On or about 21 June the Earth arrives at a point in its revolution about the sun when the sun's perpendicular rays are received in the NH at 23.5°N , the Tropic of Cancer (Figures S16 and S18a). This marks the northernmost latitude to receive perpendicular solar rays (Figure S14). At this time and place the perpendicular rays of the sun are said to stand still in their northward migration. This is referred to as the June solstice (Latin for *Sun stand still*) and marks the beginning of summer in the NH and winter in the SH. Further orbital motion of the Earth in its inclined and parallel attitude results in the southward migration of the perpendicular rays from the sun so that 3 months later, on or about 21 September, the sun's perpendicular rays strike the surface of the Earth at the equator (Figure S18b). The inclination of the Earth's rotational axis is neither directed toward nor away from the sun and heating of the NH and the SH is accomplished impartially. With the declination of the sun at the equator, there are 12 hours of daylight and 12 hours of nighttime in both hemispheres. This time is referred to as the September equinox (Latin for *equal night*) and marks the beginning of autumn in the NH (autumnal equinox) and the beginning of spring in the SH. Continuation of the Earth in its orbit results in the SH being directed toward the sun. The most direct rays from the sun are received in the SH, causing preferential heating there. On or about 21 December the perpendicular rays of the sun are positioned at 23.5°S , the Tropic of Capricorn (Figure S18c). This latitude marks the southernmost location to receive perpendicular rays from the sun. This time is referred to as the December solstice, after which further orbital motion of the Earth results in the northward migration of the sun's perpendicular rays. The December solstice signals the beginning of the winter season in the NH and the summer season in the SH. With more orbital motion, the perpendicular rays of the sun do migrate equatorward where 3 months later, on or about 21 March, the perpendicular rays of the sun strike the surface of the Earth at the equator. This is the March equinox and marks the beginning of spring for the NH (vernal equinox) and fall for the SH. Thus, the seasons advance every year in an organized manner in both hemispheres with spring following winter, summer following spring, fall following summer, and winter following fall.

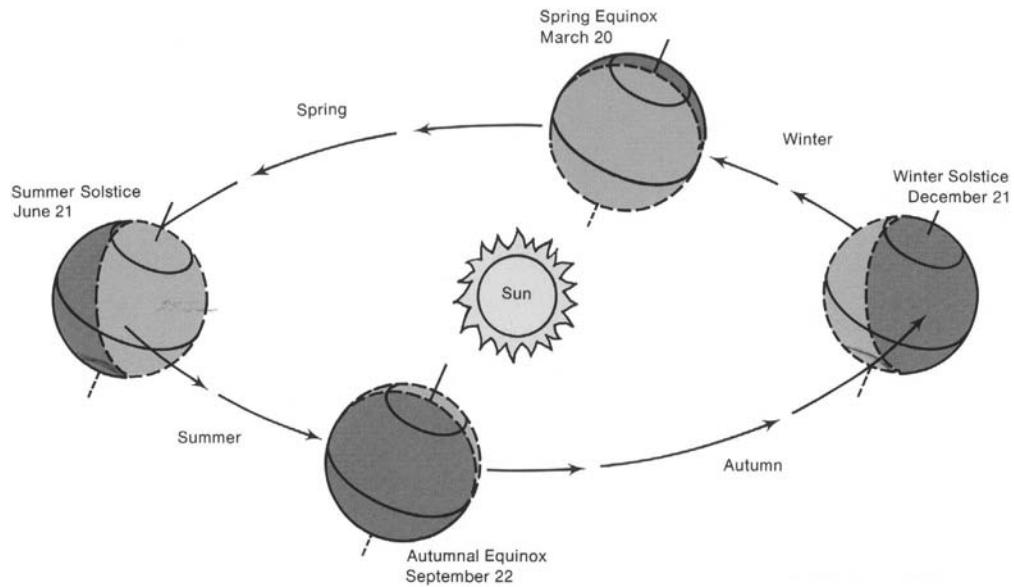

Figure S16 Revolution of the Earth about the sun. The relative variation in the inclination of the Earth's axis of rotation with respect to the sun is a principal cause of the seasons (after Strahler, 1971).

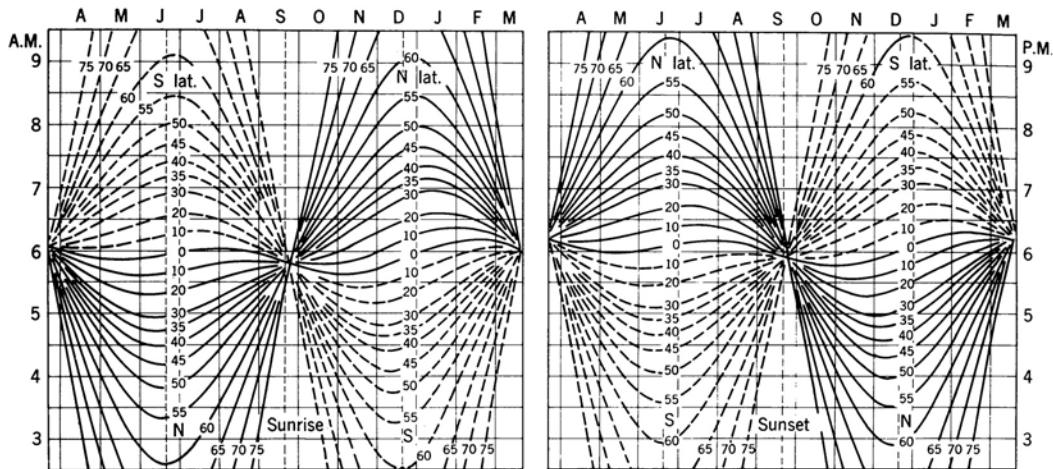

Figure S17 Sunset–sunrise diagram.

Land of the midnight sun

Nowhere are the various seasons less expressed than at the equator and more expressed than at the poles. Because the Earth is a sphere, only half of it is ever illuminated by the rays of the sun. At the sun's distance away from the Earth, its rays are approximately parallel as they are intercepted by the spherical Earth (Figure S18). The dividing line between the sunlit portion and the darkened portion of the Earth is called the circle of illumination. On the dates of the equinoxes, the circle of illumination passes through the poles resulting in 12 hours of daylight and 12 hours of nighttime at every location on the Earth (Figure S18b). Although the length of daylight and nighttime is equal everywhere across the Earth, the angle of incidence (the angle at which

the rays of the sun strike the surface of the Earth) varies as a function of latitude. At the equinoxes when the angle of incidence is 90° (perpendicular) at the equator, it is zero (tangential) at the poles. On the dates of the June and December solstices the circle of illumination passes through 66.5°N, the Arctic Circle, and 66.5°S, the Antarctic Circle. This causes the two hemispheres to be disproportionately illuminated and heated. At the June solstice the area of the Earth's surface between the Arctic Circle and the North Pole is continuously illuminated during rotation, whereas the area of the Earth's surface between the Antarctic Circle and the South Pole is continuously darkened (Figure S18a). This results in 24 hours of daylight for all locations higher than 66.5°N and 24 hours of nighttime for all locations below 66.5°S. At the

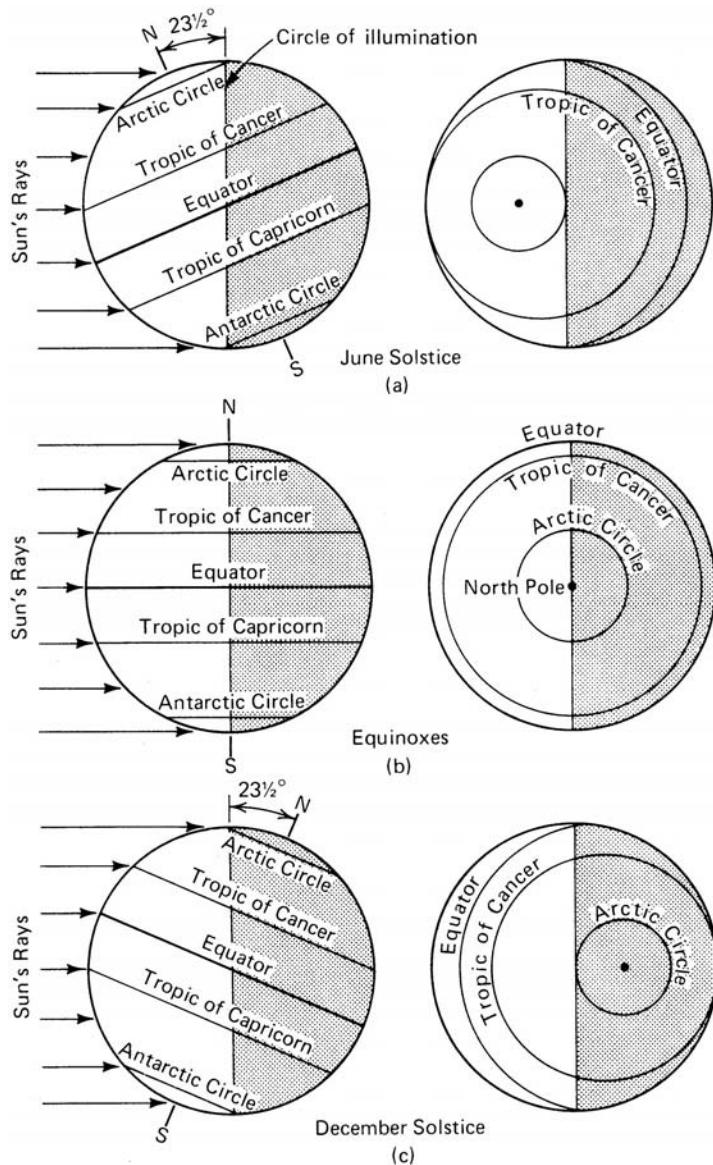

Figure S18 Characteristics of the summer and winter solstices and equinoxes (from Lutgens and Tarbuck, 1979).

December solstice it is the area of the Earth's surface below the Antarctic Circle that receives 24 hours of daylight, whereas nighttime prevails in the NH above the Arctic Circle (Figure S18c). Both poles receive 24 hours of daylight for a continuous 6 months of the year. The polar areas remain relatively cool year-round due to the low angle of incidence with which the solar rays strike the surface of the Earth.

Delineation of the seasons

With polar exceptions the identification of four periods of time with coherent climatic activities can be a difficult task. Barry and Perry (1973) suggest that adherence to just four seasons of the year is a gross oversimplification and that the actual seasons

of the Earth are many more in number. Table S4 contains the average beginning dates of the natural seasons as identified by various studies. Although there is some disagreement about the average beginning dates of the seasons, each of the studies identifies more than the traditional four natural seasons. The recognition of the seasons is further complicated by regular recurrences of seasonally anomalous periods of weather called singularities. Singularities vary in length but are most frequently expressed for a week or two. In many climatic records of the NH, a general warming trend is recognized during late October or early November. This period is called the "Indian Summer" in North America and is known by other names in various parts of the world. Another popularized singularity that occurs in the NH is that of a warming period in early to middle January. This warming trend is referred to as the January Thaw,

although surface temperatures often do not reach the melting point of water.

For long-term global climate studies it is often convenient to designate winter as DJF; summer as JJA and so on. In annual statistics, December is often set forward to the following year. When astronomical seasons are involved, their recurrence time may be greatly amplified in climate effect by the season. Thus, the quasi-biennial oscillation (QBO) of 2.172 years, will only return at the same season after 13 years (2×5 Biennial + 1 triennial)

Associated seasons

Complementing the above astronomically defined natural seasons are a host of related physical and cultural seasons whose activities are made possible by the expression of the natural seasons. The frost-free season refers to the time period between the last killing frost in the spring and the first killing frost of the fall. This time period is also referred to as the growing season and is often subdivided into smaller units of time, including the planting season, sprouting season, and harvesting season. Climatically, various elements of the weather are often temporally concentrated, making possible the identification of a wet-dry season, hot-cold season snow season, and a hail season, to name a few. Generally, a severe weather season is recognized in the North American continent by the occurrence of tornadoes in the late spring-early summer of the year, whereas a hurricane season occurs most often in late summer. Culturally, many human activities are related to the climatic events expressed during the natural seasons, i.e. tourist season, skiing season, construction season, and various sports-related seasons.

SENSIBLE HEAT

Sensible heat refers to heat that can be "sensed" by a thermometer or felt by an individual. The temperature of a parcel of air is defined as the average kinetic energy of its molecules. As more energy is added to a parcel of air, the molecules move faster (obtain more kinetic energy), which we interpret as an increase in its temperature. Consequently, the sensible heat of an air parcel is directly related to the temperature of the parcel.

In contrast to energy transfer through radiation exchange (both solar and terrestrial radiant energy) and latent heat (stored potential energy because the water is in the vapor state), sensible heat flux includes the transport of energy through conduction (molecular diffusion) and convection (moving air currents). Turbulent atmospheric motions dominate the surface boundary layer such that convection dominates the sensible heat exchange, except for within a millimeter of the surface.

Generally, interest focuses only on changes in the sensible heat and not with its absolute magnitude. Mathematically, if the pressure is held constant, the change in sensible heat (ΔH) can be related to the change in temperature (ΔT) by

$$\Delta H = c_p \Delta T$$

where c_p is the specific heat at constant pressure and, at 0°C, equals approximately 1.0 joules per gram per °C for dry air, 1.95 joules per gram per °C for water vapor, and 4.22 joules per gram per °C for liquid water. To the atmospheric physicist the sensible heat of a parcel of air is equal to its specific enthalpy, a thermodynamic property given by the First Law of Thermodynamics.

The pole-to-equator temperature gradient (warm equator and cold poles) causes a net poleward transfer of energy through sensible and latent heat fluxes as well as transport of heat through ocean currents. Of these three, however, sensible heat is the dominant transport mechanism, accounting for about half of the total poleward energy transport in the tropics and midlatitudes and virtually all of it in the higher latitudes. Tropical deserts exhibit the largest exchange of sensible heat to the atmosphere.

SIBERIAN (ASIATIC) HIGH

The Siberian (Asiatic) High is a semipermanent cell of high pressure centered poleward of 45°N in northeastern Siberia. It is one of the major centers of action during the winter in the northern hemisphere (Rossby, 1945).

The influence of the high is rarely felt above 2400 m (8000 ft), as it is made up of cold, dense air. The axis of the high tilts strongly southward as the intensity decreases. No indication of the sea level high is present at the 3000-m (10 000-ft) level (Petterssen, 1969).

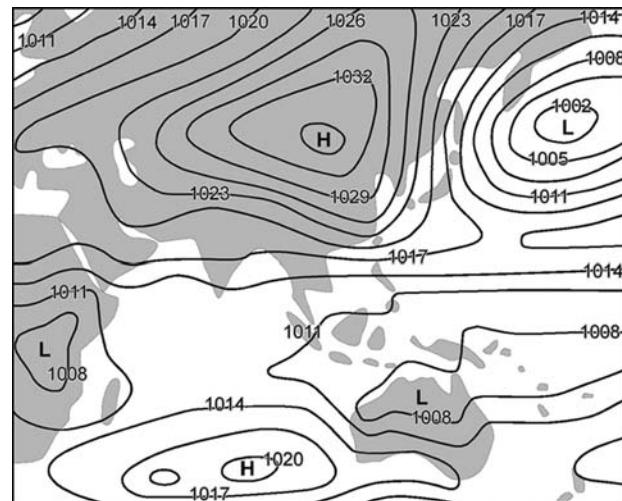

Figure S19 Mean January sea level pressure showing location of the Siberian High.

Daily synoptic weather maps for the northern hemisphere show many moving high- and low-pressure systems related to the interaction of cold and warm airmasses along the polar front. These moving disturbances can be eliminated by constructing mean charts, thereby delineating clearly the semipermanent nature of the Siberian High.

As shown in Figure S19, the Siberian High has a mean January sea level pressure of 1035 mb (30.56 in), 22 mb (0.64 in) above the mean sea level pressure of 1013 mb (29.92 in) for the world. This rather high mean pressure is attributed to the extensive continental cooling during winter of the vast Asiatic land mass (44 134 000 sq km; 17 040 000 sq miles). Indeed, the highest pressure ever recorded on Earth occurred under the Siberian High. On 31 December 1968, a pressure of 1084 mb (32.01 in) was measured at Agata, Siberia (66.83°N, 98.71°E) during an extremely cold period (Allaby, 2001). By contrast, the weaker thermal influence of the smaller North American landmass (24 063 000 sq km; 9 300 000 sq miles) results in an attenuated and divided anticyclone of 1020 mb (30.12 in) (Willett and Sanders, 1959).

The cold, dry air that develops over Asia during the winter is limited on the south by the Himalayas and other mountain ranges extending westward toward southern Europe. The mountain ranges along the eastern coast of Asia afford some restriction to the eastward spread of the cold air, whereas no major obstacles exist on the western side to prevent warmer air coming from the Atlantic. As a consequence of these topographical configurations, the Siberian High is further removed from the maritime influences of the western coast. Generally, the high covers the large area from the mountain slopes around the Caspian Sea to the Anadyr range in northeastern Siberia, centering around the Baikal region. The high is so powerful that the subtropical high-pressure belt is completely submerged (Petterssen, 1969).

The Siberian High tends to be displaced toward the Pacific side of Eurasia during periods of strong circulation. Westward displacement in the direction of Europe occurs during alternating periods of weak circulation. Weather conditions are deeply affected by these pressure changes. For example, northwest Europe will experience an outflow of extremely cold, dry continental air from Asia during the time of weak circulation (Rossby, 1945).

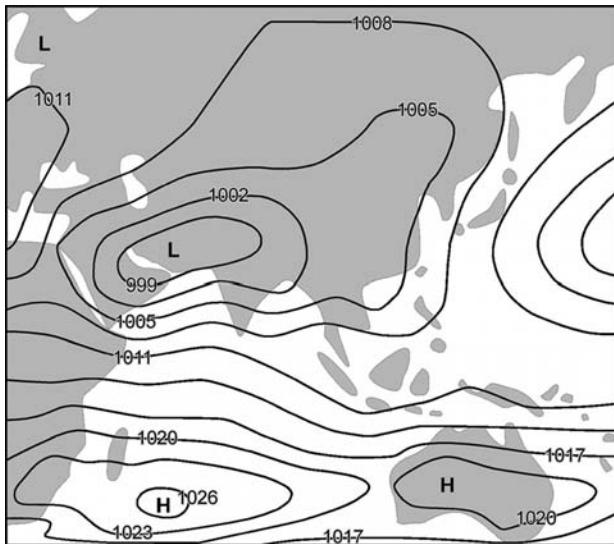

Figure S20 July mean sea level pressure over Asia.

Winds circulate clockwise around northern hemisphere anticyclones. Thus, the winter monsoon (monsoon winds being those winds whose direction reverses with the seasons) blows from the northeast in central Asia, bringing cool, dry air to the Indian subcontinent (Strahler and Strahler, 2005).

The Siberian High is associated with the coldest temperatures ever recorded in the northern hemisphere. Average January temperatures are -46.2°C (-50.1°F) for Verkhoyansk (67.7°N , 133.6°E) and -51.0°C (-60°F) for Oimekon (63.4°N , 143.2°E) in northeastern Siberia. In addition, the highest values for continentality (which by one definition is simply the temperature range between two extreme months) are found in the same region (Landsberg, 1958).

Continental heating in summer results in a low-pressure cell of thermal origin centered equatorward of 30°N . The net effect of the heating of the Asiatic landmass is to pull the tropical belt of low pressure poleward across the Tropic of Cancer (23.5°N).

As shown in Figure S20, the Asiatic Low is centered over the hot deserts and plateaus of southwest Asia during the summer. The July mean sea level pressure is 999 mb (29.5 in), or 14 mb (0.42 in) lower than normal sea level pressure of 1013 mb (29.92 in). An analogous situation develops over the arid southwestern portion of North America. A weaker low-pressure cell exists with a July mean of 1011 mb (29.86 in). The difference in the dimensions and pressure of the two continental summer lows is of course attributed to the greater land mass of Asia (Trewartha and Horne, 1980).

Winds follow the pressure gradient from high to low and flow counterclockwise around a low in the northern hemisphere. Thus, the development of the Asiatic Low results in the summer monsoons. The summer southwest monsoon winds blow across the open warm waters of the Indian Ocean. The air is forced to ascend and adiabatically cools as it strikes the high plateaus and mountains of India. This cooling lowers the air temperature below the dew point, resulting in the conspicuous rainy season of the monsoonal climates (Strahler and Strahler, 2005).

SINGULARITIES

Singularities are specific types of weather that occur fairly regularly at a specific time of the year. They are often warm or cold, wet or dry, conditions that are considered departures from the normal annual march of temperature and precipitation.

In the United States, the best-known singularities are the Indian Summer, the January Thaw, and April Showers. Clearly such features are not observed throughout all climate regions.

Table S5 Brief summary of studies of the January Thaw

Study	Geographical coverage	Period of record	Analyzed variables	Conclusions
Esten and Mason (1910)	Storrs, CT	1888–1909	Record max and min; max, min and avg. temps	Singularity
Marvin (1919)	Continental US	1778–1865	Avg. weekly temps	No strong singularity
Nunn (1927)	Northeast US	1873–1925	Avg. temps	Singularity
Slocum (1941)	Northeast US	1871–1939	Avg. temps	No conclusion
Wahl (1952)	Northeast US	1873–1952	Avg. temps, sea-level pressures	Singularity
Wahl (1953)	Boston, MA	1873–1952	Avg. temps	Singularity
Brier (1954)	N. hemisphere	1899–1939	Sea level pressure	No conclusion
Lautzenheiser (1957)	Boston, MA	1911–1950	Avg. temps	No strong singularity
Dickson (1959)	Nashville, TN	1871–1950	Avg. temps, tornadoes	Singularity
Bingham (1961)	Northeast US	1896–1956	Avg. weekly temps	No strong singularity
Duquet (1963)	Northeast US	1872–1961	Weekly avg. temps	Singularity
Newman (1965)	Boston, MA	1872–1964	Max and min temps	No strong singularity
Frederick (1966)	US and SW Canada	1897–1956	Avg., max, and min temps	Singularity
Hayden (1976)	East Coast US	1954–1970	Means of surf heights	Singularity
Logan (1982)	Portland, Maine	1965–1979	Avg. temps	No conclusion
Lanzante and Hernack (1982)	New Brunswick, NJ	1858–1981	Max temps	Singularity
Lanzante (1983)	N. America, Atlantic and Pacific Oceans	1947–1976	700-mb heights	Singularity
Kalnicky (1987)	N. hemisphere	1899–1969	Sea-level pressure	No conclusion
Guttman and Plantico (1987, 1989)	Eastern US	1951–1980	Max and min temps	Singularity
Guttman (1991)	Central Park, NY	1876–1987	Max and min temps	No strong singularity

From Godfrey et al., 2002, where references to cited articles are given.

The January Thaw, for example, is an anomalous warming that occurs in the northeastern United States in mid- to late January. As Table S5 indicates, this feature has been the topic of many studies. The conclusions are quite variable, with some indicating the existence of a singularity and others finding no consistent record.

SNOW AND SNOW COVER

Importance of snow cover

Snow cover refers to the blanket of snow covering the ground, and includes the concepts of depth and areal extent (Sturm et al., 1995). Snow cover is a key component of the global climate system through its role in modifying energy and moisture fluxes between the surface and the atmosphere, and through its role as a water store in hydrological systems. Snow is a highly reflective material; the reflectivity or **albedo** of new snow is 0.8–0.9, which means that 80–90% of the incident solar energy is reflected away from the surface. This property, combined with the excellent insulating characteristics of a snow cover, dramatically reduces the energy exchange between the surface and the atmosphere. Empirical studies have shown that mean surface air temperatures are typically 5°C colder when a snow cover is present (Groisman and Davies, 2001). This positive feedback is responsible for the rapid expansion of northern hemisphere snow cover extent in October–November. The larger-scale climatic significance of the

snow-albedo feedback is modulated by cloud cover and by the small amount of total solar radiation received in high latitudes during winter months. Groisman et al. (1994a) observed that snow cover exhibited the greatest influence on the Earth radiative balance in the spring (April to May) period when incoming solar radiation was greatest over snow-covered areas. The impact of snow on surface reflectivity is an example of a *direct feedback* to the climate system. Snow is also involved in a number of *indirect feedbacks* such as its influence on modulating sea ice growth, and linkages to cloud cover and surface temperature through snow's role in soil moisture recharge (Cess et al., 1991; Randall et al., 1994). There is an extensive body of literature linking snow cover feedbacks to monsoon circulations (e.g. Vernekar et al., 1995; Gutzler and Preston, 1997). However, recent research suggests snow's role may be limited (Robock et al., 2003). Groisman and Davies (2001) and Armstrong et al. (2003) provide more detailed reviews of the climatic significance of snow.

Snow cover is also a critical component in natural and human systems. Snow accumulation is an important resource for drinking water, irrigation, hydroelectrical generation and natural river ecosystems. The presence of an insulating snow cover is also critical for ecological systems (Jones et al., 2001). Beneath even 30 cm of snow organisms and soil are well protected from the extreme diurnal temperature fluctuations occurring at the snow surface, and exchanges of carbon, methane and other gases between the land surface and the atmosphere can continue during the winter period (Sommerfeld et al., 1993). Snow influences on soil temperature are also important for hydrology. When soil moisture freezes, the hydraulic conductivity is reduced, leading to either more runoff due to decreased infiltration or higher soil moisture content due to restricted drainage. Knowing whether the soil is frozen or not is important in predicting surface runoff and spring soil moisture reserves (Zhang and Armstrong, 2001).

Finally, snow supports a multi-billion-dollar recreation and tourism industry in midlatitudinal mountain regions of the world (e.g. Rocky Mountains, Appalachians, Alps). But snow can also be a nuisance and a hazard. Snow can play havoc with driving conditions through reduced visibility and traction, heavy loads of snow can collapse buildings, and rapid melt of snow can cause flooding. In 1987–1988 the snow removal budget for the city of Montréal was \$47 million (Phillips, 1990). In mountainous areas of the world, snow avalanches are an ever-present hazard with the potential for loss of life, property damage and disruption of transportation. McClung and Schaerer (1993) provide an excellent review of avalanche science.

Snowfall

The initial characteristics of a *snowpack* start with the snowfall process. While the physics of snowfall formation is highly complex (see review by Schemenauer et al., 1981), the basic ingredients are a source of moisture, a mechanism for vertical motion in the atmosphere to cause precipitation to form (e.g. orographic lift, frontal lift, convection), and air temperatures at or below 0°C. The form of the initial ice crystals (e.g. columnar, platelike, dendritic) depends on the temperature at formation, and the crystals may undergo considerable change as they fall through layers with different temperature and humidity. The shape and size of the final snowflakes thus depend on a host of factors, which can be further complicated by wind action breaking crystals into smaller fragments. The density (mass per unit volume, expressed in units of kg m⁻³) of natural snowfall varies with cry-

tal type, size and liquid water content, but is typically in the range 50–120 kg m⁻³ (Pomeroy and Gray, 1995). Snowfall densities vary from event to event, and there are important regional differences in snowfall densities based on temperature and precipitation climates. While some data suggest snowfall density is air temperature-dependent (e.g. Pomeroy and Gray, 1995), snowfall density is not strictly a function of air temperature, and densities can vary greatly for any given air temperature (Doesken and Judson, 1997). The density and crystal structure of newly fallen snow are important in many engineering and operational fields such as avalanche risk forecasting, design of roofs and structures to withstand snow loading, the accretion of snow on transmission lines (a particular problem in Japan where wet snow is frequent), aircraft deicing, and vehicle trafficability.

Spatial extent

Snow cover is encountered over most of the northern hemisphere mid- and high-latitudes during the winter season, and over many mountainous regions of the world for extended periods. Figure S21 shows the seasonal range in snow cover over the northern hemisphere from satellite data. The temporal variability is dominated by the seasonal cycle with average snow cover extent ranging from an average minimum extent of 3.6 million km² in August, to an average maximum extent of 46.8 million km² in late January (Table S6). Most of the global snow cover extent is located over the northern hemisphere: with the Antarctic and Greenland landmasses excluded, the southern hemisphere mean maximum terrestrial snow cover extent is less than 2% of the corresponding winter maximum snow cover extent over the northern hemisphere. In the southern hemisphere exclusive of Antarctica, most of the seasonal snow cover extent is located over South America.

While annual snow accumulations can exceed several meters in humid mountainous regions of the world, shallow snow covers in the order 10–30 cm depth are typical for large areas of the northern hemisphere that experience relatively cold, dry winters (e.g. midlatitudinal continental and polar regions). The contrast in snow depths between regions close to winter moisture sources (i.e. Pacific and Atlantic oceans) is evident in Figure S22, which shows mean February snow depths over North America derived from surface observations.

Snow cover characteristics

Over a winter season a snowpack grows and develops as a complex layered structure reflecting the weather and climate conditions of each precipitation event, and metamorphic and melt processes in the snowpack. The international standards (units, terminology, and symbols) for describing the vertical structure of a snowpack are provided in Colbeck et al. (1990). The three basic properties used to describe a snow cover are depth, density and snow water equivalent (SWE) related as follows:

$$\text{SWE (mm)} = 0.01 h_s \times \rho_s$$

where h_s is the depth of snow (cm) and ρ_s is the density of snow (kg m⁻³). The conversion from a mass of snow (kg m⁻²) to a depth of water (mm) is based on the fact that 1 mm of water spread over an area of 1 m² weighs 1 kg. Over a snow season a typical snowpack is characterized by an extended accumulation period that may include discrete melt events, followed by a rapid melt or ablation period (see example in Figure S23). Snowpack

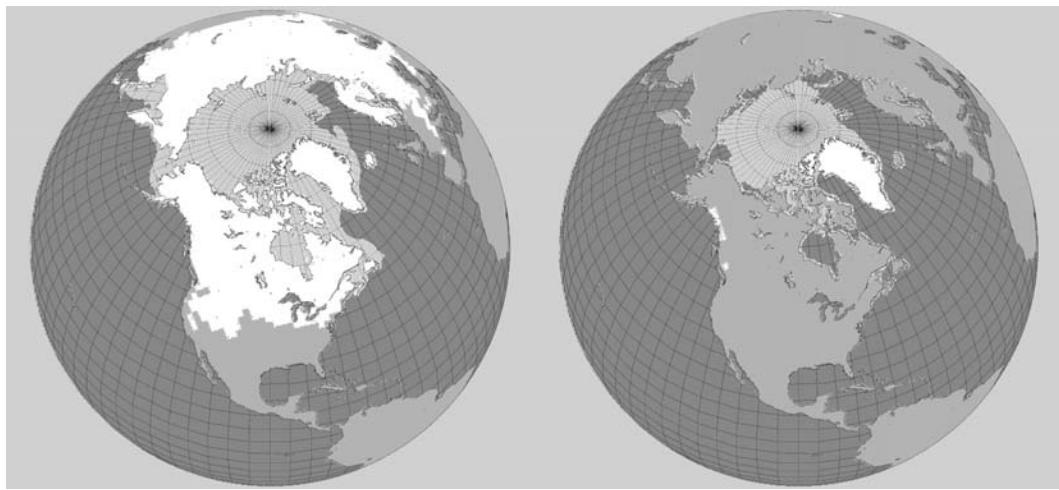

Figure S21 Mean seasonal variation in northern hemisphere snow (white) and sea ice (light grey) extent between February (left) and August (right) as derived from satellite data. Data are from Weekly Snow Cover and Sea Ice Extent, National Snow and Ice Data Center, 1996.

Table S6 Snow cover extent in million square kilometers for terrestrial portions of the globe (after Table 6.1 in Goodison et al., 1999)

Northern hemisphere	Excluding Greenland	Including Greenland
Maximum (late January)	44.8	46.8
Minimum (late August)	1.4	3.6
Southern hemisphere	Excluding Antarctica	Including Antarctica
Maximum (June–October) ^b	0.85 ^a	14.5 ^c
Minimum (January–March) ^b	0.07	13.7 ^c
Global extent	Excluding Greenland + Antarctic	Including Greenland + Antarctic
Northern hemisphere winter	44.9	60.5
Southern hemisphere winter	2.3	18.1

^a The main contribution is South America, which was estimated to have a mean winter snow cover extent of $0.45 \times 10^6 \text{ km}^2$ over the 1988–2001 period (Foster et al., 2003). New Zealand mean winter snow cover extent is estimated to be $0.06 \times 10^6 \text{ km}^2$ (Fitzharris and McAlevey, 1999).

^b These month ranges are approximations since seasonal snow cover extent in southern hemisphere mountainous regions exhibits strong month-to-month and year-to-year variability.

^c Seasonal snow cover variation in Antarctic snow cover was not taken into account.

density typically increases rapidly at the start of the season due to changes in the size, shape and bonding of snow crystals. This process is termed **metamorphism**, and is caused by temperature and water vapor gradients, crystal settlement and wind packing (Pomeroy and Gray, 1995). During the melt season, snow density can also experience rapid increases from melt and refreezing. Melting snow densities typically range from 350 to 500 kg m^{-3} . In extremely cold environments with shallow snowpacks, snow density can actually decrease over time due to the formation of **depth hoar** in response to strong temperature and vapor gradients through the snowpack. A detailed review of the physics of snow metamorphism is provided by Langham (1981).

At a continental scale, differences in climate give rise to distinct snow cover–climate regions. Sturm et al. (1995) were able to classify global snow cover into six distinct classes with unique stratigraphic attributes (tundra, taiga, alpine, maritime, prairie and ephemeral) using wind, precipitation and air temperature data. Snow cover also exhibits extensive local scale variations due to the effects of wind redistribution, vegetation interception

and sublimation, and the influence of topography on wind speed and the local energy balance. An extensive review of these processes is provided by Pomeroy and Gray (1995). Sublimation losses from blowing snow and tree canopies are important when determining the water budget of hydrological systems. Pomeroy and Gray (1995) estimated sublimation loss over prairie environments to be 15–41% of annual snowfall, and they estimated that approximately one-third of total snowfall falling on spruce and pine was lost through canopy sublimation.

Snowpack modelling

The ability to accurately model the accumulation and ablation of a snow cover is important for many applications such as flood forecasting, reservoir management, and climate system simulations. A wide range of approaches have been used to simulate the accumulation and ablation of a snowpack from simplified degree-day melt models to more complex physical models of the energy and mass balance such as Anderson (1976). In more

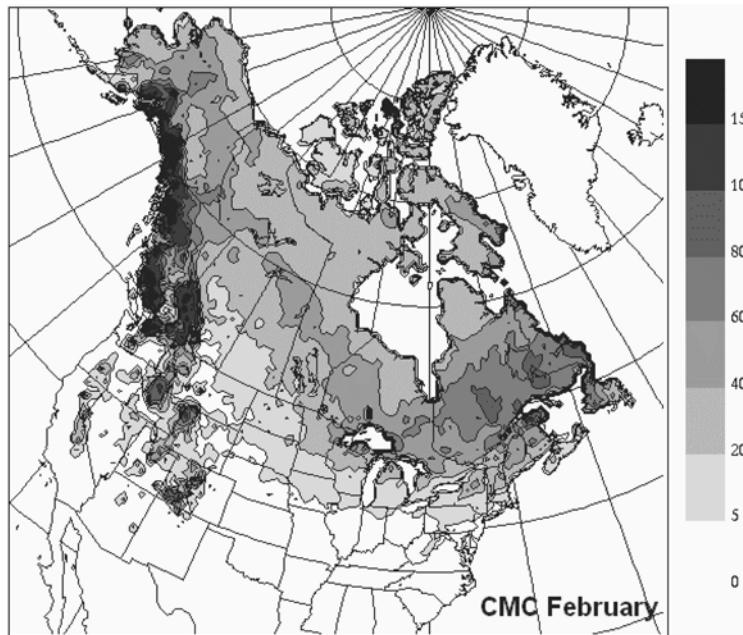

Figure S22 February mean snow depth (cm) over North America derived from an objective analysis of surface observations over the period 1979–1997 (Brown et al., 2003).

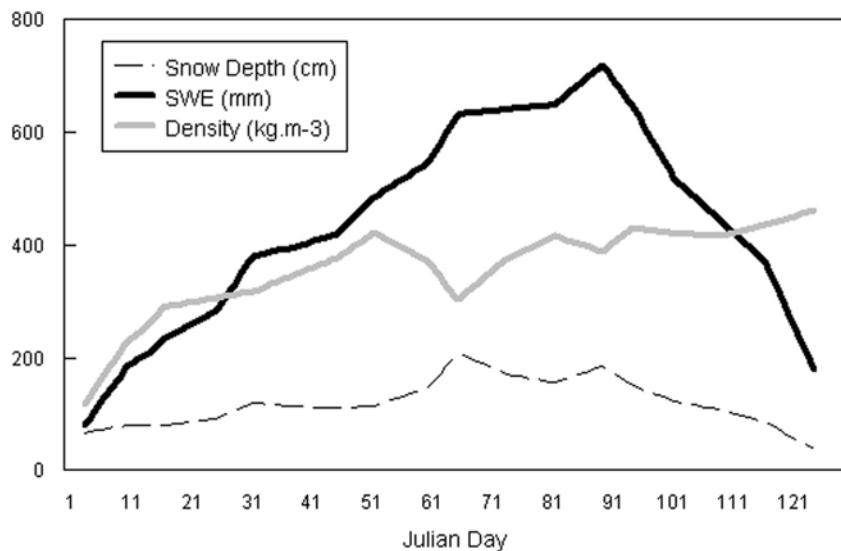

Figure S23 Temporal variation in snow depth (cm), SWE (mm) and mean snowpack density (kg. m^{-3}) from weekly snowpit observations at Col de Porte, France, 1995. Note the effect of the major snowfall event on Day 66 in decreasing the average snowpack density. Data courtesy E. Martin, Météo-France.

recent years, modelers have incorporated the physics of snow crystal size and shape evolution into physical models (e.g. Brun et al., 1992) along with improved understanding of heat transfer at the snow surface (Jordan et al., 1999), snowmelt (Marsh, 1999) and blowing snow (Pomeroy and Gray, 1995). The latest generation multilayer physical snowpack models have been shown to provide accurate simulations of point snowpack properties and

melt at open locations for a range of sites and snow climates. Accurate simulation of snow cover over an area is a much more difficult problem, however, since this involves taking into account local-scale variations in topography and vegetation that are the main factors driving spatial variation in snow cover accumulation and melt. Important areas of ongoing snow modeling research include improved representation of blowing snow,

vegetation and canopy processes, treatment of patchy snow, as well as development of approaches to include local-scale heterogeneity into global and regional climate models.

Measuring snow

The measurement of **snowfall** (the depth of freshly fallen snow that accumulates during the observing period, traditionally measured with a ruler), **solid precipitation** (the amount of liquid water in the snowfall intercepted by a precipitation gauge), and snow on the ground (depth, SWE) is a science in its own right. Reviews of measurement equipment and techniques are provided by WMO (1981), Goodison et al. (1981), Sevruk (1992), Pomeroy and Gray (1995), and Doesken and Judson (1997). Accurate information on the amount and solid fraction of winter precipitation is required for input to hydrological and climate models, but this is often difficult to provide in practice. For example, standard techniques have been developed for correcting precipitation gauges for wind-induced undercatch (Goodison et al., 1998) but not all observing sites have the required information to apply corrections. In addition, the available surface-based observational networks for snowfall and solid precipitation tend to be concentrated in populated lower-elevation areas, and in recent years many of these sites have been closed or converted to automated stations. The automation of precipitation measurements is difficult, and has important consequences for the homogeneity of climate data series.

Accurate information on the amount and spatial distribution of SWE is critical information for water resource management (e.g. agriculture, hydroelectric power generation, flood forecasting). Water authorities and utilities make use of surface-based snow surveys (and snow pillows in mountainous terrain) to monitor peak SWE values prior to snowmelt, as well as satellite imagery to map snow cover extent. Information on snow depth and SWE can also be derived from a variety of aircraft or satellite sensors with varying degrees of success (Hall and Martinec, 1985).

Temporal variability and climate change

Regional and continental snow cover exhibits large interannual variability in response to atmospheric circulation patterns that influence temperature and precipitation. Interannual variability in North American and Eurasian snow cover extent have been shown to be strongly correlated to the Pacific-North America (PNA) and North Atlantic Oscillation (NAO) circulation patterns respectively (Gutzler and Rosen, 1992). Snow cover exhibits large regional variability in response to ENSO events (Cayan, 1996; Clark et al., 2001), with a tendency for El-Niño events to be associated with greater snow cover over Eurasia and less snow cover over North America (Groisman et al., 1994b). A detailed review of snow cover-atmosphere relationships is provided by Groisman and Davies (2001).

Snow cover extent (SCE) exhibits significant negative correlations to air temperature in many regions of the northern hemisphere (see the “temperature response regions” in Groisman et al., 1994b), and for the hemisphere as a whole (Robinson and Dewey, 1990; Karl et al., 1993). This negative relationship (see Figure S24) reflects the positive snow-albedo feedback, and analysis of northern hemisphere snow cover has shown that the most significant decreases have occurred in the second half of the snow year when the snow-albedo feedback is strongest. Satellite records indicate that the northern hemisphere annual SCE has decreased by about 10% since 1966, largely due to decreases in spring and summer since the mid-1980s over both the Eurasian

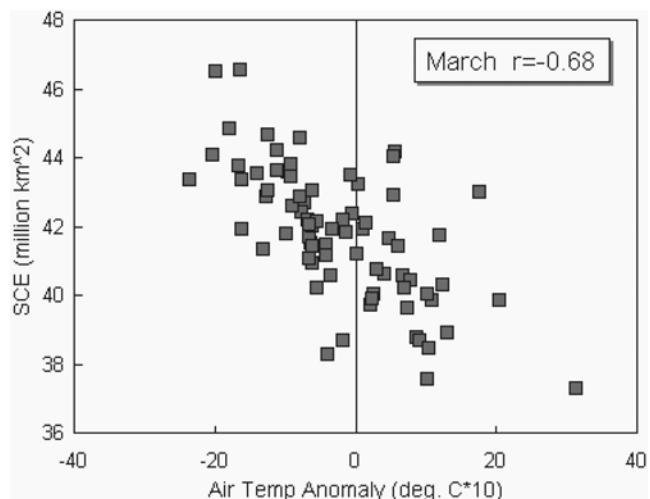

Figure S24 Scatterplot of reconstructed (1922–1971) and satellite-observed (1972–1997) northern hemisphere snow cover extent (SCE) versus northern hemisphere midlatitudinal (40–60°N) land surface air temperature anomalies for March. Air temperature anomalies were computed from the Jones (1994) gridded land temperature dataset, and the snow cover data are from Brown (2000). The inferred air temperature sensitivity for northern hemisphere March SCE is $-1.26 \times 10^6 \text{ km}^2 \text{ }^\circ\text{C}^{-1}$.

and American continents (Robinson, 1997, 1999). Analysis of reconstructed SCE information since 1915 (Brown, 2000) showed that most of the observed reduction occurred during the second half of the twentieth century. This period has been characterized by widespread trends toward less winter snow, earlier snowmelt and earlier snowmelt runoff, with important implications for water resources, e.g. reduced storage of water in the snowpack and earlier melt translate to a lower freshwater pulse for recharge of soil moisture and reservoirs, and increased potential for evaporation loss. Global Climate Model (GCM) simulations suggest widespread reductions in snow cover over the next 50–100 years in response to global warming. However, there is considerable uncertainty in model-projected regional patterns of snow cover change (Frei and Robinson, 1998), particularly in mountainous regions. A discussion of the impacts of reductions in snow cover is provided in Fitzharris (1996).

SOLAR ACTIVITY

The sun is a variable star. A variety of transient phenomena are observed on or near its visible surface, including looping prominences and explosive flares. “Solar activity” is a general, inclusive term employed to characterize these and other phenomena, along with their variations in time. Some effects of solar activity are propagated throughout the solar system by the

streaming solar wind. In the vicinity of the Earth, results of solar activity include auroras, geomagnetic storms and on occasion regional power outages (Allen et al., 1989). Telecommunications may be disrupted and the orbits of satellites perturbed. In order to understand the nature of the near-Earth and interplanetary environment it is necessary to gain an understanding of the nature and effects of solar activity.

Basic considerations

The visible surface of the sun is the photosphere. This is a layer only about 300 km thick, where the solar plasma becomes opaque to visible light. Below the photosphere is the convective zone, which is permeated by magnetic fields originating yet deeper in the sun. Above the photosphere is the chromosphere, a tenuous, normally invisible layer about 2500 km in thickness, where temperatures soar to more than 10^4 K. Above the chromosphere is the still-hotter solar corona with temperatures of about 2×10^6 K, which may be seen as a halo of light surrounding the sun during an eclipse. These three regions of the sun (photosphere, chromosphere and corona) each have characteristic forms of solar activity that will be outlined below.

Solar magnetic fields cause the phenomena of solar activity. The sun, like the Earth, has a bipolar magnetic field (like that of a bar magnet). The sun's field is rapidly and continually changing, undergoing a cycle in which the polarity reverses every 11 years or so. The magnetic lines of force of the Earth's field run roughly north-south (a poloidal field), but in the sun a combination of effects leads to fields in the equatorial and middle latitudes that trend more nearly east-west (a toroidal field). This is a consequence of the differential rotation of the sun; our star rotates more rapidly in the equatorial regions than near the poles, and the effect on deeply buried, originally poloidal field lines is to wind them around the sun's equatorial region, leading to the observed east-west pattern.

The vigorous convection in the outer portions of the sun brings internal magnetic fields up to surface regions of the sun, and leads to irregularities and disruptions of the fields. The phenomena of solar activity result from the evolution of these disturbed fields.

Sunspots and the photosphere

Sunspots are dark markings on the visible surface of the sun. They may occasionally be seen with the naked eye under conditions when the sun is partially obscured by haze or dust. Records of sunspot observations from the Orient date back many centuries (Stephenson and Wolfendale, 1988). Galileo was first to make telescopic observations of sunspots, and regular observations of high quality have been obtained since early in the nineteenth century.

Sunspots generally consist of a dark region, the umbra, surrounded by a lighter but still dark region termed the penumbra. They tend to occur in pairs, though single spots and complex groups are also seen. The leading spot of each pair has the same polarity as the other leading spots on the same hemisphere of the sun, while the trailing spots have polarities opposite to the leading spots. Thus spot pairs are thought to mark the emerging and returning locations of loops of magnetic field lines through the photosphere. The spots are dark due to their relatively low temperatures (about 2000 K lower than the surrounding photosphere). The fields are thought to block the convective motion of hot gases from below.

Bright areas in the vicinity of sunspot groups are termed faculae. These emit more radiation on average than the surrounding

photosphere, approximately canceling the deficit associated with the sunspots (Chapman et al., 1986; Foukal and Lean, 1988).

The sunspot number is one of the most ancient and fundamental measures of solar activity. Introduced by R. Wolf, the sunspot number is proportional to $(10g + s)$, where g is the number of sunspot groups visible, and s is the number of individual spots counted on the surface of the sun. Following the recognition of the 11-year cycle in sunspot occurrence by Schwabe in 1843, Wolf reconstructed the cycle back to 1610. As previously noted, the polarities of leading sunspots and the polarity of the main dipolar magnetic field of the sun are reversed in the subsequent cycle, indicating that the fundamental period of activity is in fact approximately 22 years.

Many techniques have been employed to construct a record of solar activity over longer times (Stephenson and Wolfendale, 1988). Observations of auroras and of visible sunspots have been used to reconstruct solar activity cycles before 1600 (e.g. Wittman, 1978; Stothers, 1979, Siscoe, 1980). The record of atmospheric ^{14}C preserved in tree rings yields a record of solar activity spanning more than 8000 years (Sonett, 1984; Damon and Linick, 1986). Most recently records of the isotope ^{10}Be preserved in polar ice cores have been employed to obtain a high-resolution record of solar activity in prehistoric times (Attolini et al., 1988; Beer et al., 1990). We will return to a discussion of characteristics and implications of the record of solar activity in a later section.

Chromospheric solar activity

The chromosphere may be imaged using light emitted at a wavelength of 6563 \AA ($0.6563 \mu\text{m}$). This wavelength is a characteristic of a transition of the electron of hydrogen atoms from the second to the first discrete level of excitation; it is an advantageous wavelength for observation (Gibson, 1972), since hydrogen is the most abundant element in the solar atmosphere. The 6563 \AA line is termed "hydrogen alpha".

Solar flares are often evident in H_α images, indicating that they are an important component of chromospheric solar activity. Flares are explosive outbursts resulting from the release of magnetic energy in active regions; they emit radiation at many wavelengths (including energetic X-rays and gamma radiation) and may accelerate particles beyond solar escape velocity. Solar flares may cause nuclear reactions in the photosphere and may perturb the solar wind, triggering geomagnetic disturbances some time later at the Earth.

The corona

The solar corona is best imaged at X-ray wavelengths; here the cooler photosphere and chromosphere are dark, but hotter coronal structures show up clearly. Such images show two different types of regions: those in which the coronal loop structures are closed, emerging from and returning to the sun; and regions where the fields are open, stretching outward into interplanetary space. The former regions are identified with the same solar active regions seen in photospheric and chromospheric images, while the latter are broad regions of (predominantly) a single magnetic polarity ("unipolar regions"). These regions may also be coronal holes, which are thought to be the source of high-speed streams in the solar wind.

Coronal mass ejections involve the expulsion of vast bubbles of low-density plasma from the sun. They sometimes occur in association with solar flares, and are of undoubtedly importance in determining conditions in near-Earth space.

Solar activity cycle

Sunspot minimum is characterized by the presence of only a few active regions and sunspots, and by relatively large and well-developed coronal holes. The first sunspots of a cycle appear in relatively high latitudes (about 45°N and S), with leading spot polarities opposite to those of the preceding cycle. With time the sunspots and active regions appear in successively lower latitudes, until at sunspot maximum most spots appear within 10–15° of the solar equator. More complex active regions, with many sunspots, are found at higher levels of solar activity, and these complex regions generate most of the solar flares occurring in a given cycle. The large-scale solar magnetic fields are more complex during the high-activity phases of the cycle, and coronal holes may dominate the corona only near the poles.

The level of solar activity as measured by sunspot numbers increases relatively rapidly in the first few years of the cycle, with the subsequent decay to sunspot minimum requiring a longer period of time. During the decaying phase of the cycle, extensive regions of magnetic flux migrate from the sunspot zones to higher latitudes, first neutralizing the fields prevailing there and then establishing new polar caps of opposite polarity (Newkirk and Frazier, 1982; Wang, et al., 1989).

A detailed discussion of the solar cycle would require much more space than is available here. Interested readers should consult the volumes by Zirin (1988) and Foukal (1990).

As we have seen, there are many different varieties of solar activity. It is important to remember that these diverse phenomena are related, and that they are all linked with the fundamental 11-year sunspot cycle, which itself represents a harmonic of the more fundamental 22-year Hale magnetic cycle.

Periodicity and prediction

The source of the 11-year cycle of solar activity is an outstanding problem in solar physics. There appears to be nothing in the physical make-up of the sun that would give a fundamental oscillation of this period.

The time-series of sunspot numbers has been analyzed by numerous investigators, with a remarkable diversity of results. Rozelot (1994) provides an extensive review, while Kuklin (1976) summarizes much earlier work. Most investigators might agree that the 11-year period is real (Dicke, 1978), though Wilson suggests that there are in fact two modes, one of 120 ± 4 months and another of 140 ± 5 months, which when averaged yield the 11-year cycle. There is less agreement on longer periods of about 60 and about 80–90 years (the “Gleissberg cycle”). A number of investigators find a period of about 178 years (Jose, 1965; Cohen and Lintz, 1974; Fairbridge and Hameed, 1983). Still longer periods are seen in proxy data such as those obtained from radiocarbon fluctuations in tree rings (Sonett, 1984; Damon and Linick, 1986).

Fluctuations of solar activity with periods shorter than that of the basic sunspot cycle have also been described. A 155-day period in solar flare occurrence is well documented (Silverman, 1990), and a 25.6-month (“quasi-biennial”) period is noted by several authors (Westcott, 1964; Apostolov, 1985). (The new science of helioseismology deals with oscillations of the solar surface with much shorter periods.)

Advance prediction of the level of solar activity is a desirable goal, since astronauts, satellites, space probes and the Earth itself are not immune to the effects of solar phenomena such as large solar flares and coronal mass ejections. The periodicity of

sunspot activity forms a basis for simple predictions, and methods such as that of McNish and Lincoln (1949) have been successively improved to yield forecasts of activity levels. Unfortunately the past is not a perfectly reliable guide to the future, and none of the available methods has been an unqualified success. Other models are described in Schatten and Sofia (1987), Wilson (1988) and Butcher (1990).

Another controversial subject is the possible relationship between solar activity and weather and climate on Earth. Literally hundreds of investigations on this topic have been performed, with a diversity of results. The bibliography by Fairbridge (1987) includes dozens of such studies. The hypothesis of a relationship linking solar activity and terrestrial weather has received considerable support in the form of strong positive statistical correlations reported by Labitzke and van Loon (1989) and Friis-Christensen and Lassen (1991). The question has considerable socioeconomic significance. As previously noted, a drop in the solar output of perhaps a large fraction of a percent, occurring over several decades, would lead to significant climatic cooling on the Earth. This is presently the best explanation for the occurrence of the Little Ice Age, a period of reduced temperatures and concomitant climatic and socioeconomic stresses in the seventeenth and eighteenth centuries. This episode was contemporaneous with a prolonged minimum of solar activity now known as the Maunder minimum.

SOLAR CONSTANT

The solar constant is defined as the total irradiance of the sun at the mean orbital distance of the Earth. It has a value of about 1368 W m^{-2} . The solar constant is a fundamental quantity in atmospheric physics since it represents the amount of solar energy arriving at the top of the atmosphere. The term remains in use even though the total solar irradiance is not constant.

The concept of the solar constant was introduced by A. Pouillet in 1837 (Pap, 1986). S.P. Langley devised a method for measuring the solar constant in the 1880s, and surface measurements of the solar constant were made routinely beginning in the early years of this century (Hoyt, 1979). Space-age measurements of the solar irradiance have been obtained by instruments such as the active cavity radiometer irradiance monitor (ACRIM) on the Solar Maximum mission and the Earth Radiation Budget (ERB) instrument on the Nimbus-7 satellite (Mechikunnel et al., 1988). Very accurate models of the solar total irradiance over the past half-century have recently become available (Tobiska et al., 2000).

It was recognized that the solar output might not be constant by Langley and others. However, in the first half of the twentieth century the greatest number of investigators favored the notion of an unchanging sun. Evidence suggesting variation of the solar output, obtained by C.G. Abbot and others, was thus very controversial. The difficulties in measuring the solar constant through the ever-changing atmosphere of the Earth precluded a resolution of this question prior to the space age.

Today there is irrefutable evidence of variations of the solar output of up to a few tenths of a percent, over time periods of days to weeks (Willson et al., 1981; Tobiska et al., 2000). The solar output varies in step with the 11-year cycle of sunspot activity (Willson and Hudson, 1991), with the highest irradiance and luminosity recorded near the maximum of the sunspot cycle. The amplitude of this effect approaches 0.1%.

If the solar output in addition experiences long-term variations, these are likely to have important implications for terrestrial climatic change (Schatten and Arking, 1990; Reid, 2000; and subsequent articles in that volume). Thus the subject of solar output variations on all timescales is an active area of research. In one study Shirley et al. (1990) found evidence of a relationship linking solar luminosity with the solar inertial motion.

By far the largest fraction of the solar output is found in the visible range of the electromagnetic spectrum. Some portions of the continuum of solar emissions at higher and lower wavelengths vary with the phase of the sunspot cycle (White, 1977; Tobiska, 2001). Variations in the solar ultraviolet flux (in particular) may play an important role in changes of the total irradiance of the Sun (Lean, 1989).

A special issue of the journal *Space Science Reviews* (volume 94, #1-2, 2000) contains 37 articles summarizing our state of knowledge of solar irradiance variations and their climatic effects as of the turn of the present century.

SOLAR FLARE

Solar flares are energetic eruptions from the surface of the sun. They typically originate within active regions, which are areas where internal solar magnetic fields have emerged through the solar surface (the photosphere), forming bright faculae and dark sunspots. The release of energy in flares accelerates particles to high velocities (e.g. Chupp, 1990). In some cases these particles may later be detected at the surface of the Earth, even when the flare occurs on the opposite side of the sun. Some geomagnetic storms and auroras may result from strong solar flares, while others appear to be caused by coronal mass ejections. Large flares release tremendous amounts of energy (up to about 10^{26} J in less than an hour).

The largest flares seem to pass through three stages. The preflare (or precursor) stage involves brightening of a portion of the solar surface within an active region. Loops of plasma confined by magnetic tubes emerging from the solar surface expand, sometimes over a period of several days. The impulsive phase (or flash) lasts from a few seconds to a few minutes. This phase includes the emission of bursts of X-rays and gamma rays and other radiation; a shock wave forms. The main, or extended, phase follows. The flare becomes visible in optical wavelengths, and soft X-rays and radio emissions continue. Flares are often observed in the hydrogen alpha spectrum line, which provides an image of the structure of the solar chromosphere (a thin layer immediately above the photosphere). Rust (1993) provides a review of observations of the development of flares.

The physics of solar flares is not well understood. They are linked with collisions and twisting of magnetic strands of force generated within the solar interior. The energy is thought to derive from a magnetic tension.

There are many varieties of flares. Some are confined to closed loops, while others disrupt loop structures; some are

linked with coronal mass ejections that may change the structure of the corona. Flares may be classified by the area of the chromosphere that brightens in the event; by the signal seen in solar radio wave observations (i.e. bursts); or by the enhancement in solar X-ray flux that accompanies the flare, or by other schemes (Orrall, 1991).

Flares, in common with many other solar phenomena, are more frequent at times of higher solar activity. In addition there is a well-developed cycle of flare occurrence, with a period of 155 days, whose origin is not well understood (Ichimoto et al., 1985; Bai and Sturrock, 1987).

A record of solar flare activity spanning about 10^7 years is preserved in near-surface rocks on the moon. Protons emitted from the sun in flares may produce radioactive isotopes such as ^{26}Al and ^{53}Mn in lunar rocks; radiometric dating then provides an estimate of the time of occurrence of the flare. The data suggest that the level of intensity of flare activity has not changed significantly in recent millennia.

Solar Radiation
Solar Wind

SOLAR RADIATION

Solar radiation is the common term for the electromagnetic radiation emitted by the sun. Virtually all of the radiant energy received by Earth emanates from the sun as solar radiation. Without this input of radiant energy the Earth would be a cold, dark, lifeless planet. In combination with the Earth's rotation, oceanic and atmospheric circulation systems are driven by solar radiation absorbed by the surface and, to a lesser extent, the atmosphere that surrounds it. Through photosynthesis, energy derived from the solar radiation spectrum is used by plants to convert water and carbon dioxide into carbohydrates. Indeed, the light from the sky is scattered solar radiation.

Solar output

The amount and spectral nature of this radiant energy is a function of the emission temperature of the solar disk, which is approximately 5777 K, based on the total solar emission (LeNoble, 1993).

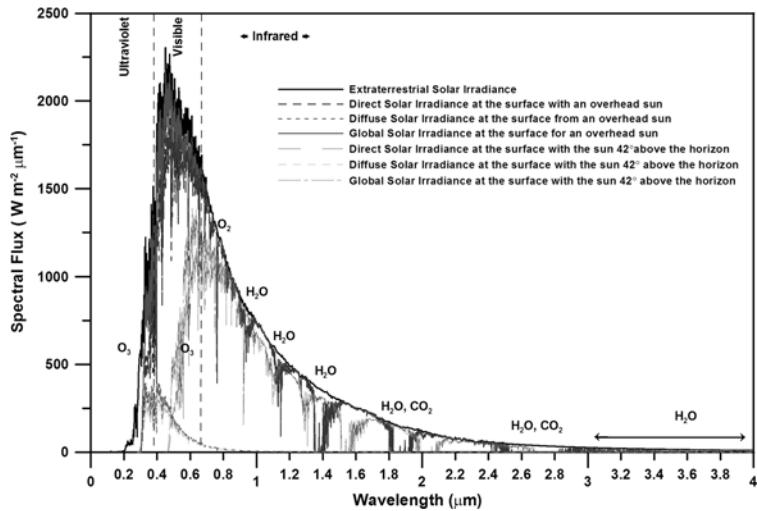

Figure S25 Extraterrestrial spectrum, direct beam spectrum and diffuse spectrum for an overhead sun (solar elevation 90°) and when the sun is at 42° elevation.

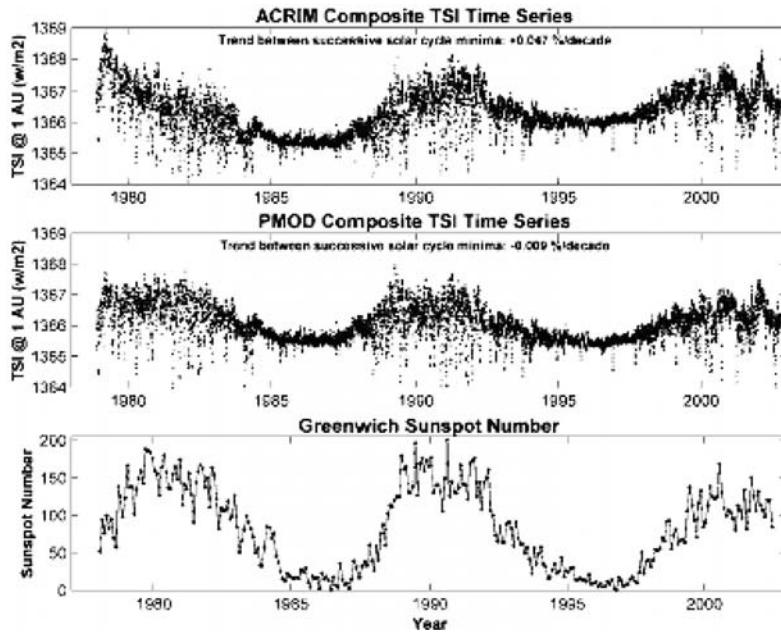

Figure S26 Variation in the total solar irradiance as published by two laboratories. The lower panel indicates the sunspot cycle (from Wilson and Mordvinov, 2003).

Small fluctuations in the emission temperature do not greatly alter the overall output of energy, but do change the spectral (wavelength) characteristics of the radiant flux, with shorter wavelengths changing more than longer wavelengths. Less than 0.2% of the energy output of the sun is emitted at wavelengths shorter than 250 nm and a similar amount is radiated at wavelengths longer than about 6 μm . The wavelength region of greatest emission is in the visible portion of the spectrum, 400–700 nm, the peak of the irradiance distribution being at 465 nm (Figure S25). The total solar irradiance (TSI), often referred to as the solar constant, is the energy flux received by the Earth from the sun and has an average value of 1367 W m^{-2} . Figure S26 illustrates the

variation of the TSI between 1979 and 2002 as measured by various satellite instruments. The fluctuations in the sun's emittance are linked to solar activities such as sunspots, auroras and geomagnetic disturbances that have an approximate 11-year cycle (see bottom panel of Figure S25). Increased solar activity leads to an increase in irradiance (Hoyt and Schatten, 1997).

Solar geometry

The actual amount of solar radiation reaching the surface of the Earth is a function of sun–Earth geometry and the absorption and scattering properties of the atmosphere that surrounds the planet.

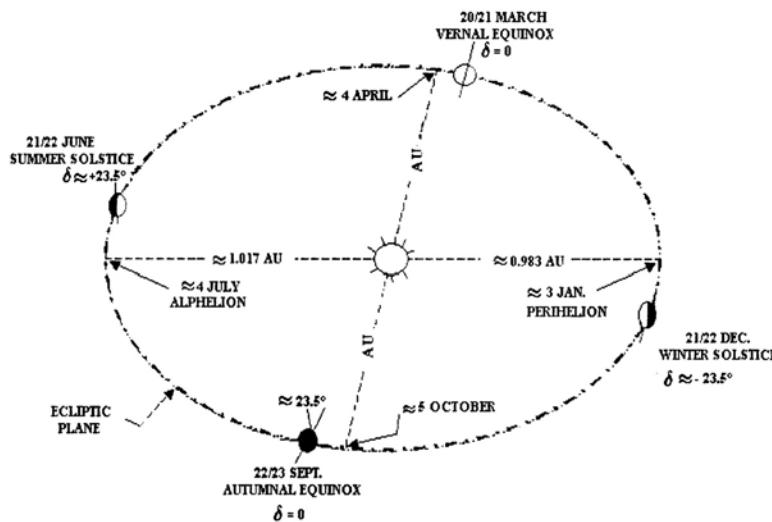

Figure S27 Orbital characteristics of the Earth about the sun (adapted from Iqbal, 1983).

The Earth's orbit about the sun is not concentric, varying between 1.47×10^8 km and 1.52×10^8 km, with an average distance of 1.496×10^8 km (known as 1 Astronomical Unit (AU)). Figure S27 is a schematic of the orbit of the Earth about the sun showing that the greatest distance between the two bodies is on 4 July and the nearest approach of the Earth to the sun is 3 January. The TSI varies by the inverse square of the distance from the sun. This variation is known as the eccentricity correction factor.

The amount of energy at the top of the atmosphere at any given location above the Earth is also affected by the tilt of the Earth's axis from the plane about which it orbits the sun (the ecliptic plane). As the Earth orbits the sun the apparent location of the sun moves south and north of the equator because of the changing angle between the sun and the Earth. The solar declination is the angular measure of this variation and varies between $23^{\circ}27'$ (north) at the summer solstice in the Northern Hemisphere and $-23^{\circ}27'$ (south) at the winter solstice. At the equinoxes, when the sun is directly overhead at the equator, the solar declination is zero. Figure S28 maps the amount of solar radiation that would reach the Earth's surface based on the changing sun-Earth distance and the changing angle between the Earth and the sun.

The final geometric factor affecting the receipt of solar radiation at a given location is the daily eastward rotation of the Earth on its axis. The angular elevation between the solar disk and the plane of the surface varies between zero at sunrise and sunset, and a maximum of $[90 - |\text{latitude} - \text{solar declination}|]^{\circ}$ when the sun is equatorward of the location. The receipt of solar radiation on a flat surface increases as the solar elevation increases, reaching a maximum at the time the sun is at its maximum height in the sky; defined as solar noon.

The Atmosphere

The amount and spectral nature of this solar radiation changes as it passes through the atmosphere (refer to Figure S25). Gases such as ozone, oxygen and water vapor absorb radiation and in so doing warm the atmosphere, while air molecules scatter radiation and particulates (aerosols) both scatter and absorb radiation. The scattering of radiation separates the total spectral flux

into two components: (1) the direct beam spectral flux, which is the spectral radiation that reaches the surface without being absorbed or scattered; and (2) the diffuse spectral radiation, which is the radiation that has been scattered in any manner. In combination, the total amount of solar radiation that reaches the surface is termed global spectral radiation or global spectral irradiance. When these fluxes are integrated over the entire wavelength range for which the sun emits, the integrated fluxes are generally known as global, direct and diffuse irradiance.

Gases absorb in various spectral regions and at various levels of the atmosphere. Ozone absorbs most of the ultraviolet portion of the solar spectrum as the rays pass through the stratosphere where the largest concentration of the O_3 is located. Water vapor is more abundant in the troposphere and absorbs the longer infrared wavelengths of solar radiation. Gases such as oxygen and carbon dioxide are more uniformly mixed throughout the atmosphere (see Figure S25). Two gases associated with human activity, sulfur dioxide and nitrogen oxides, are also responsible for the absorption of solar radiation in the UV and visible wavelength regions of the solar spectrum.

Scattering of solar radiation in cloud-free skies is primarily by air molecules. Known as Rayleigh scattering, this scattering of light is by particles whose diameter is much smaller than the wavelength of the radiation being scattered. The amount of scattering is roughly proportional to the inverse of the wavelength to the fourth power (λ^{-4}) and is responsible for the blue color of the sky seen on clear days. It can be seen in Figure S25 that Rayleigh scattering becomes negligible at wavelengths greater than about 600 nm. Scattering by particles larger than the wavelength of radiation, such as smoke, volcanic aerosols, dust or water droplets, is referred to as Mie scattering. This is more directional in nature than Rayleigh scatter, and less dependent on the wavelength of the solar radiation. The loss of color contrast in the sky during hazy or polluted days is the result of Mie scatter. Clouds are the most significant scatterer of solar radiation, being capable of increasing the instantaneous amount of solar radiation reaching the Earth's surface to values above the TSI and reducing the flux to virtually zero when thick. Figure S29, a schematic of the global shortwave radiation

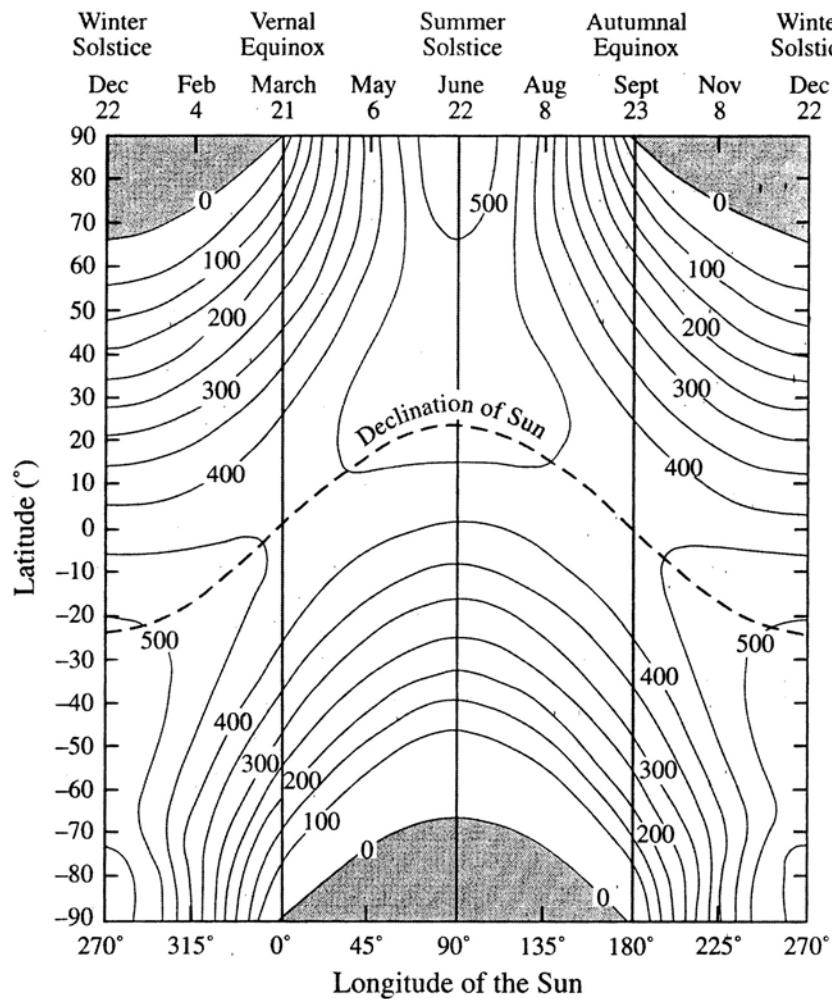

Figure S28 Geographical and temporal distribution of solar radiation (W m^{-2}) at the surface of the Earth.

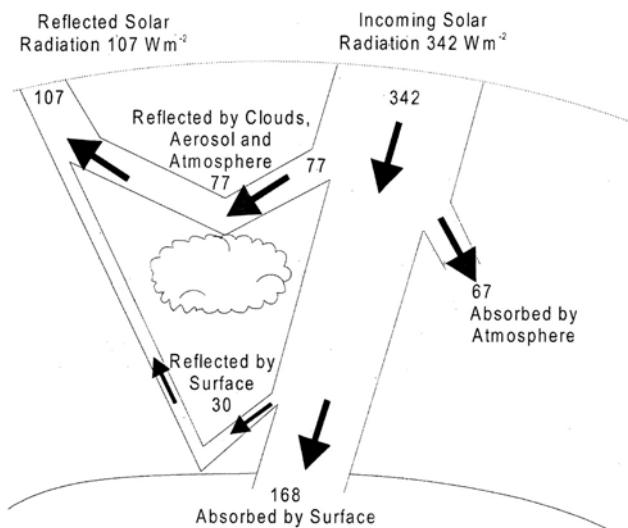

Figure S29 The global average shortwave radiation budget showing the distribution of solar radiation in the atmosphere and at the surface (adapted from IPCC, 2001).

budget, illustrates the effectiveness of clouds in intercepting and scattering radiation. Because of the effectiveness of clouds in this process, changes in global cloud cover can play a significant role in changing the Earth's climate (IPCC, 2001a). The 5 March plot on Figure S30 illustrates the effect of the passage of a single cloud between the sun and the surface, showing first a rapid decrease in the amount of solar radiation reaching the surface and then an increase substantially greater than the amount of radiation received from a clear sky when the direct beam irradiance is least attenuated.

Solar radiation at the surface

The amount of solar radiation reaching the surface of the Earth is dictated by both geometric and atmospheric factors. Absorption of this radiation at the surface, however, is related to the characteristic properties of the surface. Figure S30 shows the changes in the incoming and reflected global solar fluxes at the Bratt's Lake Observatory, part of a global surface radiation budget monitoring network (Ohmura et al., 1998). The plots on the graph show how the solar geometry alters the amount of radiation received between summer and winter with respect to the amount of solar radiation that is received at the surface and

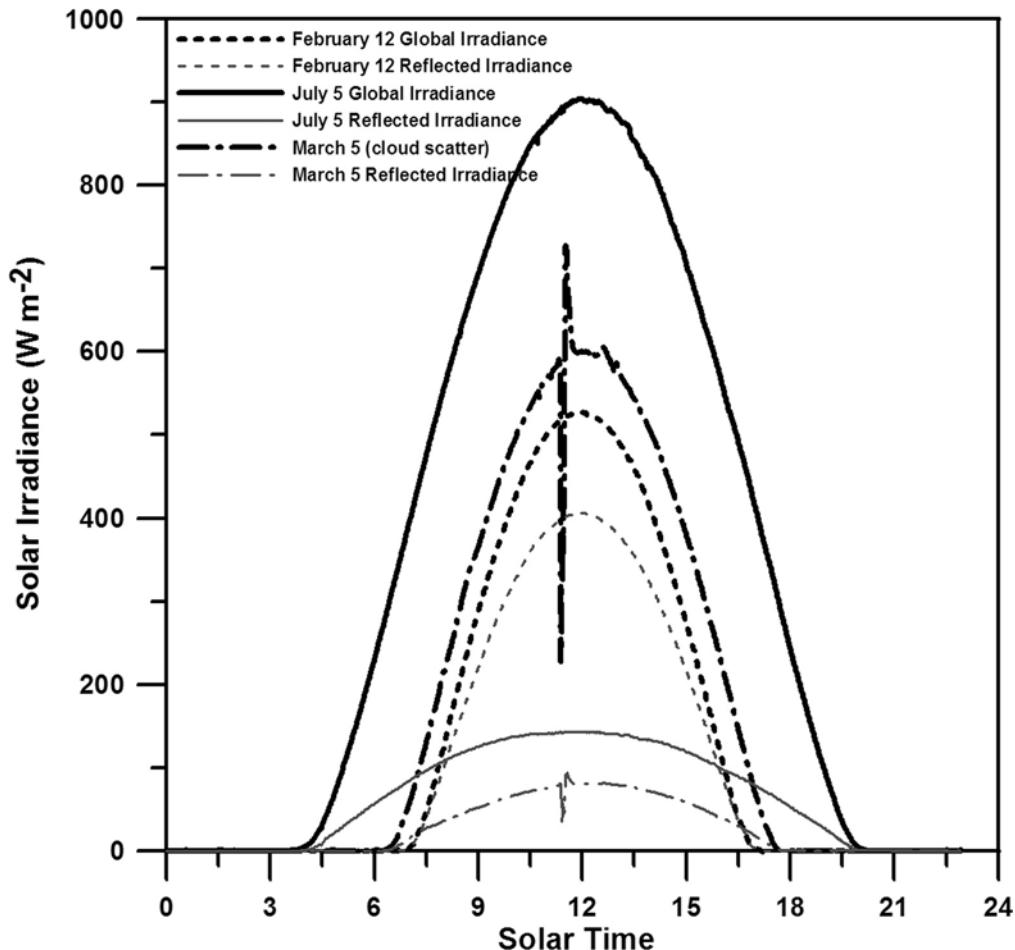

Figure S30 Global and reflected irradiance observations for three nearly clear-sky days from the Bratt's Lake Observatory (104.7°W , 50.28°N). The blue curve illustrates the effect of cloud passing between the sun and the surface. Note the increase above the normal irradiance levels caused by the scattering of radiation from the side of the cloud after reducing the surface flux by more than half. This can also be observed in the reflected irradiance. The 12 February and 5 July days show the changes in the radiation received at the surface, primarily because of solar geometry. The difference in the reflected irradiance between the two days is a function of the surface cover.

the changes that the surface plays in absorbing the radiation. The reflected fluxes in the figure are due to the differences in the land cover between summer (wheat) and winter (snow). The effect of the cloud passage on the 5 March solar irradiance curve is also apparent in the reflected flux. The energy that is not reflected is absorbed and used in a variety of processes from heating the surface, to evaporating water, to photosynthesis. The ratio between the solar radiation reflected by a surface and that incident on the surface is called the albedo. The albedo of snow ranges between 0.4 and 0.95, while the albedo of most plants ranges between 0.16 and 0.25. The albedo of man-made urban surfaces varies between 0.05 for asphalt and 0.4 for light-colored brick (Oke, 1987).

While accurate observations of the incoming and reflected solar radiation can be obtained at the surface of the Earth, satellite instrumentation is used to better understand the global distribution of the amount of solar radiation available at the surface. The global distribution of solar radiation at the surface, based on observations made by NASA/AtSR ERBE, can be seen for January and June 1991 in Figure S31. The

relationships between solar geometry and cloud cover are apparent. The amount of radiation reaching the surface during the winter is zero near the North Pole, while the flux in the South Polar region is at a maximum. In the June distribution the high solar radiation values over the Sahara region are correlated with the low cloud amount. Similarly, over the southern ocean region, which is predominantly cloud-covered throughout the year, the solar radiation reaching the surface is low.

Some countries are now producing solar radiation distributions from satellite in near real-time. These include the USA (<http://www.ghcc.msfc.nasa.gov/goesprod/GEIUSlatest.html>) and Australia (<http://www.bom.gov.au/sat/solrad.shtml>). Global maps of daily and monthly solar radiation are available from <http://www.osdpd.noaa.gov/PSB/EPS/RB/RB.html>.

Solar radiation and humans

Although solar radiation is plentiful and free, the utilization of this resource in most of the western world has been limited by

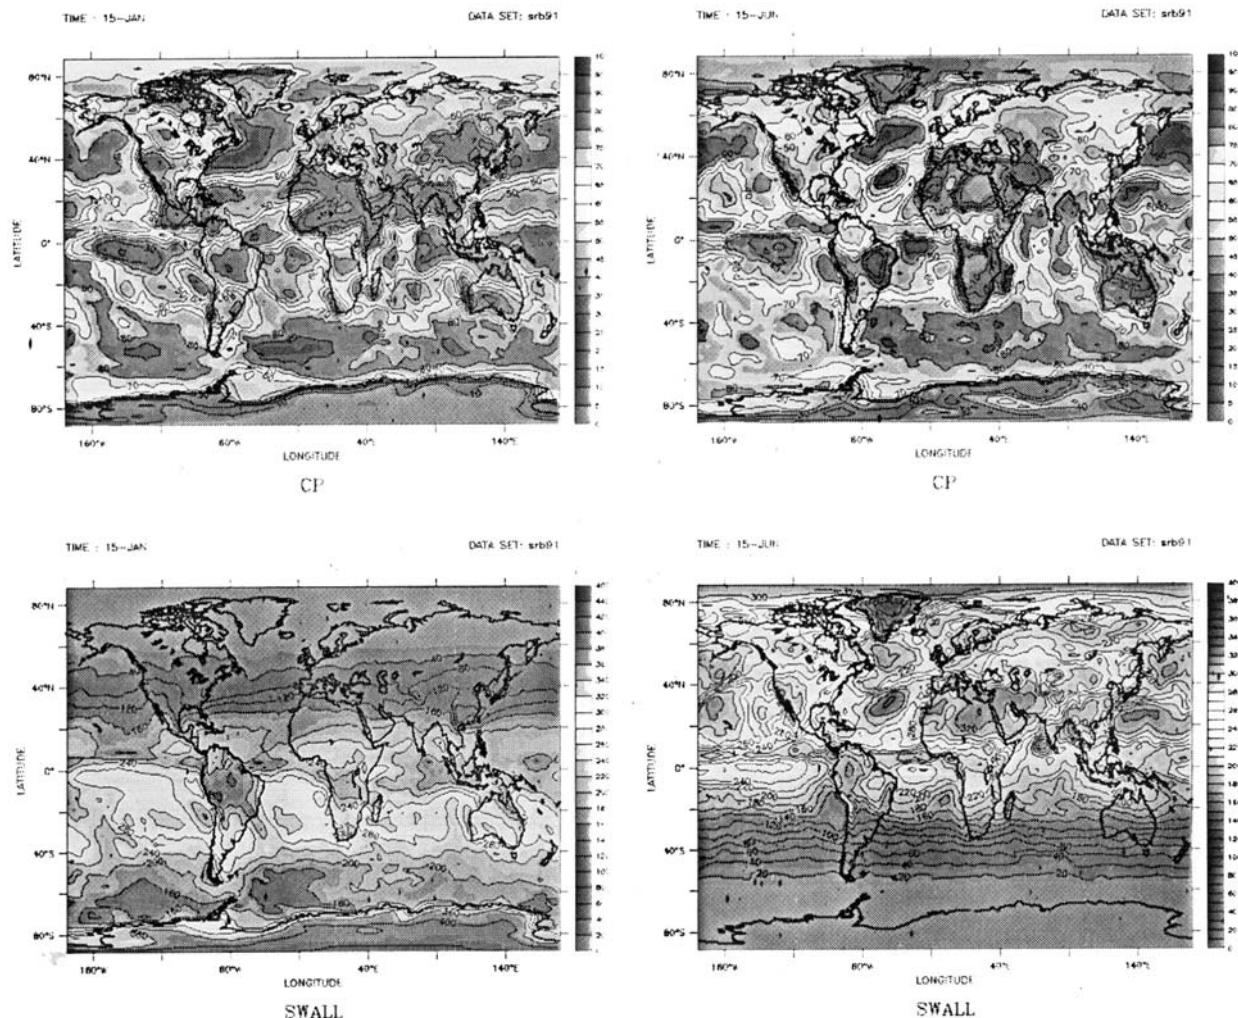

Figure S31 Surface radiation budget (SRB) distributions of monthly mean cloud amount (top) and monthly mean solar radiation at the surface (bottom) for January and June 1991 from the Earth Radiation Budget Experiment (ERBE). The cloud amount is in percent, the solar radiation is W m^{-2} (from <http://asd-www.larc.nasa.gov>).

¹Latitude is in degrees, positive north. The || indicate the absolute value of the difference.

²1 EJ = 1×10^{18} Joules (SI prefix exa).

the relatively high costs of products that utilize solar radiation, the relatively inexpensive costs associated with energy from fossil fuels and nuclear power, the high research and development costs associated with changing from conventional methods, and the lack of incentives to change (Interlaboratory Working Group, 2000). As the cost of conventional energy increases and the global population becomes more aware of the potential of climate change associated with the burning of fossil fuels, the use of solar radiation is expected to increase. Primarily, solar energy is used in the heating of water, the heating and to a lesser extent cooling of buildings, the production of off-grid electricity through photovoltaics, the use of thermal heating to produce electricity and the use of domestic parabolic collectors for cooking in rural areas of developing nations (Duffie and Beckman, 1991). The IPCC (2001b) indicates that the use of photovoltaics

increased from 37 MW to 150 MW between 1986 and 1998, with growth estimated to be to 1000 MW by 2005. The annual worldwide growth rate in the sale of photovoltaic modules is between 15% and 20% per annum, which is expected to continue through 2020 (Interlaboratory Working Group, 2000). The IPCC (2001b) estimated that by 2005 up to 5 million square meters of solar thermal panels would be in use in Europe for domestic hot-water heating. Concentrating collectors have been used for the commercial generation of power by focusing solar radiation onto a central superheat boiler to generate steam that is passed through a turbine. An example of this type of system is the California Solar One generating plant, which was first operated at 10 MW (Duffie and Beckman, 1991), but has now been upgraded to operate at 30 MW, with the eventual goal of producing 100 MW of electricity (IPCC, 2001b).

Developing countries and those countries without ready access to other energy sources have more readily embraced the use of solar energy than developed countries. Major projects using solar radiation are planned or ongoing in Brazil, India, Japan, South Africa, Uganda and Vietnam. Both the United Nations Environment Programme and the World Bank are actively involved in increasing the use of solar energy throughout the globe, but particularly in developing countries. The amount of solar radiation estimated to be available for use around the globe is between 1575 EJ² per year and 49 837 EJ per year (IPCC, 2001b). In comparison, the global energy use today is approximately 425 EJ per year (IEA, 1998).

SOLAR WIND

The visible outer blanket of the sun during a total solar eclipse is called the corona. The corona does not abruptly end but extends billions of kilometers into space. The outward movement and expansion of the corona are a function of distance from the sun. Expansion close to the sun is very slow because the pull of gravity is dominant; as the distance to the sun increases, the outward flow increases. The flow of the gas stream is the solar wind, the term originally designated by Eugene N. Parker in his classic 1958 paper on the dynamics of the interplanetary gas (see Parker, 2001).

The solar wind is a stream of ionized gas blown constantly at supersonic speeds away from the sun in all directions. The component makeup of the solar wind is mainly electrons, protons, alpha particles (hydrogen and helium atomic nuclei – both positively charged) and some heavier ions.

The beautiful display of the auroras occurs when a strong solar wind collides with the ionosphere. The solar wind also impacts satellites, communication and navigation systems. For additional details see "Solar Wind" in the *Encyclopedia of Planetary Science*.

SOUTH AMERICA, CLIMATE OF

Extending from about 10°N to 55°S, South America possesses a great variety of physical geographic features. The differences are perhaps epitomized by the contrast of landscapes associated with the Andean Mountains and the great river basin of the Amazon. This variety, together with the latitudinal extent, provides the setting for climatic diversity over the continent.

Of singular importance in describing the climate of South America is its tapered shape, with much of its area lying in tropical latitudes and diminishing in higher latitudes. This causes the property of continentality, so significant in other continents that extend into middle latitudes, to be totally absent from South America. Thus the oceans are of major and immediate importance in the climates over large areas of the continent.

General characteristics

Circulation patterns

Figure S32 shows the January and July pressure and wind patterns over South America. The seasonal shift of the systems is clearly apparent, and it is these that govern the synoptic climatology of the continent. Essentially, the major controls are the locations of the Intertropical Convergence (ITC), the Pacific and Atlantic High-Pressure Cells, and the prevailing westerlies of high latitudes.

The ITC occupies its most northerly position during the period June to September when, on average, it is located between 7°N and 9°N. Its advance and retreat are not, however, a simple linear migration. During its advance south and east over Brazil in spring and summer (southern hemisphere), the movement is retarded in northeast Brazil. This causes the climate of this region to differ markedly from the expected norm. It represents one of the several climatic anomalies that occur in South America. The migration of the ITC and associated humid

unstable westerlies produces a variety of monthly distribution of precipitation in the equatorial realm. Data illustrating this are listed in Table S7.

The second basic synoptic control is related to the location of the semipermanent high-pressure cells. As seen in Figure S32, these attain their most equatorward position in the low sun season. The eastern part of the Pacific High that influences the climates of the west coast produces subsiding stable air so that much of the land bordering the west coast receives minimal precipitation. In contrast, the Atlantic High provides much of the east coast (north of Patagonia) with effective precipitation.

The southern part of South America is influenced by the third major control, the strong westerly wind belt (Figure S32). The strength and relative uniformity of these winds are a function of the minimal continental area that extends into the circulation of the Southern Ocean.

Each of the features described – the ITC, the High-Pressure Cells, and the westerly wind belt – have important consequences

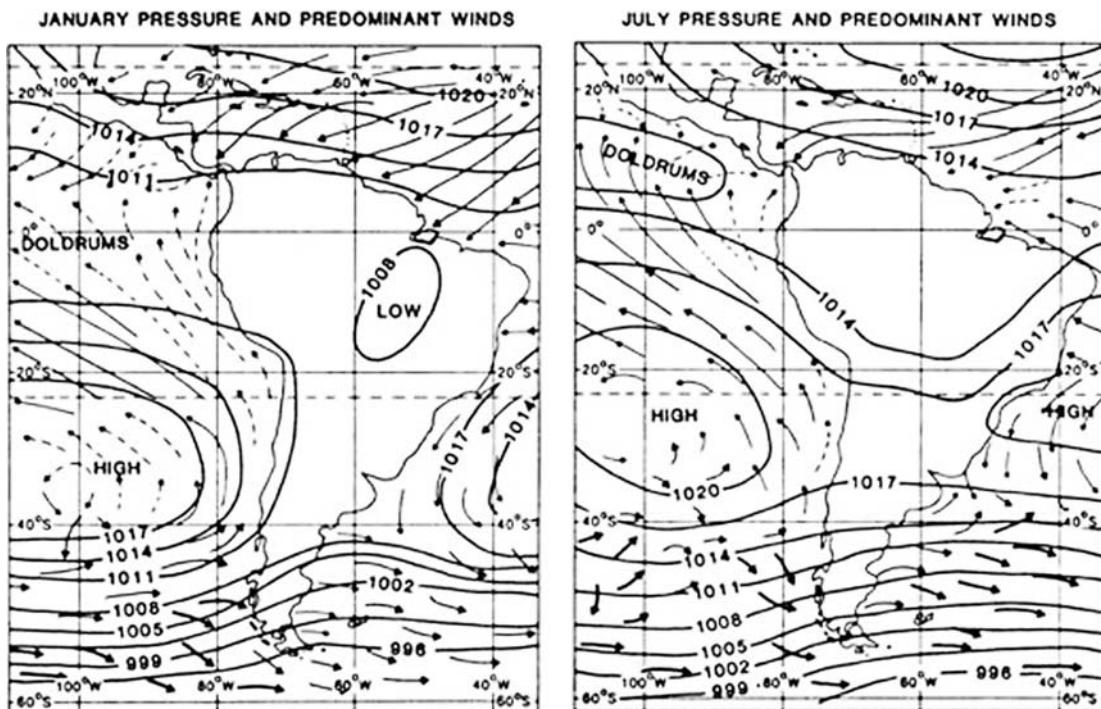

Figure S32 January and July circulation patterns over South America.

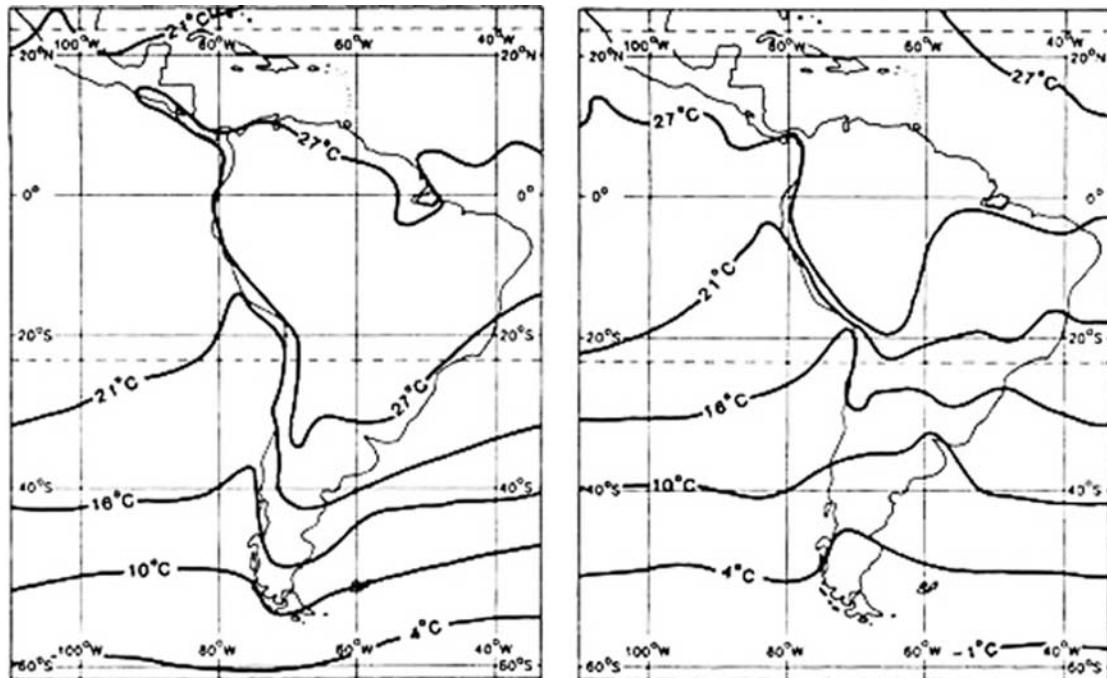

Figure S33 January and July normal temperatures for South America.

in the regional climatology of South America. Additionally, CLIVAR research (Nogu  -Paegle, 2002) shows that a South American Monsoon System (SAMS) develops over a large extension of landmass crossed by the equator where conditions vary from the forests of Amazonia to the mountain desert of the Altiplano. This gives rise to a unique seasonal pattern of convection and rainfall.

Temperature and precipitation

Figure S33 provides January and July normal temperatures for South America. The general view shows dominance of high average temperatures in the equatorial and tropical regions with a fairly even decline poleward. The southern part of the continent, given the absence of a continental effect, has equable temperatures.

Major variations from the general temperature pattern occur because of the Andes Mountains and the influence of ocean currents. As Figure S34 shows, the mountains create an altitudinal variation of temperature with well-marked zones being identified. The influence of ocean currents can be seen in the shape of the isotherms along the coastal regions. The cold Peruvian Current causes lower temperatures on the west coast, whereas the warm Brazilian Current results in a poleward shift of the isotherms.

Given the very large areas over which temperature variations are minimal, it follows that much of the climatic differences in South America often are a result of precipitation distribution. The average annual precipitation illustrated in Figure S35 indicates that high amounts occur in a broad belt from the northwest coast across the Amazon Valley region to southeastern Brazil. A second wet area is in the southwest where onshore westerlies strike the mountainous coast of Chile. Between these

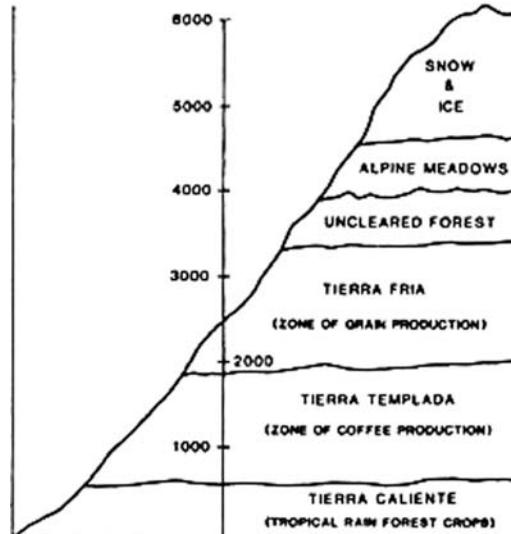

Figure S34 Altitudinal zonation of a mountain located in tropical South America.

moist areas a steep gradient to arid and subhumid regions is seen. The west coast desert and Patagonia both experience less than 250 cm of precipitation each year. The anomalous dry climates of northern Venezuela and northeast Brazil are seen on the distributional map.

Seasonality of precipitation, Figure S36, shows that, with the exception of southern Chile and the east coast area from about 25°S to 40°S, most of the continent experiences seasonal increments of precipitation.

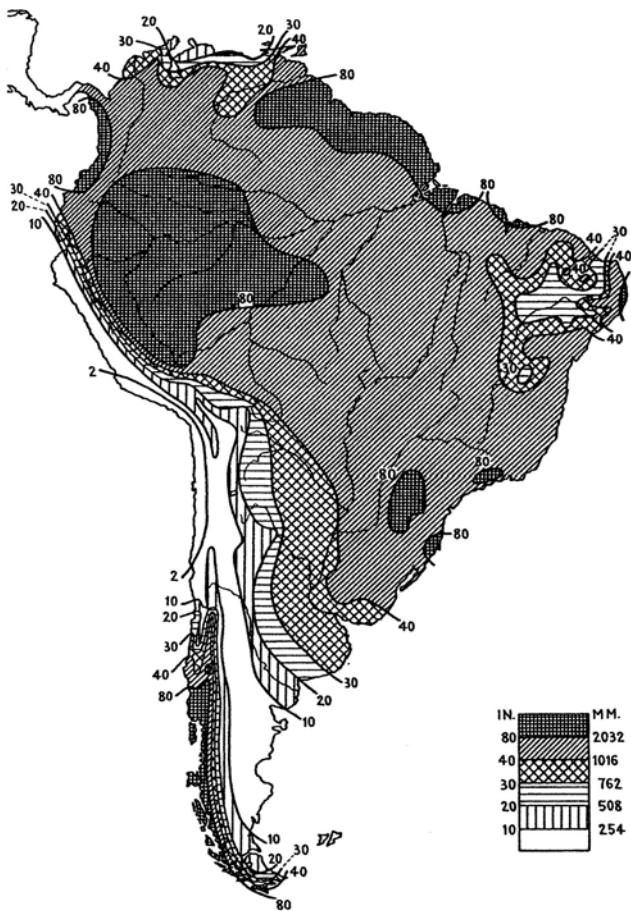

Figure S35 Average annual rainfall in South America.

Climatic regions

Using a standard climatic classification scheme (in this case the Köppen system as modified by Trewartha), the climates of South America generally can be located (Figure S37). The distribution, with the exception of the undifferentiated highlands, follows closely the distribution seen on hypothetical or model continental climatic regions. The extensive equatorial climate (Af) is bordered by areas receiving rain during the high sun season (Aw). These then give way to desert (BW, BS) on the west coast and humid climates (Ca) on the east. Thereafter the Mediterranean regime (Cs) and humid middle-latitude (Cf) climates extend from the desert to Tierra del Fuego. On the eastern side of the Andes, dry climates (BS, BW) occur in the lee of the mountains.

There are, of course, areas within the regions shown that are anomalous. These are discussed within the framework of the regional climates.

Regional climates

To describe the general characteristics of the regional climates of South America it proves convenient to use the following major divisions: equatorial and tropical regions; the

Figure S36 Seasonality of precipitation (after Kendrew, 1942, p. 361).

extratropical region west of the Andes; and the extratropical region east of the Andes.

Equatorial and tropical climates

These are areas that essentially experience high average annual temperatures with copious rainfall throughout the year (Af) or with seasonal rainfall (Aw). Additionally, the dry climates of the west coast are included in this group.

The Af climate largely corresponds to the Amazon Basin. Here, moist convergent winds bring precipitation that reaches its highest amounts where air ascends the slope of the Andes. The actual distribution of rainfall in this regime is clearly not as simple as had been thought earlier, and throughout much of the basin periods of relative dryness occur. Sample data have already been presented indicating this feature (Table S7).

The data indicate that in the lower Amazon Basin, as represented by the rainfall for Para (Belem), a dry period occurs from about September to November. This region provides the typically cited classical type of climate for Af regions. Mornings often are clear, but clouds appear before noon to lead to heavy rainfall in the afternoon. Occasionally, the rain may last for a 24-hour period and thunder characteristically occurs. The vegetation of this area is lush.

In the middle of the basin the dry season also occurs (see data for Manaus) but the total amount of rain is less. This is reflected in the less luxuriant vegetation that occurs. The upper basin, as

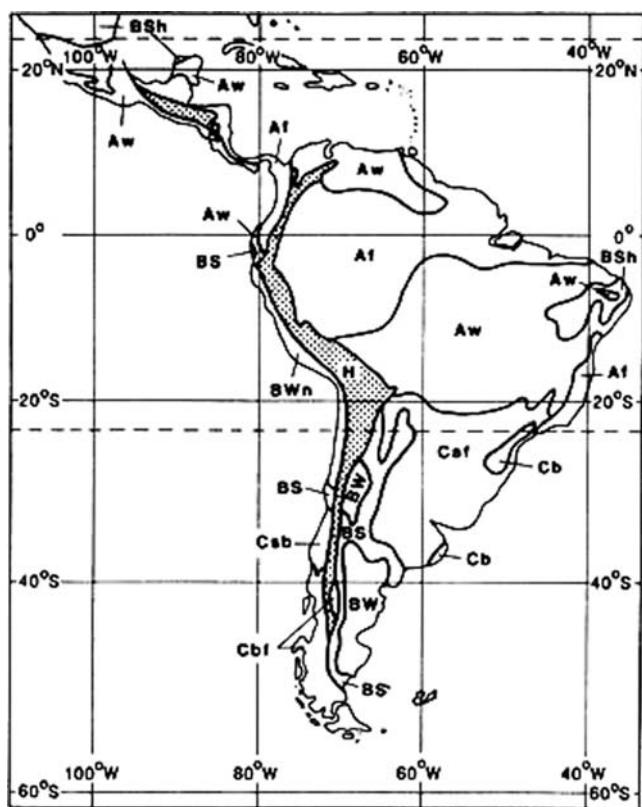

Figure S37 Climatic regions of South America according to the Köppen Classification System as modified by Trewartha. Key: A = tropical rainy climates: Af, Am, tropical rainforest; Aw, tropical savanna. B = dry climates: BS, steppe; BW, desert (h designates tropical and subtropical, n indicates frequent fog); C = humid mesothermal climates: Cs, dry summer; Ca, warm summer; Cb, cool summer. The stippled (H) area is undifferentiated highlands.

noted, is probably the wettest region and Uapes (Table S7) has in excess of 250 cm of rainfall annually.

The tropical wet and dry climate (Aw) borders the Amazon region. Characterized by rainfall during the high sun season, the areas are appreciably warmer than the equatorial rainforest. Typical data are shown in Table S8; at Cuyaba it is seen that the coolest month has a temperature 23°C, but in addition to this, it has an absolute minimum of 6°C.

From about the equator to the Mediterranean regime of central Chile on the west coast of South America aridity prevails along hundreds of miles of coastline. The dominant feature creating these conditions is the location of the Pacific subtropical high pressure. Stable, subsiding air resulting from this cell is directed seaward by the Andean mountains so that the air has minimal moisture content. It might be anticipated that during the seasonal shift of the high-pressure cells a weakening would occur in the system and that it would move away from the coastline. This does not happen since the high-pressure cell merely migrates northward and southward without any major change in its longitudinal location.

The stability of the air is strengthened by the cold offshore North Peruvian Current. This chills the lower levels of the air and diminishes any prospective convectional activity. The cooling of the air is so marked that the moisture does condense and fog is a characteristic of the coastal area. This is reflected in the Köppen designation of BWn, where the lower-case n indicates frequent fog. Table S9 provides illustrative data.

The circulation of waters off this coastline is at times modified by El Niño conditions. This occurs when the subtropical high-pressure cell is located south of its normal position and permits the northeast trades to cross the equator and flow north-easterly parallel to the coast of Peru. A warm current replaces the cold to lead to many dire consequences: one of these is the coming of precipitation to the normally arid area.

Within the general climatic region under discussion are climates that differ from what might be anticipated. Of particular interest in this case are the climates associated with

Northeast Brazil and those of the dry littoral of Venezuela and Colombia.

Northeast Brazil

This is an exceptional area in which rainfall diminishes from in excess of 100 cm along the coast to less than 40 cm inland. Rainfall that does occur reaches a maximum in summer, to give a highly unusual As climate designation of Köppen. The precise cause of the dry region is complex, involving the position of the subtropical high-pressure system over the Atlantic Ocean, the positions of the advance and retreat of the ITC, and the role of coastal and inland topographic variations. In general terms, what appears to occur is that during the southern winter almost all of Brazil south of the equator is under the influence of a greatly enlarged subtropical anticyclone, and rainfall is at a minimum over wide areas. In the summer the anticyclone weakens and equatorial air invades much of southern Brazil, with the major exception of the northeastern portion, which remains under the influence of the high pressure.

The situation in the region is complicated by the fact that even these tropical areas can be influenced by deep intrusions of polar air heralded by a cold front. During the winter months of April to October cold fronts invade Matto Grosso and the southern Amazon Basin once to three times a year. Such invasions cause a drastic fall in temperature, called friagem, and do give rise to widespread showers, often accompanied by hail.

The dry littoral regions

Along the northern margins of Venezuela and Colombia the location is such that onshore trade winds, mountains, and the anticipated presence of the ITC should provide copious rainfall. This is clearly not the case, as data in Table S10 indicate.

To explain the aridity of the area requires analysis of local divergence and subsidence over the region. In spring, the driest season, a deep easterly flow prevails with divergence up to at least 2000 m to give rise to subsidence. In summer the ITC is absent and subsidence continues, although it is not as

severe as spring and some rainfall does occur. Winter, like fall, is relatively rainy but windfield analysis still indicates divergence at the surface. In all, analysis of resultant atmospheric flow indicates that the littoral area is a region in which vertical downward motion of the atmosphere, although varying in strength from season to season, is the dominant factor. It should be noted that to this explanation must be added the suggested effects of land-sea differential friction and the shape of the coastline as contributing toward the relative aridity.

Extratropical regions west of the Andes

Along the west coast of southern South America is a poleward transition from the arid desert to a humid middle-latitude climate. A Mediterranean scrub woodland (Cs), extending some 550 km south of 32°S, occurs between these two extremes.

Atmospheric circulation of the eastern Pacific Ocean is conditioned by the location of the semipermanent high-pressure cell and its associated winds. The desert area owes its origin to subsiding air of the high and enhancement of stability by the cold offshore waters. As winter approaches, the high-pressure cell contracts and decreases in intensity; it becomes centered at approximately 25°S. This permits the belt of westerlies to migrate northward, giving the Mediterranean area its winter precipitation.

The southwestern strip of the continent has been called "one of the most monotonous unpleasant marine climates in the world" (Rumney, 1968, p. 279). As shown in Figure S32, it receives year-round onshore winds from the cool South Pacific. The lack of any continental influence causes this area to have one of the most equitable climates in the world (Table S11).

Extratropical regions east of the Andes

The most exceptional feature of this region is the rainfall deficiency that occurs to give the Patagonian desert. The apparent obvious reason – location on the lee side of a mountain barrier cannot totally explain the aridity. It appears that the westerly winds from the Pacific Ocean, on rising over the Andean chain, form an upper-level anticyclonic ridge over the mountains, with a trough to the east. The narrow width of the continent in this

area causes the trough to be located over the Atlantic, and it is thus ineffectual in providing rainfall to the dry region. This negates the formation of disturbances that typically provide rainfall for similar middle-latitude situations.

The east coastal region north of Patagonia receives rainfall partly because of the greater breadth of the continent at this latitude. The upper-air trough is now over the continent and causes cyclonic rather than anticyclonic conditions to prevail. Low-pressure systems that move eastward and southeastward bring appreciable precipitation to the Argentinian Pampa. Data applicable to stations on the west side of the Andes are given in Table S12.

Climate variability and change

Climate variability in South America is in many ways connected to the Southern Oscillation (SO) and the El Niño phenomena. Of particular significance are the anomalously moist conditions in Peru and southern Ecuador during an El Niño event. It has also been shown that droughts in northeastern Brazil are related to strong El Niño events.

Over the longer time period it has suggested that there is evidence for both a Medieval Warm Period and a Little Ice Age in extratropical South America (Cioccale, 1999). Offering evidence from altitudinal migration studies that reflect relative environmental suitability and glacial advance/retreat it is suggested that about AD 1320 a marked cooling occurred, representing the Little Ice Age. Other studies of paleohydrology and glacial activity in Argentina and Chile also suggest signatures representative of the Little Ice Age. Perhaps such might be expected, for Vargas et al. (1995) show that many rapid climatic changes have occurred in South America since the end of the last Ice Age.

Observations in more recent years indicate further changes. In the Andes Mountains of Peru the Oori Kalis glacier retreated approximately 4 m a year between 1963 and 1978. Since that time the rate has sharply increased. Glaciers in Patagonia have receded by an average of almost 1.5 km over the last 13 years. There has also been an increase in maximum, minimum, and average daily temperatures of some 1°C over the last 100 years in southern Patagonia, east of the Andes.

New interest concerning climate change and variability in South America has led to renewed research. At the same time, modeling studies, as illustrated by Nicolini et al., 2002, provide further information about the future climate of South America.

SOUTHERN OSCILLATION

This is a term introduced by Sir Gilbert Walker (Walker 1923, 1924), then director of the Meteorological Service of India, for an alternation between high and low pressure in a seesaw pattern between two specific stations, but later extended to broad

areas of the southeastern Pacific and the central to eastern Indian Ocean. These were referred to as the corresponding “nodes” (Berlage, 1957, 1959) or “core regions”. A state with southeastern Pacific pressure high is said to have a *high SO index*; when pressure is low, there is a *low SO index*. A popularized account is provided by Nash (2002).

This atmospheric pressure differential sets up a “meteorologic tide”, recorded by tide gauges (Fairbridge and Krebs, 1962), that creates a high average mean sea level during the low-pressure phase, and low MSL in the high-pressure phase.

A third correlation was obtained with rainfall data by Walker and Bliss (1932), and hence with lake levels and sediment cores. The earliest evidence of the pressure variation was reported in 1897 by H.H. Hildebrandsson for the inverse relations between Sydney, Australia, and Buenos Aires, although neither is within the nodal peak areas. In fact there are, it has since been found, worldwide “teleconnections” (Bjerknes, 1969). This term was introduced by the Baron Gerard de Geer (1858–1943) and his student Carl C. Caldenius (1887–1961) in Sweden for the long-distance linkages (e.g. to Argentina) suspected to exist in lake varve sediments, though they were difficult to prove. The small variations can serve as a “vernier” of year-to-year significance, so-called “wibble-matching”, provided that one knows the overall pattern and sidereal chronology (as distinct from the elastic radiocarbon indicators).

Another index of the Southern Oscillation (SO) is the sea-surface temperature (SST). In an illustration provided by P.B. Wright (in Oliver and Fairbridge, 1987, p.797), whose monthly values of each are shown for the period 1950–1983, represented by (a) the pressure anomaly for Tahiti (S.E. Pacific Node) minus that for Darwin (Indian Ocean Node), that is the “pressure gradient”; and (b) the SST anomaly in the equatorial belt roughly 180°W and 90°W. Simple inspection shows a general inverse relationship, warming with lower atmospheric pressure and vice-versa, but not in the detailed wiggles.

Wright (*op. cit.*, p. 796) pointed to the remarkable persistence of the SO, with anomalies maintaining the same magnitude and sign for many months over certain seasons. Between September and December (southern hemisphere spring) there is a 3-month lag correlation between SO and SST (0.91), but February to May it is much less (0.36). There is notable year-to-year variability, the years with the lowest SO index corresponding to El Niño (EN) years, which means warm SST in the southeastern Pacific. The intimate relationship between SO and EN years has led to their joint identification as “ENSO”, although they are not always very closely linked.

Solar forcings

Inasmuch as the teleconnections show that both SO and ENSO phenomena have worldwide repercussions, their explanations must necessarily be complex and planetary in nature. Accordingly, the ultimate source must lie in the sun and effective solar radiation, which, contrary to most assumptions, is remarkably variable and closely related to the spin-rate of the sun. This variance is at least partially predictable, being related to the torques set up in the photosphere by planetary dynamics such as the Saturn–Jupiter beat (19.8593 yr), or various Earth–moon and Earth–Venus cycles (Fairbridge and Sanders, 1987; Windelius and Carlborg, 1995).

Linkage of the sun to the Earth’s climatic systems follows two systems: (a) electro-magnetic radiation with the UV playing a significant role, through ozone production in the upper

atmosphere; and (b) particle and plasma radiation in the solar wind. Because of the particle magnetization this influence is focused on the magnetic poles and the two auroral ovals. It plays an important role in the Atlantic Oscillation.

The first of these two solar forcings has its direct effect in the troposphere, focused on our equatorial belt, and consequently influences the Walker Circulation. The principal energy source of the latter is in the rising air over the countless islands and volcanic peaks of Indonesia and New Guinea. Its major variance is the QBO, the Quasi-biennial Oscillation, which has a mean period of 2.172 yr. But inasmuch as the Earth’s climatic seasons relate closely to a 12-month frame, an astronomically defined pulse is likely to be amplified at “round-number” peaks, in this case ($\times 6$), theoretically at 13.032 yr, but in most climatic time series is simply 13 yr.

The moon is also involved in these cycles, playing an eccentric role because of the difference between the lengths of the solar and lunar years. The extreme perigee–syzygy alignment occurs at a little over 26 yr (QBO $\times 12$). On a longer term, the ^{14}C flux determined from tree rings provides a 69.5/104.26/208.522-yr spectral series (Thomson, 1990), respectively QBO $\times 32/64/96$.

Lunar forcings

The lunar linkage with the QBO suggests an oceanic tidal factor in the SO global role. It is controlled by the position of Indonesia and New Guinea in the Walker Circulation, which is dominated by the orographic forcing and upward flow of warm air generated by the high volcanoes and mountainous islands. This archipelago is uniquely placed on planet Earth astride the equator, and it is also midway between the world’s two largest continental shelves (Sahul and Sunda), each more than 1.5 million km². A rising tide over such a shelf margin brings cold offshore water onto the shelf and gives a minor cooling pulse to the atmosphere. At spring tides this pulse is larger and with more important cyclical enhancements the tides assume an even greater role (Wood, 2001). When the ENSO brings higher sea levels and warmer waters to these shelves the net oceanic flow is always from east to west, although modulated by the tide cycles. According to Currie (1995) these tide cycles are maximized at the 18.6-yr nodal intervals, and then appear worldwide, appearing in the spectra of every geophysical time-series from pressure to SST, to sea level, and other important parameters.

This region at the junction of the Pacific and Indian oceans is thus critical, not only for the SO, but also for global climate. It creates a unique “Warm Pool” (sometimes referred to as the “Western Pacific Warm Pool”). Its linkage to lunar cycles introduces a boundary current relationship. If one considers geostrophic currents such as the Kuro Shio or equally well to the Gulf Stream, as they head north, their velocities increase as the moon’s zenith shifts northward (by over 1100 km) during the 9.3-yr hemicycle of the 18.6-yr lunar period. Due to the Coriolis Effect the acceleration causes a fall of sea level on the left and rise on the right, when SST will rise. These relationships were first observed in the North Atlantic by Russian workers (Lamb, 1977) but apply equally in the Pacific and to both hemispheres.

Exact coherence of terrestrial climate patterns to lunar and solar cycles must not be expected because of the dominance of the 12-month cycle of sunshine (insolation). Thus the QBO is a biennial cycle for a while and then jumps to triennial. The lunar cycle of 9.3 yr only corresponds to the Earth’s orbital

period every 186 yr (20×9.3). The Earth–moon perigee–syzygy cycle, with closest approaches and alignments with the sun, is some 52 yr, but its season varies from four times per year to five, creating 13-yr and 26-yr subcycles. No regular annual cycle is seen. In phase in 1953 and 2005, it coincides with major ENSO years in 1983 and 1997. Those same years mark synchronous events of the solar synodic rotations and the moon’s perigee–syzygy cycle. The latter is almost in phase with the apsidal cycle of 8.849 yr.

El Niño links

Comparison of the SO with the El Niño historical series shows a close association, but also some gaps and unexpectedly missing years. Nevertheless the Quinn et al. (1978, 1983) historical base provides an excellent long-term reference. Two important aspects call for attention: (1) there is no systematic correlation with the sunspot cycle, and flare phenomena are too irregular to be considered. Nevertheless, as mentioned above, the solar influence on the Walker Circulation and the 2.1721-yr QBO needed to be taken into the models. Over 50 ENSO events in four centuries match the QBO, and of these 14 are classed as “super” or “very strong”. (2) Coincidence of many lunar periodicities is seen, notably the 8.849-yr apsidal cycle and the 9.3-yr declination hemicycle. These two also affect the Walker Circulation, so that both solar and lunar forcings are involved. Synergy can be deduced from the fact that at 69.508 yr there are $32 \times$ QBO of 2.172 yr and $4 \times$ lunar tidal beats of 17.3769 yr.

Long-term astronomic control is shown by the Quadrature Cycle (of Stacey, 1963) when all the planets are at approximately 45° to one another in the celestial sphere, and

$$4448.485 = 64 \times 69.508 = 2048 \times \text{QBO}.$$

The 69.508 period is especially significant because it appears in the dendrochronological spectra, notably the ^{14}C flux which is inversely related to solar radiation and linked not so much to the sun, but mainly to cosmic radiation. Nevertheless, the inverse ^{14}C flux pattern is present in the warm cycles of the Greenland ice cores (Stuiver and Braziunas, 1988).

The lunar cycle of 558.14 yr (Wood, 2001), which is the extreme proxigee–perigee–syzygy–perihelion peak, is marked by the resonance intervals of several planetary beat frequencies. Notable is the Saturn–Jupiter lap of 19.8593 yr which ($\times 7$) has an important resonance at 139.015 yr ($= 64 \times$ QBO; and $1/32 \times 4448.485$), the perigee–syzygy precession, but is also locked in to the lunar systems by the nutation and declination period of 18.603 yr ($\times 30 = 139.015$ yr). Correspondingly, the 93.015-yr period that is well known in Swedish tidal history (Pettersson, 1914a,b), and is $1/6 \times 558$ yr, and the 31-yr tidal periods ($1/18 \times 558$ yr) many of which (± 1) are present in the ENSO records, e.g. 1976–1914–1884–1821–1791–1728–1696–1634–1574–1539/41. Observational gaps are of course present and the “old year/new year” problem causes the ± 1 yr anomalies. The perihelion epoch of the 558.14-yr tide cycle also causes a juggle between December and January dates. The next major ENSO should be in 2006/7.

Linkage with climatic proxies is provided by the 208.52-yr cycle in the tree-ring ^{14}C flux (Thomson, 1990). It coincides with ENSO events in 1552–1701–1969. In the astronomical frame it corresponds with the moon’s perigee–perihelion–syzygy and Jupiter/Mercury laps and its $1/8$ signal is 26.06534 yr (in turn, $\times 12$ QBO, and 2×13.0325 yr, the Uranus–Jupiter–Venus synod). Important El Niño dates include: 1969, **1932**,

1857, **1728**, 1708, **1671**, **1652**, **1634**, **1578**, **1541** (very strong or “super” El Niños are shown in bold face).

Evidence of “super-El-Niños” in the geological past is provided by the proxy of ancient beachridges which are well preserved (and isotopically dated) along the semiarid coasts of Peru (Ortlieb et al., 1995). Human populations were also involved by the fluctuations in climate and the effect on foodstuff supplies, so that geoarcheological evidence could be cited.

Multiples of the 31-yr lunar cycle have been found to correlate very closely with the isotopically determined dates, after sidereal correction (Ortlieb et al., 1995). We can use AD 1541 as a well-established anchor point (Table S13).

Conclusion

The range of the ENSO teleconnection can now be traced directly through the “sluice-gates” of the Indonesian archipelago to the Indian Ocean, and thence to the Indian monsoonal rains and pressure anomalies. This east–west flow weakens appreciably with the ENSO, and with the larger lunar fluctuations can lead to “monsoon failures”, droughts and catastrophic starvation (although modern organization and foodstuff reserves can now mitigate the worst events). The seesaw relationship of the SO in general to the El Niño in particular (first described by Walker and Bliss, 1932), is illustrated in the sketch by Harrison and Larkin (1998), showing (a) the “positive” sea-level pressure (SLP; low MSL) over northern Australia and the adjacent Indian Ocean, favoring (b) equatorial westerlies, a warming of the eastern Pacific, and (c) negative SLP (high MSL) associated with the southeastern Pacific and the El Niño in Peru and Ecuador (with heavy rains). Rainfall anomalies around the globe are reviewed by Ropalewski and Halpert (1987). Not shown is the displacement of the cold Peru (“Humboldt”) Current with weakened upwelling and SE trade winds, matched in the northern hemisphere by a similar shift of the cold, south-setting California Current and NE trades, while warm currents hug the coasts, south-setting in Peru and Ecuador, north-setting in Mexico and California. Use of coral-growth proxies for SST (Evans et al., 2002) shows that not only is the SO a major forcing, but overall Pacific SST cycles occurred over the last four centuries, that cluster around El Niño peaks (1634, 1686, 1720, 1791, 1844, 1900). The

Table S13 Peruvian beachridge dates (calibrated radiocarbon: Ortlieb et al., 1995), compared with a projection of the lunar 31-yr tidal peaks, showing long-term fluctuations of the Southern Oscillation

Beachridge dates	Tidal dates	Historical events
AD (BP)	1541 (AD)	Spanish Conquest of Peru
1500 (450)	1504	End of Columbus’ last voyage
1252 (940)	1231	
600 (1565)	611	Classic Maya stage
130 (1820)	140	
95 (1855)	109	
BC		
290 (2238)	288 (BC)	
787 (2735)	784	
1180 (3130)	1187	Chira Ridge J (Peru)
1480 (3430)	1466	Chira Ridge L (Peru)
1650 (3600)	1652	

systematic monitoring and study of ENSO is thus a matter of worldwide importance for both scientific and social needs.

Acknowledgments

Appreciation is expressed to Dr James Hansen (GISS/NASA) and colleagues for helpful discussions, and especially to our deceased associates, notably J.E. Sanders and F.E. Wood.

SPORTS, RECREATION AND CLIMATE

Recreation and sports have been vital elements in most all societies for many centuries. These activities require leisure time, and modern economies have allowed both the time and resources to make recreation and sports available to all. In the United States alone, over a *quarter of a trillion dollars* is spent yearly on recreation. Recreation consists of a myriad of activities and ranges from hiking in the wilderness to watching the World Cup Final of soccer (football) with over 100 000 other souls in attendance. Such activities have been studied by applied climatologists and meteorologists, and their work has been nicely outlined by Perry (1997). The World Meteorological Organization (1996) has published a booklet promoting the value of weather and climate information to sports and recreational activities.

Outdoor sports are, above all, subject to the vagaries of the atmosphere. Thornes (1983) characterized sports into three types with respect to the atmospheric environment. The first is specialized weather sports that must have a certain mix of conditions to take place. Thus, if one wishes to participate in snowboarding, snow must be present. Or, if kite flying is planned, sufficient wind must exist. The second type is weather interference sports. Baseball, rugby, tennis, and polo are examples of this type. Performance can be negatively affected by the atmospheric conditions and the condition of the playing surface. The third type is weather advantage sports in which performance may be enhanced by going first, last, or choosing position. In some respects snow skiing fits this category because the notoriously changeable winter conditions and the packing of the course taking place with successive participants.

Physiological considerations

The basic biometeorological considerations of sports performance have been well researched and are outlined by Tromp (1980). There are well-known effects of thermal stress and high altitude. As sports are performed, the tendency is for human heat production to exceed the ability of the body to dissipate the heat in all but the coldest weather. Therefore, the core

temperature of an athlete's body tends to creep higher and higher and increase dehydration, with its concomitant decreases in athletic performance. The interaction of the atmosphere with sport has been accorded long and loving debate. At Coors Field in Denver (1600 m), much speculation has been accorded altitude's role in increasing the number of home runs, but recent data suggest the characteristics of local winds and the quality of pitching play at least as much a role as altitude (Chambers et al., 2003). At Laramie, Wyoming, the University of Wyoming's football stadium intimidates opponents with the sign "Welcome to 7220 feet". Altitudinal effects were brought to prominence during the Mexico City Olympics of 1968. The city, at 2300 m, was the highest venue of any modern Olympic Games and presented a multiplicity of effects. At this altitude the air has 30% less oxygen than at sea level, so sports that required endurance performances all saw decayed times from previous Olympics. However, another altitudinal effect is decreased density of the air resulting in less frictional resistance. Races at distances of less than 400 m, relay races, and the long jump all saw records. Caution must be used when assessing climatic influences on sport performance. Fitness, skill, and mental outlook play roles that are as least as large.

Objective climatologies of human comfort have been applied to recreation and sports. Yapp and McDonald (1978) developed a thermodynamic climatology of human recreation. They considered the combined influence of solar radiation, temperature, humidity, wind, Earth surface type, and clothing in a thermodynamic model of human comfort. Then they classified locations based on their thermodynamic suitability for recreational activities. DeFreitas (1990) has analyzed various climates as to their recreational potentials.

Cimate and the origins and diffusion of sport

Elements of climate can be seen in locational aspects of sports (Rooney, 1974). From a standpoint of logic it can be stated that as individual sports were invented and evolved, they did so in reasonable harmony with their local climatic environments. Golf, originated in Scotland, has thermodynamically optimal conditions that range in the upper teens and low twenties Celsius – conditions that mimic Scottish summers. Baseball is slow-paced and more suited to the summers of the American midlands than soccer, which requires more endurance per game.

The geographic differences in production of players with superior skills at a sport are partially attributable to climate. The childhood years see sports played at the grassroots. Although there are some ice rinks in Florida, it is apparent that a relatively small percentage of children use ice rinks. In Canada most children play hockey on the outdoor ice and snow that lasts so much of the winter season. The consequence is that, in North America, the National Hockey League talent pool is concentrated in Canada. Conversely, when examining the origins of Major League Baseball players, there is a preponderance of talent from the southern United States where mild winters allow year-round play.

Whereas it can be argued that sports have partially evolved with respect to the climate present in a society, it is also clear that climate should not be construed as defining all locational aspects of sports. The strong imprint of human society is seen in the dissemination of sports into disparate climates far beyond their climatic origins. Golf has been transplanted to much of the

world and is enjoyed by enthusiasts even in many locales where summer thermodynamic conditions are dangerous. In another instance, cricket – a favorite game in the British Isles – was ported to the Indian Subcontinent during colonial rule. Although cricket is more comfortably played in the British Isles, the sport is widespread in India and Pakistan where warm-season conditions are less comfortable. In the United States, major sports evolved with noted seasonalities relating to comfort of play and spectatorship. The beginnings and ends of these seasons have become blurred as dictated by revenue considerations. American professional football was once a fall sport and finished before Christmas, but its playoffs now string all the way through January; the result is some games are played in brutally cold weather that is dangerous for fans and players alike. The Superbowl, however, is always played at a predetermined city that is climatically benign or has a domed stadium. The most popular sport in the world is soccer; it has spread over the globe to be played in venues in every inhabitable climate. No matter whether it is in climates of Amazonia or Siberia, soccer is played and excellence in performance achieved.

Some sports are played during the most extreme conditions: American football games at every level have the reputation of going on despite the weather conditions. Sports competitions are canceled or postponed because of inherent danger to the participants or spectators. Baseball, for instance, becomes dangerous when the pitcher cannot control the flight of the ball due to heavy rain. Golf tournaments are halted when lightning is in the vicinity.

Lessening the atmospheric impact

As sports have developed, two technologies have attempted to diminish the effects of weather conditions on individual events. They are the advent of artificial turf and the increased presence of domed stadia. Fans of European football (soccer) and American football are well aware of the connection between the wear-and-tear on the athletic field and the quality of play during the season. In the deteriorating conditions of fall into winter, mud and unsure footing become more common, and skill might play a lesser role. To obviate this effect, artificial turf with improved subsurface drainage has been placed at many venues at considerable expense.

Some outdoor sports have been played indoors for many decades. Ice hockey was the first major sport to make the transition. The space taken up by a rink is small enough so that the activity can be fit into many modest-sized arenas. This increases player and fan comfort and enables better control of the smoothness of the ice surface. As buildings became larger, space-extensive sports were placed inside. In the United States the Astrodome opened in 1965; this was an attempt to bring baseball inside out of the oppressive heat and humidity of the Texas Gulf Coast summers. The Astrodome began its existence with natural grass turf and semi-transparent roof panels to allow entrance of sunlight. The panels proved impossible as a backdrop for fly balls, so they were painted over and the grass died; ironically, this necessitated the first installation of artificial turf. Through time, domed stadia were put in large cities where the climate provided many inclement days during a sports season. The logic of the existence of the Kingdome, Seattle's original domed stadium, is obvious. The presence of an indoor venue made possible a full slate of home baseball

games in the rain, drizzle, cool marine west coast climate of Seattle. Likewise, the dome in Minneapolis allows baseball and football to be played in comfort in a climate that provides many cold days in their respective seasons. As architectural technologies improved, domes were made retractable. In Toronto, Seattle (the newer dome), and Phoenix, hugely expensive retractable domes allow competition to be “outdoors” when conditions permit! In the building of domes, local societal concern and beliefs often supersede climate. The Green Bay Packers football team proudly plays on “the frozen tundra of Lambeau Field” to the consternation of teams from warmer climates; the cold climate is a source of pride.

Travel for recreation

The citizens of modern societies have had increasing opportunities to travel for recreation. Inherent to this translocation is the cursory climatic expectations of most travelers. Doekson (1996) states “part of the enjoyment in travel and tourism is derived from experiencing at first hand the elements of the weather that define a region’s climate”. Tourists, therefore, travel long distances drawn by the promise of a location’s climate and seasonality.

During the Raj in India, the British Colonial administration made a yearly summer switch from the Ganges Plain to Simla (2200 m) to enjoy milder temperatures and more comfortable recreation. Today, climatology is taken into account as cruise lines reposition their ships to be in the most attractive regions by season. To wit, some of the cruise ships in the Alaskan summer trade migrate to the Caribbean for the winter season. Residents of the cloudy northern European plain make pilgrimages to the Mediterranean to bask in the plentiful sunshine. Likewise, residents of the California lowlands flock to the Sierra Nevada to enjoy the snowpacks of the high-altitude winters.

Bioclimatology

SPRING GREEN WAVE

In midlatitude climates with strong seasonal contrasts, the transition from winter to spring is often abrupt, and characterized by rapid plant growth and development (Schwartz, 1994). Early satellite observations showed how this onset of vegetation activity moves poleward across the landscape like a wave, and thus it became commonly known as the “green wave” (e.g. Rouse, 1977). Despite such simple verbal imagery, the green wave is a multifaceted collection of processes and phenomena that can be observed and measured in many ways. Primarily, it is a time marked by profound changes in the interactions between the atmosphere and biosphere, as plants again become more active participants in the exchange of energy, mass, and momentum between the land surface and atmosphere. Recently, much progress has been made toward understanding these interactions better, especially in measuring the effects of climate change on the biosphere, and implications for climate modeling (Menzel, 2002; Schwartz, 2003). Research efforts have combined developments in remote sensing with phenology, the traditional study of plant and animal life stage events driven by environmental factors (primarily temperature) in spring (Reed et al., 1994; White et al., 1997; Schwartz et al., 2002).

Early modeling work showed that plant phenological development (e.g. first leaf appearance) in spring does not usually occur gradually, but very rapidly over a short period of time, driven by the occurrence of specific synoptic-scale weather events (warm sectors of low-pressure systems, Schwartz and Marotz, 1988). These findings validated phenological events as a sharp and integrative measure of the onset of the spring season. Further, spring phenology is among the most sensitive signs of plant and animal responses to changing temperatures (Chmielewski and Rötzer, 2002). Thus, conventional species-based observations can serve as valuable independent measures of change (Menzel, 2002). For example, phenological observations show that the onset of spring has gotten earlier about 5–6 days over the last 40 years in many parts of Europe and North America, but no similar changes are apparent in China (Menzel and Fabian, 1999; Schwartz and Reiter, 2000; Schwartz and Chen, 2002). Even so, most current surface phenology observation networks are independently administered, largely uncoordinated, and do not cover many places on Earth. A coordinated global monitoring network is being slowly built that combines appropriate native species in each region with widely adapted cloned “indicator” plants, such as lilacs, to help interconnect the species responses between regions (Schwartz, 1999). However, this network is far from complete, and even when finished will not provide the full-surface global and regional coverage needed for planet-wide biospheric monitoring. Some needed phenological information can be extracted from satellite-based sensors, but these satellite measures themselves are limited by cloud-cover interference and other problems. Fortunately, many of these issues will be effectively addressed by a networking scheme that combines satellite-based, phenological model output, and surface phenological observations (Schwartz, 1994, 1998; Zhao and Schwartz, 2003; Figure S38).

Besides monitoring year-to-year changes in plant and animal responses, phenological events can also be valuable indicators of the progression of seasonal changes in the surface energy balance and associated meteorological variables. Earlier long-term studies showed that phenology can highlight abrupt springtime changes in diurnal temperature range, relative humidity, visibility,

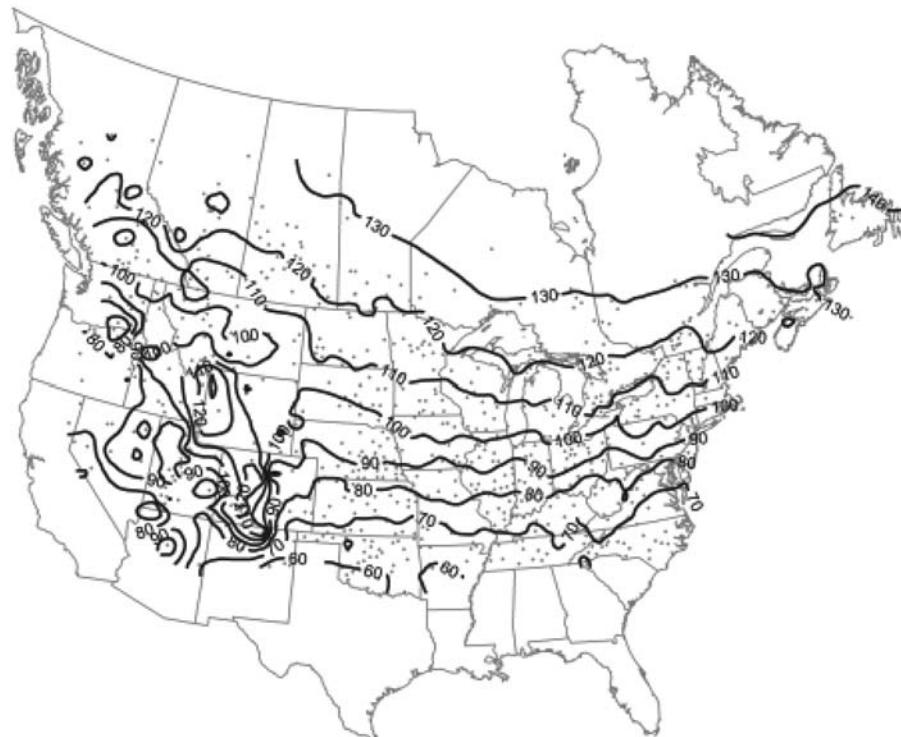

Figure S38 Average 1961–1990 spring indices (SI) model first leaf date (1 January = 1).

and other variables affected by the rapid upturn in plant transpiration and photosynthesis (e.g. Schwartz, 1992). Recent work has confirmed that these changes are ultimately driven by changes in the latent–sensible heat balance, and related to carbon flux (Fitzjarrald et al., 2001; Schwartz and Crawford, 2001; Wilson and Baldocchi, 2000). As new phenological data become available globally, and analyses continue, spring phenological studies have excellent potential to further advance global change science, through coordination with information coming from satellites and carbon flux monitoring sites around the world.

STANDARD ATMOSPHERE

The Standard Atmosphere is defined as “a hypothetical vertical distribution of atmospheric temperature, pressure and density, which, by international agreement, is taken to be representative of the atmosphere for purposes of pressure altimetry calibration, aircraft performance calculations, aircraft and missile design, etc.” (Huschke, 1959). In terms of climatic utility, it represents an approximation of annual average middle-latitude conditions.

History

In his review of the Standard Atmosphere, Sissenwine (1969) suggests that the derivation of a standard for conditions through the atmosphere dates back to 1864. At that time, to aid in providing fairly realistic temperatures for ballooning and mountaineering, the French adopted a simple system. Following World War I, English-speaking countries used various standards, but it was not until 1924 that the first true *standard* was proposed by the International Committee for Air Navigation (ICAN). It used a pressure profile computed from equations and a decrease in temperature of $6.5^{\circ}\text{C}/\text{km}$ to 11 km and thereafter isothermal conditions. A parallel development in the United States by the National Advisory Committee for Aeronautics (NACA) produced a Standard Atmosphere slightly different from that suggested by ICAN, but the NACA standard remained in use in the United States until 1952. With the extension of high-altitude commercial flights after World War II, the International Civil Aviation Organization (ICAO), a successor of ICAN, was established and in 1952 adopted a new Standard Atmosphere. Shortly thereafter, in 1962, the US Committee on Extension of the Standard Atmosphere (COESA) proposed a standard that incorporated new upper-air research based on observed data rather than those interpolated from theoretical estimates. Data represent idealized middle-latitude, year-round, mean conditions for daylight hours for the range of solar activity between maximum and minimum sunspot activity. The most recent version is the US Standard Atmosphere, 1976.

The standards

Complete tables for Standard Atmosphere are provided in many sources. Sissenwine’s article (1969) is particularly useful. Not only does it supply a complete listing of the 1962 COESA Standard Atmosphere, it also provides data applicable to Supplemental Atmospheres. These include monthly (January and July) values as well as those applicable to areas other than those of middle latitudes.

Sample values of the 1976 US Standard are given in Tables S14 and S15. Up to 32 km, values are the same as those of the ICAO Standard Atmosphere and the lowest 50 km are those accepted by the International Standards Organization (ISO). Values for greater heights are derived using rocket and satellite data.

STATISTICAL CLIMATOLOGY

Given the vast quantity of climatic data, statistical methods have wide applicability and utility in the study of past, present, and future climates. The data are a testament to the efforts of countless scientists and volunteer observers all over the world, and make statistical climatology both possible and powerful. Still, climatic processes and phenomena are not observed everywhere at all times and it is often difficult to detect meaningful climatic signals amidst substantial variability in both space and time. By using both traditional and innovative statistical methods, however, climatologists are able to detect and quantify rates of climatic change, estimate the probability of extreme events, and reveal uncertainties in our current understanding of climatic processes and models.

Statistical graphics

Graphical methods sometimes are not included in discussions of statistical approaches; however, they often are the most useful, powerful, and compelling component of any data analysis. The creative and innovative use of illustrations of all kinds is at the heart of many climatic analyses (see Cleveland, 1993; Schmid, 1983; Tufte, 1983 for general discussions of statistical graphics and scientific visualization). Essential descriptions of climatic data – such as histograms, time-series plots, and maps – are used to evaluate data quality and illustrate key relationships. Even more importantly, careful use of statistical graphics and maps can help to generate scientific questions and research hypotheses.

Histograms, for instance, are used to describe overall frequency distributions (Figure S39a). They are particularly important in climatology, where large amounts of data must be visualized and assessed. Percentiles and the existence of outliers also may be derived and evaluated from histograms. By spreading the weight of individual observations over a range of values, kernel-density methods (Silverman, 1986) provide a smoother alternative to the sometimes discontinuous histogram (Figure S39b).

Time-series plots of various types are critical in the visualization of trends, cyclical behavior, and other types of variability (Figure S40a). After detrending (usually by linear least-squares regression), persistence or autocorrelation within a time-series often is more evident (Figure S40b). Scatterplots of lagged relationships (Figure S40c) and autocorrelation functions (Figure S40d) further illustrate persistence or “memory” in climatological time-series. For instance, the climate system has relatively little memory from year to year when it comes to hemispherically averaged air temperature anomalies (Figure S40).

Maps of all kinds – contours of pressure, temperature, or precipitation, graduated-circle maps, etc. – are invaluable in visualizing data. In addition, it is often necessary to reduce the dimensionality of data that are sampled in two or three spatial dimensions as well as in time. By averaging one or more of these dimensions (or using other types of filtering), space-time patterns are more discernible. When global-scale air temperature is averaged over all longitudes, for instance, it becomes evident that the two warming periods during the twentieth century were very different in their latitudinal extent (Figure S41).

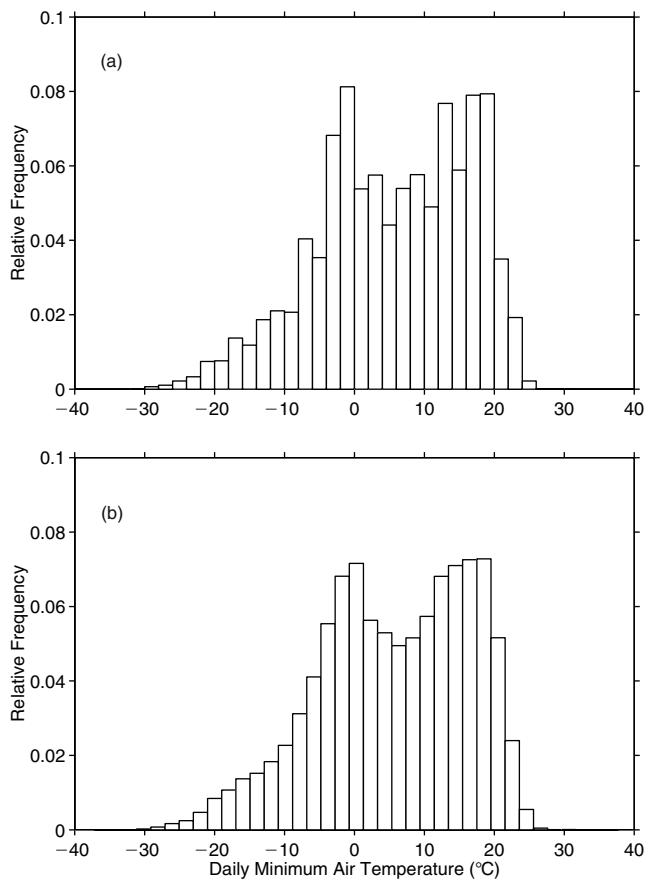

Figure S39 Histograms of daily minimum air temperature (°C) at Lincoln, Illinois, from 1961 to 1990: (a) bins of original data and (b) bins with kernel-density smoothing applied. The bimodal nature of the distribution is more apparent after the kernel-density smoothing has been applied. Data from US Daily Historical Climate Network.

Probability distributions

Probability distribution *functions* may be fit to empirical distributions (i.e. those depicted in Figure S39). While many climatological variables may be assumed to have prescribed distributions – normal distribution for air temperature, gamma distribution for precipitation, Weibull distribution for wind speed – it often is worthwhile to examine the characteristics and fit of a number of distributions. For instance, as averages, monthly and annual air temperature generally follow a normal distribution; however, daily air temperature may have more complex distributions, with extended tails or bimodality (e.g. Figure S39). Straightforward transformations of precipitation data have been shown to sometimes produce better probability models than the standard gamma distribution (Legates, 1991). For analyses where extreme events are of interest, a number of specialized distributions are available. Extreme value distributions are particularly important in determining “return periods” for extreme events, such as the 50- or 100-year precipitation amount (Katz et al., 2002). The interactions between changing parameters, such as mean and variance, and their resulting influence on the

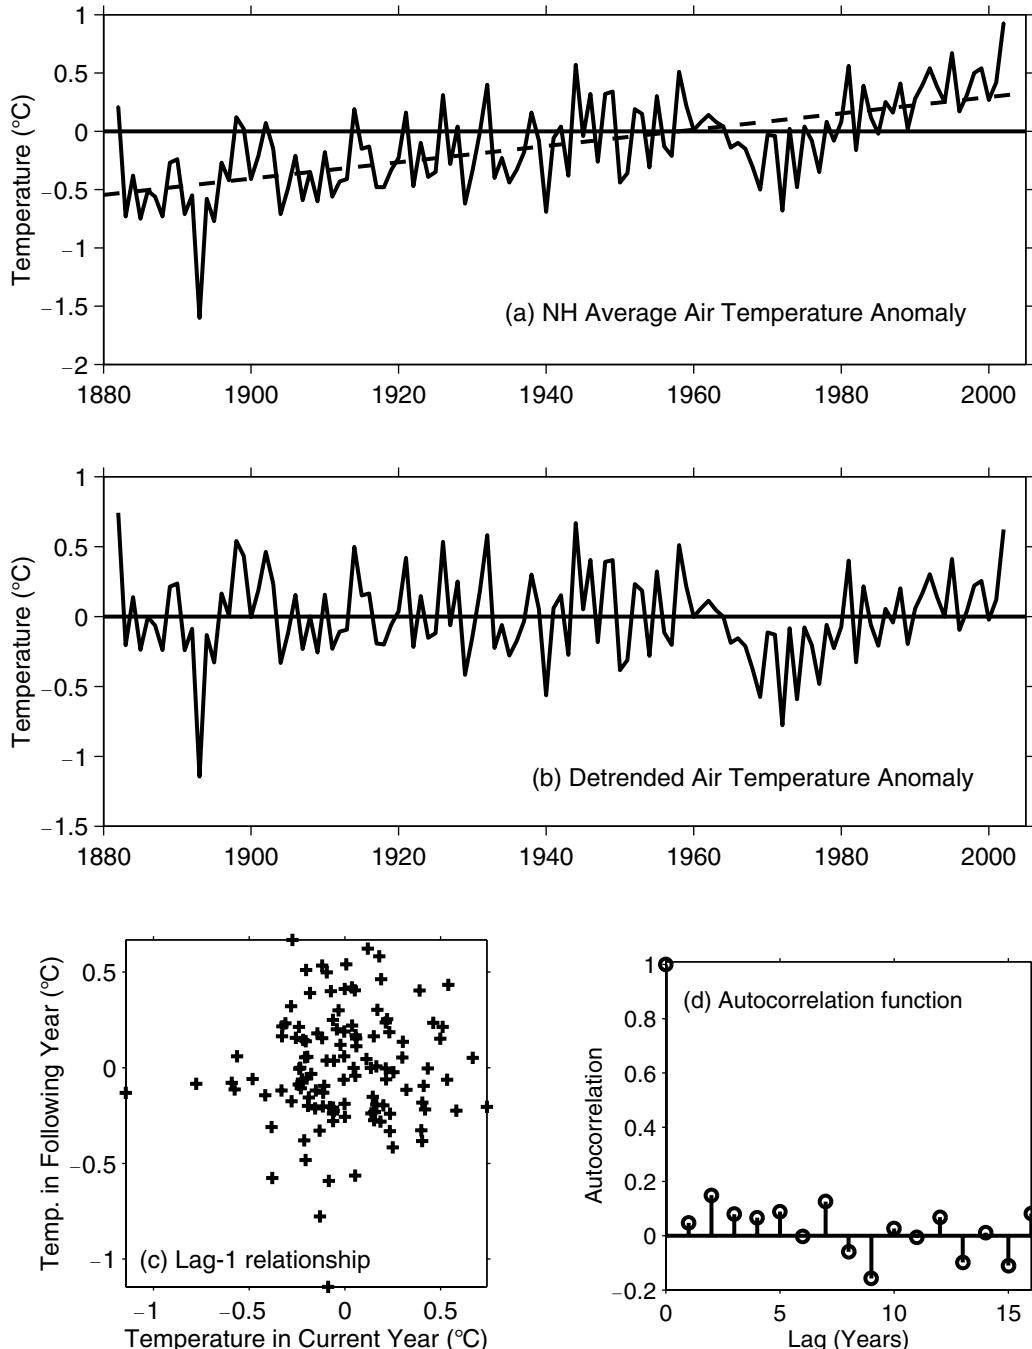

Figure S40 Visualization of northern hemisphere average air-temperature anomalies ($^{\circ}\text{C}$) during January: (a) original data with linear least-squares trend (dashed line), (b) detrended northern hemisphere air-temperature anomalies, (c) lag-1 relationship between current year's anomaly and the following year's anomaly, and (d) autocorrelation function. Data from Jones and Moberg (2003).

probability of extreme events also is of critical importance in climatic change research (Katz and Brown, 1992; Mearns et al., 1984; Robeson, 2002a). A wide range of probability models for climatological variables, both discrete and continuous, are discussed by von Storch and Zwiers (1999) and Wilks (1995).

Regression

The estimation of bivariate and multivariate relationships via regression is one of the most common and powerful statistical tools in all of science. Regression analysis develops an equation that relates a dependent variable to a set of independent variables. As a result, regression can be used: (a) to

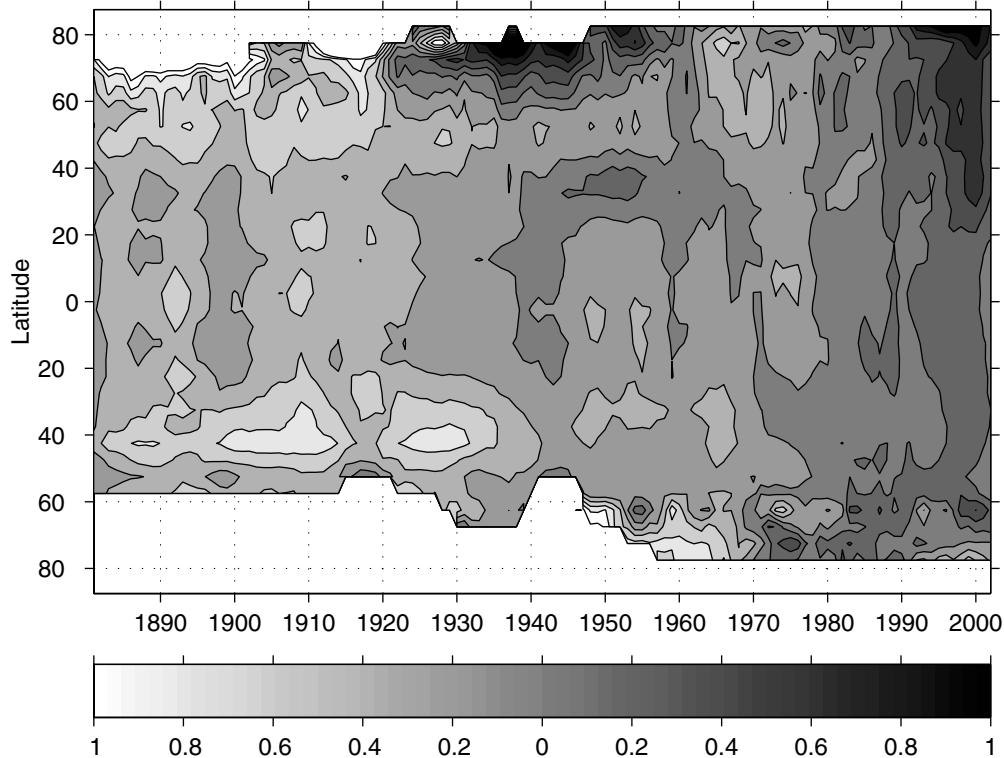

Figure S41 Zonal averages of annually averaged air-temperature anomalies ($^{\circ}\text{C}$): an example of a time-space “slice” of climatic data (contour interval is 0.2°C). In this representation of global-scale near-surface air temperature variation, longitude has been averaged to leave latitude and time as the remaining dimensions. As a result, it becomes clear that the warming during the 1930s and 1940s occurred primarily in the high northern latitudes while the warming in the latter portion of the twentieth century was more widespread. Adapted from Delworth and Knutson (2000) using data from Jones and Moberg (2003).

evaluate the strength and sensitivity of statistical relationships between variables and (b) to estimate “missing” values of the dependent variable, which would include both interpolation and extrapolation (including forecasting). Diagnostic tools associated with regression, such as the coefficient of determination (R^2), are used to evaluate the amount of variability that can be accounted for in one variable by knowing the values of other variables.

As an example of a simple regression analysis, air temperature and atmospheric pressure data for 83 winter days near Bloomington, Indiana can be used to estimate the relationship between those variables and dewpoint temperature (Table S16). The regression analysis tells us that air temperature has a direct relationship (positive regression coefficient) with dewpoint temperature while atmospheric pressure has an inverse relationship (negative regression coefficient). The relationship is relatively strong, with air temperature and pressure “explaining” nearly 85% of the variability in dewpoint temperature ($R^2 = 0.846$). In addition, the sensitivity of the dependent variable to the independent variables can be estimated from the magnitude of the regression coefficients: for a 1°C increase in air temperature, dewpoint temperature is expected to increase by 0.85°C . For each 1 mb increase in pressure, dewpoint temperature is expected to decrease by 0.3°C . These relationships also make intuitive sense. Through its influence on water-vapor capacity and its covariation with evaporation, air temperature controls and limits dewpoint

Table S16 Regression analysis of daily dewpoint temperature, air temperature, and atmospheric pressure for 83 winter days near Bloomington, Indiana, during 2001

Predictor	Regression coefficient	Standard error	t	p-Value
Constant	302.34	63.29	4.78	0.000
T_a	0.85258	0.05905	14.44	0.000
P	-0.30137	0.06202	-4.86	0.000

Notes: The regression equation is $T_d = 302 + 0.853 T_a - 0.301 P$, where:

T_d is dewpoint temperature ($^{\circ}\text{C}$)

T_a is air temperature ($^{\circ}\text{C}$)

P is atmospheric pressure (mb)

$R^2 = 0.846$

temperature. Also, synoptic-scale pressure systems during winter in Indiana are such that high-pressure systems are associated with dry air of continental origin and low-pressure systems transport moist air of maritime origin.

Whenever regression is used, it is critical to consider the limitations and conditions of the data used in model development. In the example shown in Table S16, the primary limitation is that the regression was developed using only winter days for 1 year at one location. It would not be advisable to apply the regression equation at other times of year and at other locations without careful consideration of the potential errors that might occur. Also, the representativeness of the 1 year’s data should be

considered (i.e. whether this one winter represented the range of conditions that can occur).

Although ordinary least-squares (OLS) regression is the most widely used method for estimating regression coefficients, a number of alternatives are available. OLS is particularly sensitive to *outliers* (although outliers can be defined in many ways, they are “unusual” values; in regression, when the outliers occur at the tails of the distribution of the independent variable, the outliers also are known as *influence points*, as they can strongly influence the regression coefficients). For data that contain outliers, a number of robust (or resistant) regression methods can be evaluated, usually in concert with OLS. Whereas OLS minimizes the sum of the squared residuals (residuals are the difference between the observed and estimated values of the dependent variable), robust methods include those that: (a) minimize the sum of the absolute values of the residuals, (b) minimize the median residual, and (c) use OLS after a certain proportion of the data has been “trimmed”. The book by Rousseeuw and Leroy (1987) contains detailed information on robust regression methods, whereas Lanzante (1996) has a number of examples using climatic data.

Variations through time

Trend detection

Although climatologists frequently analyze climatic data for linear trends, there are many different types of temporal variability that occur in climatic time-series. These include nonlinear trends, cyclical variability, quasiperiodic behavior, and discontinuities. The data “window” that is available is a key component of any analysis of temporal variability. It is critical to keep in mind that variations outside the window, if they were known, can change the interpretation of variations inside the window. A “trend”, for instance, may be part of a long-term oscillation that is not apparent within the data window (Figure S42).

The regression methods discussed above can be applied to time-series data to estimate linear trends with time (e.g. Figure S40a). Linear trends estimates are useful for studying a

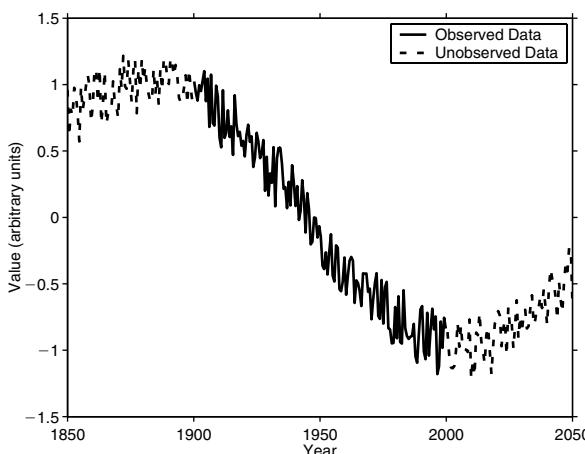

Figure S42 Hypothetical data that are sampled only during the twentieth century. The downward trend during the twentieth century is part of a long-term oscillation that is not apparent within the data window.

variety of types of climatic change, including changes in air temperature (Easterling et al., 1997), extreme precipitation events (Zhang et al., 2001), wind speed (Pryor and Barthelmie, 2003), and growing-season length (Robeson, 2002b).

Smoothing and filtering

Moving averages, also known as running means, frequently are used to reveal variability in a time-series that is masked by either a prominent periodicity (such as a daily cycle) or high levels of variability (“noise”). A moving average, however, is but one special case of a large class of linear operators known as *digital filters* (see Hamming, 1983 for a general discuss of filters, and Holloway, 1958 or Panofsky and Brier, 1958 for overviews of their application in climatology). Although the filters usually used in climatology are designed to smooth a time-series (smoothing filters are known as “low-pass” filters, as they “pass” low-frequency information and remove high-frequency information), filters can be designed to have a wide range of properties (e.g. high-pass and band-pass filters; Hamming, 1983).

The general form of most digital filters is

$$y_t = \sum_{i=-k}^k w_i x_{t+i}$$

where x_t is the original time-series at time t , w_i are the filter weights, and y_t is the filtered time-series. The filter weights usually sum to 1, so that the mean of the filtered time-series is the same as the mean of the original time-series. The filter has length of $L = 2k + 1$ and usually is symmetric about the center weight (w_0).

For instance, a common filtering application involves daily air-quality data, which sometimes have a quasi-weekly cycle that is related to the weekday–weekend commuting pattern. To remove this cycle, a seven-point (equally weighted) moving average could be applied, where all of the w_i are 1/7 (Figure S43a). Moving averages of this type not only can be designed to remove periodicities, but they help to visualize longer-term patterns. In actuality, equally weighted moving averages have properties that make them unsuitable for many kinds of filtering (e.g. they “leak” high-frequency information). As a result, filters that have smoother shapes – such as Gaussian filters – frequently are used to remove high-frequency noise. The Matlab technical programming language has numerous tools for exploring digital filters and their properties.

Spectral analysis

Another approach to analyzing variations of climatic processes with time is to analyze data in the frequency domain. Frequency-domain approaches transform climatic data into a series of periodic (e.g. cosine) functions, each with a characteristic frequency, amplitude, and phase. Frequency represents the time scale, such as one cycle per year, while amplitude indicates how much variability is in the time-series at that time scale (e.g. Figure S43b). Phase (not represented in Figure S43b) represents the timing of the peak of the periodic function. Many climatological analyses are naturally done in the frequency domain since numerous climatic phenomena are well represented by periodic functions (e.g. daily and annual cycles of air temperature and solar radiation).

Spectral analysis is a key tool in the analysis of past climates, particularly in identifying the relationships between Earth’s orbital parameters and ice-age climates (e.g. Hays et al., 1980)

and in analyzing solar influences on climate (e.g. Chambers et al., 1999). In addition to describing periodic and quasi-periodic variations with time, many calculations (e.g. filtering, estimation of autocorrelation functions, etc.) are more straightforward when done in the frequency domain. See Bloomfield (2000) for further discussion of frequency-domain methods.

Variations through space

Spatial visualizations and analysis of climatic information provide highly interpretable tools for analyzing climatic data. Some of the most useful and provocative graphics in the 2001 Intergovernmental Panel on Climate Change (IPCC, 2001) volume, for instance, are the maps of air temperature and precipitation trends during the twentieth century. Well-constructed maps can be used to summarize statistical results, as well as to explore climatic data. A number of useful statistical approaches also can be used to evaluate data that are explicitly spatial, such as spatial autocorrelation, semivariance analysis, and eigenvector analysis.

Spatial dependence

Nearly all climatic variables are such that nearby locations are more similar to one another than are distant locations. This

similarity represents the spatial dependence of the variable and it can be measured in a number of ways. Spatial autocorrelation measures the degree of similarity of locations while semivariance measures the degree of dissimilarity.

Spatial autocorrelation can be expressed as a single number (as in the case of Moran's I) that usually measures the strength of the similarity between contiguous neighbors. Spatial autocorrelation also can be expressed as a function, whereby the correlation of a variable with itself is calculated over a number of spatial lags and then plotted against the distance of each lag (Figure S44). Spatial autocorrelation functions can provide information on the dominant spatial scales of variability (e.g. thousands of kilometers for synoptic-scale phenomena) and also suggest appropriate weighting functions for spatial interpolation (Thiebaux and Pedder, 1987).

Climatological variables frequently have spatial autocorrelation functions that vary with direction, or are anisotropic (Thiebaux, 1976). Solar radiation, for instance, should be more similar in east–west directions than in north–south directions. This information can inform climatologists on how best to sample and interpolate spatial climatic variables – different sampling strategies or spatial weighting functions may be needed in north–south directions than in east–west directions.

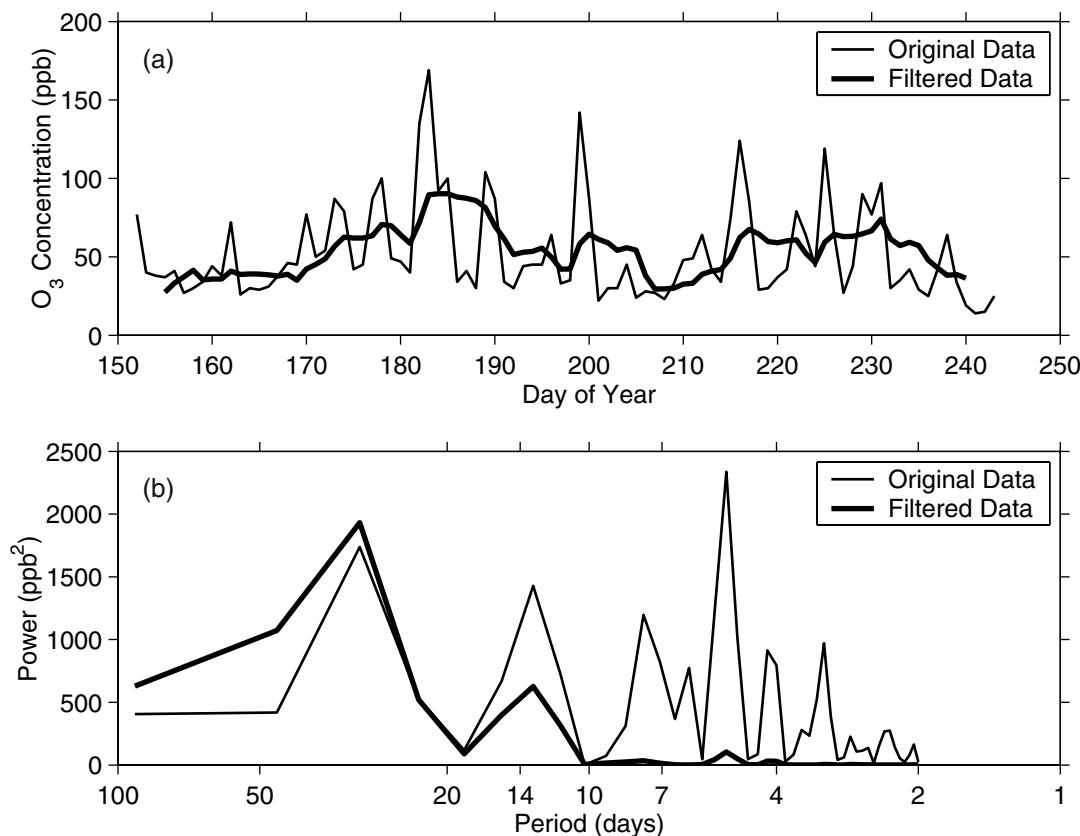

Figure S43 Ambient ozone data (maximum 8-h concentration for each day) from Narragansett, Rhode Island, during the summer of 2002: (a) time-series before and after applying a seven-point equally weighted moving average and (b) power spectrum before and after applying moving average. The moving average smooths the time-series, thereby removing much of high-frequency (short period) information, while preserving low-frequency (long period) information. Equally weighted moving averages, however, are not recommended in most filtering applications, as they “leak” at high frequencies (e.g. note the small peak between 4 and 7 days in the filtered power spectrum).

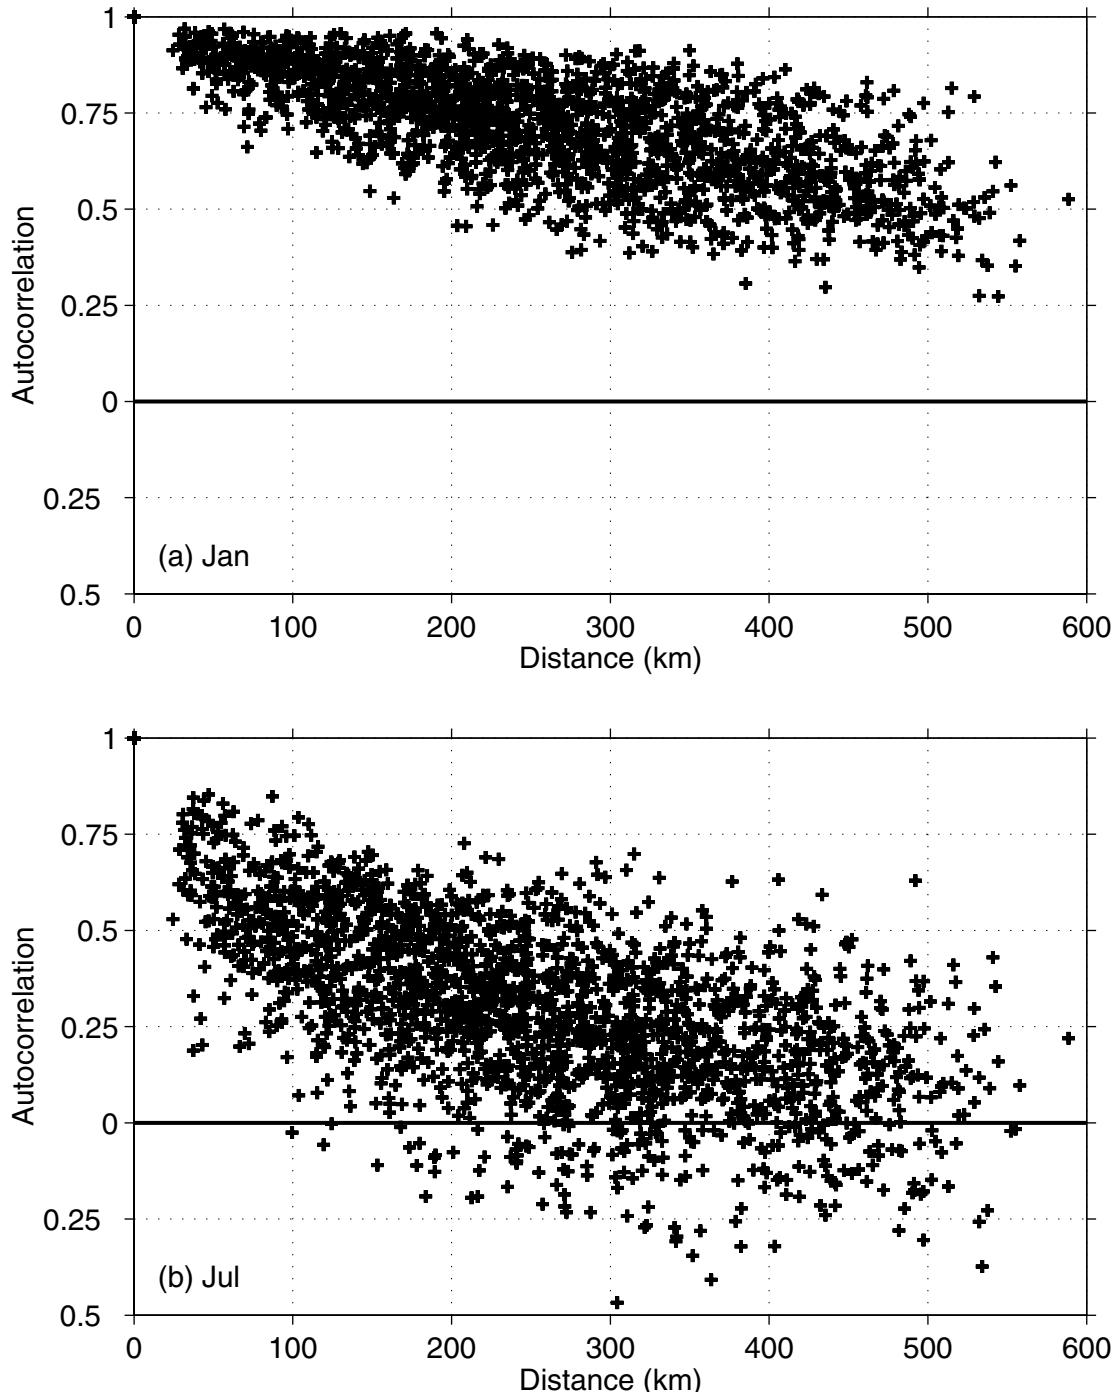

Figure S44 Spatial autocorrelation functions for January and July precipitation using 1961–1990 data from the states of Illinois and Indiana (data are monthly averages from the US Historical Climate Network stations). January precipitation shows much greater spatial coherence, with locations that are more than 500 km apart still having relatively high autocorrelations. July precipitation, on the other hand, has relatively little spatial coherence, as spatial autocorrelations drop quickly (e.g. below 0.5 at distances of ≈ 100 km).

Spatial interpolation

Although gridded data from computer models and satellite-based sensors are widely used in climatology, many climatological variables are sampled at irregularly spaced locations, such as

networks of surface climate stations. To be compared with models or satellite data – or simply to construct a contour map – irregularly spaced data are interpolated to a regular grid. Interpolation also is needed for spatial averaging – the global aver-

age temperature is not the simple mean of all the thermometer-based measurements that are made. The data are interpolated to a grid and then averaged according to how much area each grid point represents.

All methods of spatial interpolation estimate values at locations that were not in the original sample, usually using some form of distance-weighting or spatial function fitting.

Some methods, such as objective analysis and kriging, make explicit use of spatial autocorrelation functions or semivariograms to determine optimal spatial weighting (Davis, 1986; Thiebaux and Pedder, 1987; Isaaks and Srivastava, 1991). The choice of interpolation method can be important (Lam, 1983; Robeson, 1997); however, in data-rich regions, most spatial interpolation methods produce similar results. Adding additional explanatory variables – such as elevation data, though, can substantially improve spatial interpolation results (Daly et al., 1994; Willmott and Matsuura, 1995).

Significance testing

While tests for statistical significance continue to play important roles in climatology, it is a rare occasion when classical, parametric significance tests are directly applicable. Climatic data frequently have characteristics – such as autocorrelation, nonnormality, heteroscedasticity, and excessive sample sizes – that limit the effectiveness of traditional procedures.

In many cases the sample sizes of climatic data are extremely large. At many primary weather stations, for instance, many variables are observed on an hourly basis. Statistical tests performed with samples that contain thousands of observations can produce “significant” results that are scientifically unimportant. For example, two locations where monthly average pressure data are available for 50 years ($n = 600$) would need to have a correlation of only 0.08 to produce a significant result at the 0.05 level for type-I error (i.e. $\alpha = 0.05$). In such cases statistical significance can be misinterpreted if only the significance of the test and not the correlation itself is reported.

Climatic data are nearly always autocorrelated – in both space and time. Autocorrelation results in “effective” sample sizes that are much smaller than the number of observations (n). For instance, if an air-temperature time-series that consists of 100 years of observations ($n = 100$) produces a trend estimate of $1^{\circ}\text{C}/100\text{yr}$ with a standard error of $0.5^{\circ}\text{C}/100\text{yr}$, the trend would generally be considered “significant” (i.e. for a two-tailed test, the associated t -value would be 2.0 with a p -value of 0.048). If the time-series has positive autocorrelation (as most air-temperature time-series do; Katz and Skaggs, 1981), the number of “independent” observations is less than 100. For a time-series where first-order autocorrelation dominates, an established method (Chatfield, 1975; Mitchell et al., 1966) for estimating the effective sample size is

$$n' = n \frac{1 - r_1}{1 + r_1}$$

where n' is the effective sample size and r_1 is the first-order autocorrelation coefficient. Using the equation above with $n = 100$ and $r_1 = 0.7$ produces $n' = 23$. Applying this level of autocorrelation to the regression trend example would change the $1^{\circ}\text{C}/100\text{yr}$ trend to “not significant” (note that autocorrelation is estimated using the regression-trend residuals and, therefore, is not influenced by the trend itself, which is a form of

nonstationary mean). While a number of procedures are available (e.g. Santer et al., 2000), most produce even more conservative estimates of n' than the one above. Regardless of which procedure is used, it is clear that consideration of autocorrelation is essential when determining if a relationship is deemed “significant”.

Computer-intensive methods (Efron and Gong, 1983) also are used in climatology to evaluate statistical significance and confidence. Bootstrapping methods intensively resample the original data (with replacement) to generate empirical probability distributions. This can be particularly important for variables that do not have theoretical distributions (such as mean absolute error or MAE) or when assumptions of statistical tests are not met. Cross-validation usually entails successively removing one or more data values at a time and then estimating the removed values using the remaining data. This process is repeated in order to generate unbiased estimates of “predictability”. Cross-validation has been used in climatology to evaluate climate forecasts and to evaluate spatial interpolation methods (Michaelson, 1987; Robeson, 1994).

Model evaluation

Models of all kinds should be compared with independent observations to evaluate their utility. Sometimes this procedure is called “model validation”; however, that term connotes a binary decision as to whether a model is valid or not. In reality, the evaluation of a model is a subjective procedure that utilizes a wide range of graphics and statistical measures. Essential graphics include scatterplots of model estimates (P_i) against the observations (O_i) and histograms of model error ($e_i = P_i - O_i$). Error measures such as root mean squared error and mean absolute error also are essential; however, neither preserves the sign of the error. Although correlation is useful in evaluating “fit” when developing statistical models, it is not recommended for independent evaluations of models, as models with large error can still produce high correlations (i.e. when the model estimates covary with the observations, but there is a large systematic error). See Willmott (1981) for further discussion of model evaluation.

In model evaluation, as in all areas of statistical climatology, the continued development of new methods is critical. Due to extensive sample sizes, spatial and temporal autocorrelation, and unusual data types (such as multidimensional vectors) frequently encountered in climatology, standard statistical methods frequently are not appropriate. Climatologists, therefore, must continue to explore the creative use of maps, statistical graphics, and alternative statistical methods.

SUNSPOTS

Sunspots are relatively cool, dark areas that are up to 50 000 km in diameter. They represent the visible manifestations of convection cells near the surface of the sun's photosphere. Marking concentrations of strong magnetic fields (2000–3000 gauss), they have lifetimes of a few days up to some weeks. At the solar surface the field is only about 1 gauss. They vary in number and size in a complex pattern of fluctuations, notably with the following periods: 27 days (the sun's rotation rate), 6–17 years, average $11.12 (\pm 6)$ yr (solar cycle), and 178–179 years (all-planet synod). Characteristically observed in pairs of opposite magnetic polarity, individual spots appear to be connected beneath the surface by tubes of high-energy particles. Energy is released in the solar core by the transmutation of hydrogen to helium under appreciably enhanced pressure and temperature, the latter estimated at about 20×10^6 K. The temperature drops near the surface (photosphere) in places to as little as 4200 K but then rises again in the surrounding corona to about 1 million K. The total solar energy output is 3.86×10^{33} erg/s. A minute fraction of this output is modulated by quasi-periodic stress variables, affecting the solar wind and electromagnetic radiations that seem to focus on the sunspots.

The sun and solar activities

On a clear day the sun appears as a bright, featureless orb and care must be taken to warn young people not to look at it without protective systems or blindness ensues. In ancient China and in western Europe, over the last two millennia, sunspots have been observed with the naked eye on foggy days, by twilight, through volcanic or desert dust, or with pinhole observation devices. In China, in particular, sunspots were seen to vary in number, size, shape, and distribution, sometimes in arrangements and in sequences that were found to correlate in mysterious ways with the climates, crops, harvests, and the general good or bad fortune of the emperors. The records of sunspot variability, together with those of auroras (related to the magnetic fields), were carefully preserved and used as a basis for astrologic forecasts. The unwise, or unlucky, astrologers who failed in their tasks were usually executed, which custom, perhaps, may help in part to explain the dedication of the observers. The earliest documented record of sunspots, together with auroras and the 76-yr passage of Halley's Comet, may have been in 467 and 466 BC (historical details are provided by Schove, 1983).

A single sunspot is seen as a dark area or *umbra*, surrounded by a brighter ring or *penumbra*. Over a few days a given spot

may grow from a pinpoint to a large feature, typically up to 37 000 km in diameter. In very active areas several spots may merge into a group extending over as much as 150 000 km. A group has a mean lifetime of about 1.5 months. The spot displays a strong magnetic field, up to 3100 gauss, characterized by plasma flow in or out of the spot, according to magnetic polarity, at a velocity of up to 3 km/s. The middle of the spot is a relatively cool region having a temperature of 4600 K within the granular-patterned photosphere at about 6000 K. The photosphere is generally regarded as a gaseous layer of convection cells that pulsate up and down in a cyclic way about every 5 minutes (Shirley and Fairbridge, 1997).

In the chromosphere (the brightly colored solar atmosphere, situated above the photosphere), but visible only during eclipses, a bright region, or *plage*, with a vortex structure, rises above and surrounds the sunspot. The appearance of a plage precedes that of the spot and has a longer life span (200–300 days), being accompanied by an enhanced magnetic field. Filaments of a plage may undergo a short-lived breakout called a *flare*. A single spot may be characterized by up to 40 flares in the span of its lifetime.

A solar flare is a highly energetic event that is accompanied by the emission of *solar cosmic rays*. The latter are corpuscular or particle radiations, as distinct from and in addition to electromagnetic radiation, such as enhanced *X-rays* and *ultraviolet (UV) radiation* (especially Lyman-alpha flux) that occur at the same time. These transmissions modulate the *solar wind* to interact with the Earth's magnetic field and with stratospheric gases. Very important eruptions are characterized as *proton events*; on such occasions charged particles are carried down in large numbers into the Earth's troposphere, affecting the terrestrial climate. Ordinary solar flares do not affect total ozone in the stratosphere, but proton events can cause a drop in ozone by more than 20%, probably by the production of NO_x, which destroys the O₃. Ozone is important to climate, in that it is the stratosphere's major greenhouse gas. These solar phenomena interfere also with terrestrial electronic, radio, and television transmissions.

Although the *solar constant* is relatively stable at $2.00 \pm 0.04 \text{ cal/cm}^2/\text{min}$ (equivalent to 1395 W/m^2), satellite observations demonstrate small variations in the sun's luminosity over the 22-yr solar magnetic cycle. Longer-term periods, e.g. around 80 yr, appear to reflect small variations in solar radius (Gilliland, 1982), which in turn probably reflects spin rate (see also under Causes below). Day-to-day variations up to 0.4% occur during peaks of enhanced solar activity. The annual global average of incoming solar radiation at the top of the atmosphere is 350 Wts/m^2 , of which only 51% reaches to the surface of the Earth, 16% being absorbed in the atmosphere and 35% being lost by reflection from clouds, snow, etc. (albedo). The mean surface air temperature at the Earth's surface is now 15°C but the long-term average over many millions of years is about $18 \pm 5^\circ\text{C}$. In spite of astronomical arguments that the sun's radiation has changed through time (because the sun is a waning star), there is evidence of the existence of the sunspot cycle in late Precambrian time, and proxy evidence (from sediments, geochemistry, and paleontology) that there has been no gross variation of mean surface temperature on Earth for something more than 10^9 yr.

Solar activity-climatic relationships

The question of how the various solar transmissions modulate the terrestrial weather and climate is one of our ongoing

problems, ranging from astrophysics to climatology. The linkages are complex and variable but fall into certain distinctive categories: (1) solar emissions (as ionized particles or so-called corpuscular emission); (2) electromagnetic radiation such as infrared, visible, UV, and radio waves, and as magnetic fields; (3) by changing radii, tilt and velocity (sun, planets, Earth, moon); and (4) by changing terrestrial parameters (geomagnetic, spin rate, atmospheric chemistry and dynamics, and oceanic processes). It is little wonder that there have been innumerable claims and counterclaims about sunspots and weather, ranging from the reckless to the ultraconservative, indeed, the one being often as foolish as the other. A reasonably balanced appraisal has been presented by Agee (1980). Short-term variations are difficult to pin down, but well-planned studies are now beginning to show results. The fluctuating height of the tropopause, for example, is found to match the sunspot cycle, with evidence of both particulate and electromagnetic radiation. We can learn more from the geological record.

Particularly useful, as a guide for monitoring long-term solar behavior, is the evidence of radiocarbon (¹⁴C) fluxes preserved in tree rings that have now been counted and correlated back for more than 10 000 yr (Suess, 1978; Stuiver and Braziunas, 1989). The particulate bombardment by cosmic particles of nitrogen atoms in the stratosphere generates ¹⁴C, which has a half-life of 5730 yr (although conventionally taken in dating records as 5568 yr, an earlier estimate). This low-energy radioactive isotope, combined in molecular form as CO₂, gradually sinks into the troposphere; entering trees during photosynthesis, it becomes incorporated in the wood (with a short time lag), or in the ocean it becomes incorporated in the CaCO₃ of invertebrate animals such as foraminifera and clams and planktonic plant life. Because of variable mixing rates and contamination, care must be taken with correlations, but in favorable places the tree-ring width (as a climatic proxy for precipitation or favorable temperature) correlates nicely with the ¹⁴C values, a clear sun-climate relationship (Sonett and Suess, 1984).

Besides the direct observations of sunspots, there is also a wealth of long-term records of *auroras*, which serve as a supplementary index of solar activity (Siscoe, 1980; Schove, 1983; Suess and Tsurutani, 1998). The aurora represent a stratospheric optical display seen at high latitudes, oriented about the magnetic poles (aurora borealis and aurora australis), and active during periods of enhanced solar emissions, thus during sunspot peaks and during energetic solar flare events. The incoming solar (and galactic) cosmic rays are largely screened off by the Earth's own geomagnetic field, but this field intensity is not constant and varies with the terrestrial spin rate. It becomes weaker when the spin rate drops, and the rotation itself is modulated by solar activity. During a weakening of the main dipole field, however, the quadripolar influences increase, and sometimes auroral effects can be seen as far as 45° away from the magnetic pole. This could mean they could be visible even to latitude 35°N when the north magnetic pole is in that same quadrant. In the Middle Ages there were thus occasional auroral observations made in Constantinople, Baghdad, and Cairo (Siscoe, 1980). The reconstruction of an over-2-millennium record of sunspots by Schove (1983) has thus a powerful support from auroras, another and quasi-independent proxy resource. A third independent control of the longterm sunspot record has been provided by the ring-by-ring analyses of dendrochronological series (Stuiver and Braziunas, 1989). Over the last millennium,

from the integrated evidence, protracted periods of sunspot weakness or “death” have been given identifying names: the Maunder Minimum (1645–1715), Spörer Minimum (1420–1530), Wolf Minimum (1280–1340), and Oort Minimum (1010–1050). Comparable (names) periods are traced back for over 5000 yr, always being associated with cold episodes in Earth history.

From the terrestrial climatic point of view, besides the flare effects (mentioned earlier), probably the most important stratospheric reaction to incoming pulses of solar radiation associated with the sunspot cycle is the creation of ozone (O_3) from oxygen by the solar UV flux, particularly in the shorter wavelengths. In addition to ozone being the principal greenhouse gas of the stratosphere, surges of ozone concentration are accompanied by a rise in ambient temperature. Its concentration fluctuates markedly in terms of the sunspot cycle (Callis et al., 1979). The behavior of the ozone layer is complicated, however, because of the slow sinking and diffusion of this gas into the troposphere and the liberation by humans of a large number of atmospheric pollutants. However, the chlorofluorocarbons, once thought to be a serious destructive agent of ozone, are now somewhat discounted. Ozone, nevertheless, is important for human health from several points of view; major influenza epidemics, for example, correlate with the sunspot peaks (Hope-Simpson, 1978).

The sun's rotation and orbital motions

The dynamic, changeable nature of sunspots is partly related to the *rotation of the sun*, which normally has a period of about 27 days (first determined in 1613 by Galileo). On Earth we observe a 27-day fluctuation in the cosmic-ray intensity (Forbush, 1966), the geomagnetic field, the UV radiation, stratospheric ozone, and other atmospheric parameters. The sun's rotation period is very close to that of the moon's sidereal cycle, so that they are sometimes in phase for quite a long time. Also, it has occasional accelerations. Changes of the solar spin rate are seen to correlate with the UV transmission, terrestrial ozone, and certain tropospheric (climatic) processes.

The sun does not rotate as a solid body, however, but having highly fluid (gaseous) outer layers it exhibits differential rotation (so-called Spörer Effect). The photosphere rotates much slower than its core. Sunspots near the equatorial belt are seen to rotate faster than those near the poles. In 1863 R.C. Carrington found the equatorial spin rate about 25 days, grading smoothly to a near-polar rate of about 32 days. In their life cycles the sunspots erupt first in solar midlatitudes (30° to 40°) and then slowly drift equatorward where they disappear. Maximum numbers are seen at 10° to 20° in each hemisphere. Plotted for both solar hemispheres, over an 11-yr interval, the spots make a distinctive, repeating pattern, Maunder's Butterfly Diagram.

In addition to the 27-day cycle, the sunspots vary in size and number over an approximately 11.12-yr cycle, a periodicity known as the *Sunspot Cycle*, or because of its many other ramifications, the *Solar Cycle*. It is hardly a cycle in the pure sense, inasmuch as it varies greatly in strength and in length, from around 6 to 17 yr, and is thus more accurately defined as a quasi-periodic fluctuation of about 11 ± 6 yr.

In the course of one sunspot cycle the magnetic tube on the sun's photosphere rises and erupts with the first spot, the *p*-spot (i.e., preceding), succeeded shortly after by its companion, the *f*-spot (i.e., following). The magnetic polarity of the *p*-spot

matches that of the corresponding polar region, which alternates on average once every 11 yr, discovered by G. E. Hale in 1908. This *heliomagnetic (Hale) cycle* of about 22.34-yr represents a dispersed pattern of magnetic fields contrasting with a weak dipolar field that reverses every 11 yr (Babcock, 1961). Over the course of one cycle the total magnetic flux varies by a factor of three, but in the sunspot areas the flux rises by up to three orders of magnitude.

The phase and amplitude of the Sunspot Cycle also fluctuate somewhat regularly over a cycle of approximately 178–179 yr (Jose, 1965; Fairbridge and Hameed, 1983), which is equivalent in length to the All-Planet Synod (of Ren and Li, 1980) and to the variance in the sun's motion with respect to the barycenter. This long cycle also is reflected in the precession of the sun's orbit around the systemic barycenter (center of mass), as first shown by Jose (1965); it has been calculated for the last 12 centuries by Fairbridge (1984a). The mean period is 178.73376-yr.

As in the case of planet Earth, which precesses because of its ecliptic tilt and equatorial bulge being gravitationally affected by the body of the moon, the sun undergoes a similar precession. The sun is tilted to 5° from the mean plane of the planets, and as a nonrigid body it is also an oblate spheroid, so that the combined revolutions of the planets cause a precession of the solar orbit. However, because the vectoral distribution of the constantly changing collective gravitational effect of the planets, the sun, in its orbit around the barycenter, is constantly accelerating or decelerating.

A long-recognized feature of the solar system's periodicities is the phenomenon of *commensurability* (Stacey, 1967), which, following the pattern of the *Titius-Bode Law*, means that many of the longer planetary cycles associated with sunspot behavior are also *beat frequencies* of the fundamental periods (Mörth and Schlämmering, 1979). Thus, for example, the Saturn-Jupiter lap (synodic cycle), with an average length of 19.859-yr occurs exactly nine times during the 178.7-yr cycle. The sun's orbit around the barycenter (to be discussed under Causes), although variable in length, also has an average length of 19.859 yr ($= 9 \times 178.7$ yr). Alignments of Jupiter alone with the heliocenter and barycenter generate a cycle of 177.94 yr (the “King-Hele Cycle”). There are always 16 sunspot cycles per 177.94-yr period.

Wolf numbers

The commonly accepted index of sunspot numbers, the *Wolf numbers*, defines the average daily value as follows: $R = k(10g - f)$, where k = a calibration constant for any given observatory, f = number of spots observed on the solar disk, and g = number of groups. The relative number R is also sometimes called the Zürich number, after the principal observing station (Waldmeier, 1961). Averages are provided by month and year. The cycles are numbered for identification, beginning with cycle 0 (min. 1745.0, max. 1750.3); cycle –12 began in 1610.8 and cycle 21 began in 1975.

The Wolf number is observed to fluctuate from minimums (R_m), approaching 0, to maximums (R_M), which display an extraordinary range of variance, from about 10 to over 200. Short cycles (10 yr or less) have high Wolf numbers, and long cycles (11 yr or more) have low ones. The Wolf number tends to be higher for the cycle of positive polarity (northern hemisphere), so that the 22-yr heliomagnetic cycle is sometimes regarded as the more fundamental signal. Correlations between Wolf numbers and features of the Earth's climate have met with

varied degrees of success or failure, in part due to excessive mixing of conflicting signals. One factor, so far unexplained, is the two-stage response of the climate reaction. The double sunspot cycle responds differently from the single (Willett, 1962). Cycles with higher numbers (>80) may be the reverse of the lower ones. Most successful results so far have resulted from comparing the Wolf numbers over the centuries: protracted low peaks match the colder epochs (of several decades).

Attempts to predict the timing and amplitude of future Wolf maximums have proved to be a risky lottery that has caused much embarrassment. Essentially, there are three methods employed, but so far no consensus has been reached. The methods used are: (1) spectral pattern analysis employing statistical techniques on the astronomically based sunspot-observational data, i.e., since Galileo's first use of the telescope during cycle –12, which began 1610; (2) long-term cycle analysis (employing the historical data plus that furnished by ancient proxy sources, interpreted in terms of planetary–solar cycles, e.g., Fairbridge and Hameed, 1983); (3) planetary dynamic analysis (e.g., Jose, 1965: employing our knowledge of the physics of the solar system), there being essentially two sources of energy: (a) the angular momentum of the system, which amounts to 3.148×10^{50} g/cm²/s, with a translational kinetic energy of 1.99×10^{42} erg; and (b) the rotational energy of the planets, which is 0.7×10^{42} erg, the separate spin motions generating an interplanetary torque that in turn critically affects the sun's spin and its sunspots (Mörth and Schlamminger, 1979; Landscheidt, 1984). The mechanical effect of the sun's gaseous surface is akin to the crack of a cowboy's stock whip – a resonance crescendo effect, triggering flare eruptions and electron showers. Of the different methods, (1) is the usual one adopted but, although useful as a first approximation, it is almost doomed to fail because of the short term of the database. Methods (2) and (3) essentially coincide and therefore tend to be mutually confirmatory, but (3) offers a far more refined signal (see below).

Causes of sunspots

The cause of sunspots essentially is related to the thermal convection within the sun and to activity in the photosphere, but the dynamics appear to be exogenetically modulated. The problem has many complex and controversial aspects. The variability and periodicity of solar activity have led many investigators to consider the possibility of planetary interference (e.g. Schuster, 1911; Huntington, 1923). A correlation between the spectrum of sunspot numbers and various planetary periods and synods makes it extremely probable that some sort of gravitational dynamic process is involved (Johnson, 1946). Even the period of Mercury (88 days) is represented in the sunspot spectral analyses (Bigg, 1967), as are the periods and beat frequencies of certain other planets, notably Jupiter, Venus, and Earth. A simple vertical tide-raising mechanism, however, is ruled out because the amplitude generated by even the greatest planets is inadequate to produce a tide on the sun of more than a few cm. Horizontal tides, however, are appreciable and can be observed (Pimm and Bjorn, 1969).

The gravitational dynamic theory goes back to Sir Isaac Newton (in *Principia*, 1687 transl. 1729/1947), who pointed out that the mutual gravitational attraction between the sun and each of the planets resulted in a common center of mass (the systemic *barycenter*, analogous to the center of mass that exists

in the Earth–moon pair). Because of the planetary revolutions around the barycenter, as mentioned above, the sun describes a miniorbit, which is in plan (e) an *epitrochoid* (a small loop within a large loop). The smaller one is mainly controlled by the 11.86-yr period of Jupiter, and the larger one by the 29.65-yr period of Saturn. Or (b) a *cardioid* (a simple loop with a cross-over), which alternates several times with the epitrochoid (Fairbridge and Sanders, 1987; Charvatová 1997). These two major planets are responsible for 86% of the orbital angular momentum of the solar system. Additional inputs by the other planets contribute to the precession of the entire system, so that each solar miniorbit is different (sun's revolution varying 9 to 14 yr), but returning to a close alignment with most of the planets within a 90° sector once every 178 to 179 yr (so-called All-Planet Synod, APS). As Newton remarked, if “all the planets were placed on one side of the Sun, the distance of the common centre of gravity of all from the centre of the Sun would scarcely amount to one diameter of the Sun.” That distance, however, varies from nearly zero (at peribac: minimum sun–barycenter radius, minimum orbital velocity) to $> 1.5 \times 10^6$ km at apobac: max. sun–barycenter radius, max. orbital velocity). Angular momentum is exchanged between sun and planets as the velocity accelerates or decelerates.

Effective solar radiation to the Earth (calculated by Borisenkov et al., 1983) varies constantly because of the changing distance between the sun and the Earth; three changeable orbital systems are involved: the sun's, the Earth's and the moon's. Furthermore the emission from the sun are in great variety.

The constantly changing planetary alignments of spinning celestial bodies generate not only a torque on one another, but also on the sun, expressed as:

$$\Delta L = \int_{t_0}^{t_1} \gamma(t) dt$$

The strongest pulses develop when Jupiter laps Saturn every 19.875-yr. This Saturn–Jupiter lap (SJL) is literally the *Pulse of the Solar System*. Numerous terrestrial climate series possess an ~20-yr periodicity. As pointed out by Landscheidt (1981), four consecutive pulses define a wave with a quasi-period of 79.46-yr that marks off the epochs of lowest orbital velocity and relative minimum distance of the sun from the barycenter. An empirical cycle of ~80 yr in the sunspot numbers has long been identified as the Gleissberg Cycle with distinctive heliomagnetic behavior (Gleissberg, 1965), and represented in such terrestrial climate series as tree-rings (Maksimov, 1952), in sedimentary varves (Anderson and Koopmans, 1963), and in ¹⁴C variations (Stuiver and Braziunas, 1979). The SJL hemicycle of 9–10 yr appears also to be present in many terrestrial climatic series, especially when it coincides with short sunspot cycles (see also note below on flare periodicity).

In summary, there are two principal perturbing elements concerned with solar activity: (1) orbital alignments of planets that control the trajectory of the sun's miniorbit and its angular momentum (Jose, 1965); and (2) rotational torque of the planets. The first relates to long-term effects (the sunspot cycle and longer periodicities), the second mainly to short-term processes such as high-energy flare activity (particularly X-ray bursts). Concerning the latter, the angular acceleration of the vector of the tidal forces of Venus, Earth, and Jupiter form a cyclic pattern of about 120 days.

There is still a third factor: the sun's own spin rate. Quoting Landscheidt (1984): "The Sun, rotating on its axis, and the Sun, revolving around the center of mass (CM), could be looked at as coupled oscillators capable of internal resonance, resulting in slight positive or negative accelerations of the Sun's spin." Slowing tends to enhance activity, and speeding up decreases that activity. Historical observations disclose a speed-up just before the great seventeenth-century sunspot dearth, the Maunder Minimum, and recently a similar phenomenon has been noticed.

Jumps or jerks in the sun's spin rate were noted, for example, in 1967 and again in 1970, coinciding exactly with alignments of Jupiter, the sun's center, and the barycenter (Shirley and Fairbridge, 1998). Jupiter carries 61% of the system's angular momentum and (with the other planets) appears to transfer some of this energy to the sun, involving both the sun's revolution (velocity) and its rotation (spin rate). Jupiter's conjunctions and oppositions of this sort vary from 3 to 15 yr, but they generate a mean periodicity of 9.8 yr, epochs marked by highly energetic flare events.

From the terrestrial climatic point of view it seems to be no random coincidence that similar jerks in the Earth's motions (both angular velocity and spin rate) were observed, likewise in 1967 and 1970, for example, and again in 1974 and 1981. They are associated with alternation of zonal and blocking circulation regimes and large changes in the angular momentum of the atmosphere, which also is transmitted to the oceanic gyres. In the oceans the current velocity affects temperature (SST) and, because of both the Coriolis effect (the tilt on the sea-surface topography) and the steric effect (expansion or contraction of water body) there will be a corresponding series of sea level changes. The latter have long been a mystery, because the amplitude of these sudden changes grossly exceeds the limits explicable in terms of glacioeustasy (melting or development of ice caps), and are too rapid for tectonoeustasy (plate tectonics).

Inasmuch as the net angular momentum of any rotational system must be conserved, an acceleration of the atmospheric circulation may be compensated in part by a decrease in the motion of the solid Earth's lithosphere and mantle. Below the mantle–core boundary, furthermore, there is a layer of about 100 km that behaves as a turbulent liquid, separating the outer spheres from the solid inner core. The latter tends to maintain its own angular momentum, so that the slowing of the outer layers is recorded by an apparent acceleration of the core. This acceleration can be monitored by watching the rate of drift of the geomagnetic intensity field. Normally the latter drifts westward at about 0.2°/yr (about 20 km/yr near the equator), which means that the core is turning a little faster (to the east) than the crust and mantle. Small variations in the regional distribution of mass in the core and the dynamic motions at the boundary combine to cause long-term secular changes in the value of gravity and the height of the geoid as monitored by repeated satellite observation. Short-term jerks or abrupt changes in the geomagnetic field are now regarded by Alldredge (1984), however, as exogenetic. It should be noted that specialists in geomagnetics and in the geophysics of the Earth's core have in the past tended to attribute all these dynamic phenomena to the endogenetic convective turbulence of the core. Many meteorologists, in contrast, tend to think of the atmosphere as existing in its own little in self-contained world, whereas some solar physicists place a time clock deep in the interior of the Sun (Dicke, 1978), both of which would seem to be emphatically denied by the evidence presented here. However, it seems in point of fact that all the phe-

nomena are interconnected: sunspots, flares, spin rates. All are triggered ultimately by the energetics of the angular momentum of the solar system (3.148×10^{50} g/cm²/s). In a basic NASA/JPL study, Dickey and Eubanks (1985) wrote: "Changes in the gravitational attraction of the Moon and Sun deform the Earth and change the Earth's moment of inertia, this, in turn causes periodic variations in Earth rotation." Corresponding changes are measured in the Earth's oblateness. Thus Earth rotation and polar studies are embarking on a new era.

Just as spring tides are generated on Earth by the moon twice during the synodic month (291/2 days), at both full and new-moon phases, the jerks in the sun's spin rate occur at alignments, both in conjunction and opposition, of Jupiter with the sun and barycenter. The mean periodicity of flares so generated is just over 2 yr (Landscheidt, 1984). This is one-quarter of the 9.8-yr flare cycle and one-fifth of the sunspot cycle, although we should recall that these are all average lengths and cannot be used casually for predictive purposes.

Quasi-biennial oscillation

On planet Earth the Quasi-biennial Oscillation Cycle (QBO of about 2.172-yr) is commonly ascribed to a self-generating dynamic relationship in the atmosphere. It was first discovered in American temperature data by Clayton in 1884 and has been the topic of innumerable subsequent studies. Correlations have been pointed out between the QBO and pressure, equatorial stratospheric winds, wine harvests, sea level, lake varves, tree rings, ozone, and other variables (Ebdon, 1975, among others). Inasmuch as terrestrial climates and their proxies respond much more vigorously to the 12-month seasonal determinism, a 26-month pulse is likely to conform to a biennial series for some time and then jump in phase to a triennial. Schove (1983, p. 230) recognized that strong but short solar cycles (~10 yr) are generally associated with 2-yr weather cycles, whereas weak but long solar epochs (often ~12 yr) are more likely to match 3-yr sequences. This characteristic has been successfully used as a vernier device by Schove (1983, p. 333 ff.) for correlating floating time series (tree rings, varves) during the Holocene.

Schove (1983, p. 319, i.e., a reprint of his 1964 paper) had recognized a pressure parameter in his weather series that could be traced back to the equatorial Walker Circulation and the Southern Oscillation. That, in turn, is found to be often linked also to the El Niño phenomenon, and indeed today they are commonly abbreviated together as ENSO. The Southern Oscillation is a classical ocean-atmosphere feedback system, with global signals, such as tropospheric pressure and temperature, cloudiness, and atmospheric CO₂. It is periodically modified either in the east (Pacific) by a weakening of the southeast trade wind, a reduction of upwelling off Peru with warm-water invasion (El Niño), or in the west (Indian Ocean) by eruption of cold air from central Asia (Monsoon fluctuation). Very roughly, three QBOs make one El Niño (~7 yr), but there is little regularity. Historians have traced El Niño back four centuries; important years recently have been 1925, 1930, 1934, 1941, 1943, 1951, 1953 (mild), 1957–1958, 1965, 1969, 1972, 1976–1977, and 1982–1983. Catastrophic flooding is associated with the El Niño in the mountainous and semiarid coastal areas of Peru (documented for example in 1701, 1720, 1728, and 1891). The El Niño of 1925 saw the greatest floods since the Spanish occupation; on the coast, off Lima, the SST rose from 15°C to 26°C in 3-months. The situation was very similar in 1982–1983.

Sunspots and the lunar connection

A series of papers by Currie (1984) and others have indicated a strong signal in terrestrial climate series from the lunar nodal period (18.61-yr), which is also the cause of a nutation of the same period in the Earth's orbital precession cycle (Borisenkov et al., 1983, showed its insolation effect). In long-term proxy records, e.g., from North American tree rings, from the Nile, and from ancient China (Currie and Fairbridge, 1985), it is evident that in certain periods the 11-yr sunspot cycle is identifiable, but in others it is not, being replaced by the 18.6-yr lunar period (Wood, 1978, 2001). Currie has demonstrated that the lunar tidal effect normally develops a triple-phase standing wave around the northern hemisphere, analogous to the simplest Rossby wave. When the maximum lunar-solar tide (which peaks 4 years later than the maximum lunar declination) is in phase with the sunspot cycle, the climatic effects are sometimes suppressed, sometimes enhanced. From time to time, however, the phase is strangely reversed, a "flip flop" of a 180° within one or two cycles (Currie, 1984). Fairbridge (1984b) compared the Nile floods and droughts (since AD 622) with both the solar and lunar cycles, finding indeed that in some centuries the droughts matched the sunspot maximums and in others the minimums, whereas in other epochs the lunar cycle was dominant.

The long-term lunar period of about 556 yr, the Precession of the Lunar Perigee (PLP), discovered by Pettersson (1914) and often called the Pettersson Cycle, is also the hemicycle of the 1112-yr Outer Planets quadrature cycle (of Stacey, 1967), and every third alignment, 1668 yr (Stacey's Zero Check) seems to correlate with the high sea levels of the Fairbridge (1961) eustatic curve.

Conclusion

One key to understanding all these terrestrial climate trends is the *amplitude* and the *timing* of the solar emissions, which have been suggested in some of the early papers. Evidently the sunspots have a message, but many more studies are needed before it can be clearly read and used as a tool for reliable prediction.

SYNOPTIC CLIMATOLOGY

The term synoptic climatology was adopted at the headquarters of the US Air Force in the early 1940s in reference to analyses made of past weather situations in order to assess the frequencies of different operational conditions (Jacobs, 1947). Synoptic is used by meteorologists to denote the synchronous weather conditions typically depicted on a synoptic weather map. By extension, because large-scale atmospheric circulation systems such as cyclones and anticyclones are analyzed from such weather charts, features with a horizontal dimension of *ca.* 1000 km and a lifespan of about 5–7 days are called synoptic-scale systems. In a broad sense, therefore, synoptic climatology is the study of local and regional climates in terms of the properties and behavior of the atmosphere over and around a given area; the information used in such studies is primarily that shown on synoptic weather maps (Barry and Carleton, 2001; Yarnal, 1993; Court, 1957; Hare, 1955; Jacobs, 1946). Synoptic climatology is a major branch of climatological study in parallel with dynamic climatology, microclimatology, bioclimatology, paleoclimatology, and applied climatology. The modern term climate dynamics encompasses concepts and methods of both synoptic and dynamic climatology.

The basic procedures involved in a synoptic–climatological study are, first, the determination of categories of atmospheric

circulation type (or other comparable descriptors of synoptic-scale weather processes); and, second, the statistical assessment of weather conditions in relation to these patterns. It has been common practice to distinguish a small number of types of airflow or pressure pattern from daily weather maps and then to calculate average values for each type of temperature and daily precipitation totals at weather stations. Indeed, these studies began almost as soon as weather maps were first produced in the late nineteenth century by such well-known meteorologists as Abercromby (1883) and van Bebber and Köppen (1895). An illustration of the contrast between mean conditions and the aggregate effect of different airflow patterns on afternoon winter precipitation frequencies in Hokkaido, Japan, is shown in Figure S45. This emphasizes the contribution made to the interpretation of climatic regimes through use of a synoptic framework for analysis instead of the calendar intervals employed in conventional climatic statistics.

Synoptic climatological classifications

Classifications of atmospheric properties and processes can be made on the basis of various synoptic features including: the pressure pattern, the airflow direction and isobaric curvature, streamlines, the large-scale steering pattern of the midtropospheric circulation, and derived properties such as divergence and vorticity (LeDrew, 1984). The spatial scale of the analysis may be regional (*ca.* 10^6 km^2) up to hemispheric (Yarnal, 1984); the time interval considered is usually 1 day, but may be a synoptic interval of up to 5 or 6 days. Table S17 sets out the range of methods that have been used, according to the spatial scale. For convenience, approaches used in identifying synoptic types can be considered under three headings. First, the sea-level pressure map (or upper-level contour chart) can be regarded in a static sense and the map pattern over a given area at a specified time forms the basis of classification. Second, there are kinematic classifications where the large-scale movement of pressure systems is examined. The most important approach here is the Grosswetter classification scheme developed in Germany by Baur (1951; Hess and Brezowsky, 1977). Similar work was undertaken in the United States (Elliott, 1951). Third, observations of weather elements may be grouped directly into sets of weather types or complexes; Russian climatologists use the term complex climatology in this connection.

Until the 1960s, synoptic classifications were developed through subjective manual procedures. By studying numerous daily weather map sequences the researcher gains familiarity with the more commonly recurring patterns of synoptic weather map features and thereby designates a limited number of map pattern types. The recognition of numerous types will reduce the variability of weather conditions within each category but, unless a very long record is considered, most type categories will be represented by only a few cases, which makes their characterization difficult. Conversely, if few types are distinguished then each category inevitably contains a wide variability of weather conditions. From several empirical studies of the pressure patterns and associated weather over the European Alps, it appears that the variability of weather conditions (as defined by the standard deviation of individual weather elements) shows a significant decrease as the number of types distinguished in a synoptic classification increases from 10 to 30, but little change thereafter (Fliri, 1965). Modern analyses almost invariably use objective classification procedures, taking advantage of the

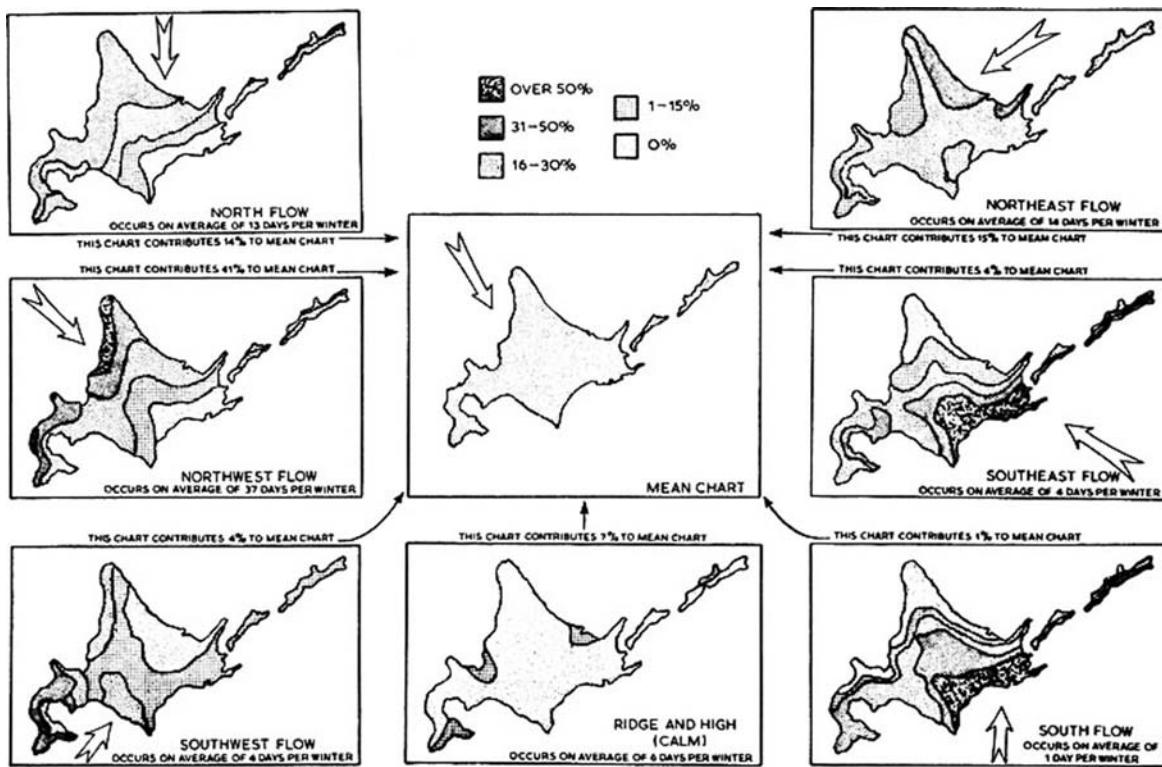

Figure S45 Percentage frequency of days at 1800 hours having precipitation amounts for preceding 6-hourly period greater than 1 mm (0.04 inch) in Hokkaido, Japan for December–February (from Jacobs, 1947).

availability of digital datasets on pressure fields or wind fields, and of meteorological observations. A variety of such objective procedures now exist. The major ones are:

1. Correlation analysis of pairs of maps with an arbitrary assigned level of similarity. Categories are then determined by some type of grouping or clustering method.
2. Objective specification of pressure or height fields by principal component (or empirical orthogonal function) analysis followed by some clustering procedure.

Correlation methods (Lund, 1963) examine the similarity of pressure patterns over an area by correlating grid point pressure values for each possible pair of maps. The pattern (key day) that has the largest number of maps correlated with it (using a threshold of, say, $r = 0.8$) is selected as type A, and these cases are abstracted and the next largest group is designated type B, and so on. On completion of this process, each case is rechecked to see that it is assigned to the key-day group with which it has the highest correlation. An analogous classification procedure using sums of squares has been developed by Kirchhofer (1973) and widely applied to develop regional classifications for the Alps, the western United States, and the Canadian Arctic. The two procedures are essentially the same (Willmott, 1987). Both of these approaches assign classes on the basis of the shape of the pressure patterns but do not take account of the intensity of pressure systems.

The earliest studies in objective specification of isobaric or contour patterns made use of Fischer–Tschebyschev orthogonal polynomial equations (Friedman, 1955; Hare, 1958; Malone,

1958), but later workers generally use the more flexible empirical orthogonal functions (principal components or eigenvectors). These are the optimal set of mathematically determined functions that provide the most efficient representation of variance in the dataset. Each function is mutually uncorrelated (orthogonal) in space and the coefficients of the functions are orthogonal in time. The method is described in standard statistical texts and various meteorological studies (Grimmer, 1963; Joliffe, 1986; North et al., 1982). The first few principal components of pressure fields usually describe simple zonal and cellular patterns. An individual pressure map is represented by some combination of these components and a classification based on principal components is constructed by defining arbitrary ranges of the coefficient (or amplitude) of each component (Kruizinga, 1979). Typing via map patterns and principal components each has its own advantages and drawbacks. The orthogonality constraint of eigenvectors can be avoided by using obliquely rotated principal components, but examination of this technique is not yet far advanced (Richman, 1981).

The Grosswetter concept involves the identification of large-scale weather patterns over a region. Local weather conditions will differ, but overall there is a large-scale (synoptic) interrelationship. A Grosswetterlage (large-scale weather pattern) is the mean pressure distribution (at sea level) during a time interval during which the position of the stationary (steering) cyclones and anticyclones and the steering within a special circulation region remain essentially unchanged (Baur, 1951, p. 825). Later work takes account of the 500-mb midtropospheric circulation patterns also. A daily catalog of *Die Grosswetterlagen*

Source: After Wanner (1980).

Mitteleuropas is published monthly by the Deutscher Wetterdienst (1994). Russian meteorologists have extended this approach to hemispheric circulation patterns. In the classification developed at the Arctic and Antarctic Research Institute, St Petersburg, by Vangengeim (Girs, 1966) and at the Institute of Geography, Moscow by Dzerdzevski (1962) broad categories of zonal and meridional circulation and associated cyclone tracks are distinguished, with subdivisions according to the number of sectors affected by amplified waves or blocking of the westerlies and associated meridional motion. Daily catalogs of these classifications are available from 1900 to the present.

The categorization of weather types from combinations of the joint occurrence of several weather elements (temperature,

cloudiness, wind speed, etc.) has proved of limited value in interpreting climatic conditions. The selection of six classes of temperature, three of cloudiness, four of wind speed, and three of precipitation, for example, gives rise to a system with 228 possible combinations. Frequency data on some specific climatological contingencies may be of general climatological interest, however, and especially if a suitable means of synoptic interpretation is adopted. Objective weather types have been determined in one case study for Madison, Wisconsin, using principal component analysis (Christensen and Bryson, 1966). These types are shown to have a synoptically realistic spatial pattern. This approach for individual stations was also applied by Kalkstein et al. (1987) using weather data and synoptic circulation variables to obtain a temporal synoptic index. Subsequently, Kalkstein et al. (1996) developed a continental-scale analysis of weather types (spatial synoptic classification) (SSC) based on airmass characteristics. A calendar for six types based on the SSC method has been prepared for 327 stations in North America, spanning over 40 years (Sheridan, 2002).

Applications

Many regional synoptic catalogs have been developed. A large number of these are described by Barry and Perry (1973) and Barry and Carleton (2001). In several instances climatic analysis has not proceeded beyond the development of the catalog, but certain catalogs have been widely used. Illustrations are given of some of these applications. The most common application of synoptic catalogs is in the quantitative characterization of regional climatic conditions. This has included analysis of the local and regional weather characteristics of the synoptic types, their annual frequency, and typical sequences. German climatologists have used the Grosswetter catalog extensively to analyze temperature and precipitation conditions in central Europe; British climatologists have similarly made use of Lamb's catalog (1972) and objective procedures to reproduce the type categories have been developed by Jones and Kelly (1992) while El-Kadi and Smithson (1996) use the Kirchhofer approach to generate comparable sea-level pressure patterns. The Lamb catalog is currently maintained using an objective procedure, and the latter has been used back to the late nineteenth century, by the Climatic Research Unit at the University of East Anglia, UK. Such baseline characterizations should be an essential element in all climatic descriptions. For some other areas special-purpose synoptic groupings have been devised to examine such diverse questions as urban influences on air pollution, airflow patterns favoring dispersion of particular spores and insects, critical forest-fire weather conditions, and so on.

A question of general climatological significance concerns the delimitation of natural seasons. The tendency for particular calendar intervals to be characterized predominantly by a certain type of weather regime is well established. This has been shown for the British Isles, Europe, and East Asia, as well as in a broader hemispheric framework by Bradka (1966), Bryson and Lahey (1958), and Lamb (1964). In northwest Europe, for example, spring is characterized by high variability of temperature and precipitation, whereas fall weather tends to be much more persistent, with a high frequency of anticyclonic conditions. More controversial is the purported occurrence of weather singularities; i.e. the recurrence of some weather characteristic about a specified calendar date. Examples include the 20–25 January thaw in New England and the onset of summer rains in

Arizona–New Mexico about 1 July. These events are most usefully interpreted in terms of tendencies for recurrent circulation regimes, but even so it is known that long-term trends in the relative frequency of such singularities occur, presumably in relation to changes in the hemispheric circulation patterns.

Another basic topic where synoptic catalogs find application is in studies of climatic fluctuations. It is a commonly held premise that such fluctuations arise, at least in part, as a result of the changing frequency of particular types of circulation pattern. Hence, if northerly outbreaks of Arctic air in winter become more frequent, winters are likely to become more severe. However, studies suggest that changes in the frequency of identified types of pressure pattern provide an insufficient basis on their own for inferring changes in associated climatic factors (Barry et al., 1981; Yarnal, 1985). This is because, among other things, synoptic catalogs do not generally take account of the intensity or duration of the pressure patterns or airflow regimes, synoptic types are each associated with a range of possible climatic conditions, and because the internal characteristics of a type may themselves vary over time due to other external factors (such as changes in sea-surface temperatures, in atmospheric stability, in incoming solar radiation).

Originally it was hoped that synoptic catalogs would find extensive use in long-range forecasting. It was considered that recurring sequences of weather patterns could perhaps be recognized, enabling predictions to be developed when similar precursor conditions were present. Some limited applications of this approach have indeed been possible, particularly when computer searches for analog situations are made. However, there are usually only a few close analogs of any large-scale situation when this approach is applied to 15–30-day intervals, and when consideration is given not only to the surface and upper-air patterns, but also to external variables such as snow cover or soil moisture content, sea-surface temperature anomalies, and so on. Moreover, the subsequent weather developments do not always proceed in a similar direction when given apparently analogous starting points! Nevertheless, the application of a synoptic climatology can serve as an important check on numerical simulations using atmospheric general circulation models (Kidson, 1995).

TAIGA CLIMATE

Location and definition

The vast majority of the world's people live in the middle latitudes between 30° and 60°. Using the Köppen system of climate classification there are two major climate regions in the middle latitudes. The Mild Midlatitude climate is designated by the upper-case letter "C" and is exemplified by Mediterranean, Marine West Coast, and Humid Subtropical climates. The Severe Midlatitude climates are designated by the upper-case letter "D" and include the Humid Continental climate of New York and Chicago and the Sub-Arctic climate of Moscow and Montreal. The circumpolar sub-Arctic region generally coincides with 50–70°N latitude and includes much of Alaska, Canada's Northwest Territories, as well as northern Europe and Asia. The sub-Arctic climate region generally coincides with the boreal forest and is sometimes referred to as the "Taiga", the Russian word for forest (*Taiga*, 2000).

Climatic characteristics

High latitudes have large annual variations in daylength and solar input. Additionally, albedo varies widely from a maximum in winter when snow covers the surface to a minimum in the summer, especially in the dark green boreal forest. The continental climate of Edmonton in Alberta, Canada, has an annual temperature range of 31.4°C (Figure T1). The annual temperatures in the sub-Arctic, which can range from -54°C to 21°C, exhibit the greatest range of all climate regions (Kaplan, 1996). While the summers in the Taiga are relatively cool, temperature maxima can exceed 30°C (86°F). In Verkhoyansk, Siberia, annual temperature ranges have been recorded from -70°C to 30°C. Most of the year the Taiga climate is dominated by cold, Arctic air, and this realm serves as the source region for continental Arctic airmasses.

The average annual precipitation total in the Taiga is only 12–50 cm (5–20 in), yet low evaporation rates result in a moist climate (Eugster et al., 2000). As the climograph for Edmonton shows (Figure T1), the precipitation has a marked annual cycle

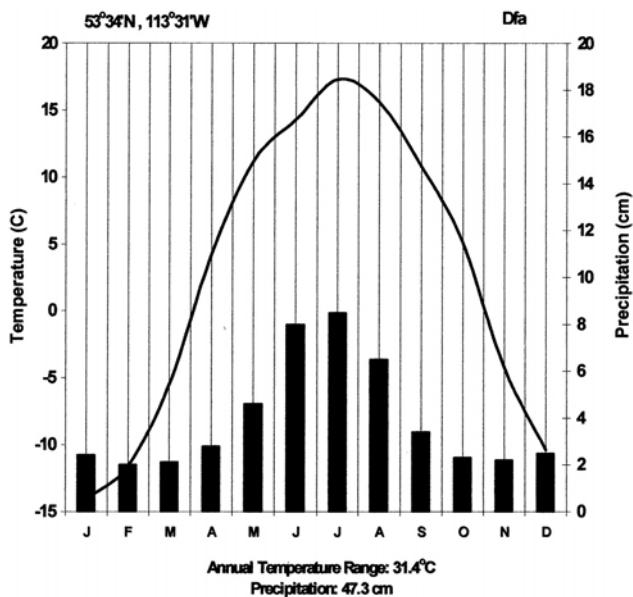

Figure T1 Climograph of Edmonton, Canada (after Eugster et al., 2000).

with the maximum amount falling as rain in the summer. Winter precipitation is in the form of snowfall and the amounts are very small; however, snow remains on the ground because the temperatures are so low (Strahler and Strahler, 2002). The mean monthly temperature in the Taiga can remain below freezing for up to 7 months, and there are only 50–100 frost-free days. Therefore, winters are long and harsh and there is a short, cool summer punctuated by a very brief fall and spring (Quayle, 1999).

Flora and fauna

The boreal forest constitutes a nearly unbroken band of coniferous trees typifying the dominant vegetation of the sub-Arctic climate zone and extends across the higher latitudes of North

America and Eurasia (Figure T2). Specifically, the Taiga refers to the more open-canopy form of the boreal forest found in the northern reaches of this biome, or in the transitional ecotone between the dense coniferous forest and the frigid Tundra (Eugster et al., 2000).

In Europe and North America the boreal forest is composed mostly of evergreen species in three main genera: pine (*Pinus*), spruce (*Picea*), and fir (*Abies*). Broadleaf deciduous trees include the alder (*Alnus*), birch (*Betula*), and golden patches of aspen (*Populus*) dot the landscape in the fall (Strahler and Strahler, 2002). In northern North America widely spaced black spruce trees are common. In Siberia the deciduous larch or tamarack (*Larix*) is found in this climate zone, and in western Russia and across Scandinavia the Scots Pine is a widespread species. These forests also extend southward along mountain ranges (Oliver and Hidore, 2002). The giant sequoias are the largest living things and the Taiga is the largest biome on Earth.

Several characteristics of conifers demonstrate their ability to maximize a short growing season and winter drought conditions. The narrow needleleaf has a relatively small surface area to reduce transpiration during winter months when the ground is frozen. These needle-shaped leaves also have a thick, waxy cuticle into which the stomata are sunken, thereby escaping desiccating winds. The dark color and low albedo of conifers enables enhanced absorption of solar radiation. By retaining their foliage, evergreens can photosynthesize as soon as the short growing season begins, and the conical shape of conifers allows snow to shed easily (*Taiga or Boreal Forest*, 2003).

Animals of the Taiga include the snowshoe hare, whose heavy coat of fur changes colors to blend into the background of the season. Mice and moles burrow beneath the snow in tunnels to escape the fierce winds of the sub-Arctic. Many species of birds, such as the insect-eating wood warbler, migrate to escape the harsh winter. Some birds survive year-round, such as the seed-eating finches and sparrows, and the omnivorous ravens. Other animals of the Taiga are the lynx, lemming, bobcat, bear, badger, beaver, fox, red squirrel, elk or wapiti (referred to as the red deer in Europe) and moose (known as elk in Europe) (*Taiga*, 1996). The many members of the weasel family include the fisher, pine martin, mink, ermine, sable, and wolverine.

Soils

The soils of the Taiga are of the order spodosol and are generally nutrient-poor. As a result of the acidification of the soil beneath

needleleaf trees, podzolization occurs. These edaphic conditions contribute to patchy vegetation. For example, the larch forests survive in waterlogged substrate underlain by permafrost with shrubby undergrowth. The jack pine (*Pinus banksiana*) forests of North America occur on sandy outwash plains, and numerous bogs result from the poorly drained soils overlying glacial depressions. In the bogs are plant species that typify the tundra, such as mosses, cotton grass, and members of the heath family.

The great ice sheets of the most recent Ice Age scraped and shaped the landscape beneath the Taiga. Flowing ice contributed to severe erosion and exposed bedrock across vast areas. In many locations glacial debris blankets the surface. The boggy areas formed in shallow rock basins that were infilled with organic materials such as peat. The impermeable bedrock below does not permit percolation and saturated, mucky soils result.

While the growing season of the Taiga is short, there are a limited number of crops grown. In Finland, Sweden, and lands surrounding the Baltic Sea, crops include wheat, barley, rye, and oats. In conjunction with dairy farming, these crops provide subsistence. In the sub-Arctic areas of eastern Canada the major (nonmineral) export is lumber and pulpwood from the coniferous forests. Similarly, in Sweden, Finland, and European Russia, pine and fir are the primary plant resources as they are exported in the form of pulp, paper, cellulose, and lumber for construction.

Concerns

In recent decades public concern for the integrity of the northern needleleaf forest in conjunction with key international conferences led to a greater degree of governmental commitment to sustainable forest management. There is an enhanced awareness of the boreal forest ecosystem as a crucial component of biological diversity particularly, as well as of sustainable development in general. Also of concern is the rate of climate change that is forecast for the boreal forest. The rate of increasing temperatures that is predicted to occur over the next century is ten or more times faster than the warming that took place during the past 10 000 years (*New York Times*, 1997; IPCC, 1992; Korpilahti, 2002).

Because climate and vegetation are inextricably linked, such rapid changes in climate have been shown to affect plant distributions and alter compositions of natural communities (Graham and Grimm, 1990). Many species respond individually, rather than as communities, to climatic change. There are unique species such as the bristlecone pine (*Pinus longaeva*) and the

Figure T2 The taiga, cartographer T. Truckenbrod.

giant sequoia (*Sequoiadendron giganteum*) that have maintained their present locations for thousands of years, demonstrating substantial physiological tolerance to climatic variations (Kutner and Morse, 1996). However, a temperature difference of a few degrees, or slight variations in rainfall patterns, can determine whether some species survive or become extinct.

Evidence from fossil pollen records reveals migration rates of various tree species since the end of the last glacial period. According to a study by the Environmental Protection Agency (1989), beech and maple trees migrate at a rate of 10–20 km per century, hemlock migrate 20–25 km per century, and pine and oak species migrate 30–40 km per century. However, research (Schwartz, 1992) suggests that during the next century plant species may be required to shift as much as 500 km, which is well beyond the migration rates of many species.

Those species that cannot tolerate rapid climate change, and that have the ability to migrate, will likely do so, resulting in a number of new associations. In addition to differences in migration propensity and rates, community types will be altered due to changed disturbance regimes and competition as well (Davis, 1989). As atmospheric scientists are only beginning to piece together the many variables and mechanisms that are involved in climate change, the myriad repercussions of such rapid change also are just beginning to be revealed.

TELECONNECTIONS

“Teleconnection” refers to the tendency for atmospheric circulation patterns and their associated weather conditions to vary directly or indirectly over large and spatially discontiguous areas. Teleconnections are characterized by well-defined spatial patterns that can persist over long periods of time. Because of the persistent and recurring nature of teleconnections, they are sometimes called “modes of low-frequency circulation variability”.

In the extratropics the ability of large-scale atmospheric circulation features to be teleconnected over large distances is related to the wave structure of the westerlies. At any given time the middle tropospheric flow in the westerlies can be characterized by a series of transient shortwave features superimposed upon a set of much larger quasistationary Rossby waves. The ridge and trough structure of the Rossby waves creates conditions through which geopotential heights and associated surface pressure patterns vary directly or indirectly within different parts of the wave train. Variations in the position or amplitude in one portion of a Rossby wave are teleconnected to other portions of the wave train. The quasistationary nature of Rossby waves and the tendency for ridges and troughs to be anchored in particular locations contribute to the spatial persistence of patterns.

Extratropical teleconnections

Patterns of teleconnection are often explored through the construction of simple one-point linear correlation maps or through the use of empirical orthogonal functions, such as principal components analysis (Barry and Carleton, 2001). For example, Figure T3 shows a map of the correlations between January 500-hPa geopotential heights at 55°N, 115°W and 500-hPa heights over much of the northern hemisphere. Most noteworthy in Figure T3 is the strong inverse relationships that exist between January 500-hPa geopotential heights over western North America and those over eastern North America and the north Pacific Ocean. This particular teleconnection is called the Pacific–North America (PNA) pattern (Wallace and Gutzler, 1981; Barnston and Livezey, 1987; Yarnal and Leathers, 1988). In its positive mode the PNA pattern is associated with a Rossby wave train that features amplified ridging over western North America and deep troughing over eastern North America and the north Pacific. A negative PNA is characterized by a de-amplification or reversal of these features.

The PNA pattern represents one of many extratropical teleconnections that have been identified for the northern hemisphere. In the PNA example the centers of teleconnection are aligned in a west-to-east pattern and are associated with meridional variations in the Rossby wave structure. By contrast, other patterns are characterized north-south-oriented features. The North Atlantic Oscillation (NAO) is an example of a north-south teleconnection pattern and is characterized by inversely varying pressures and geopotential heights between the regions surrounding Iceland and the Azores (Rogers, 1984).

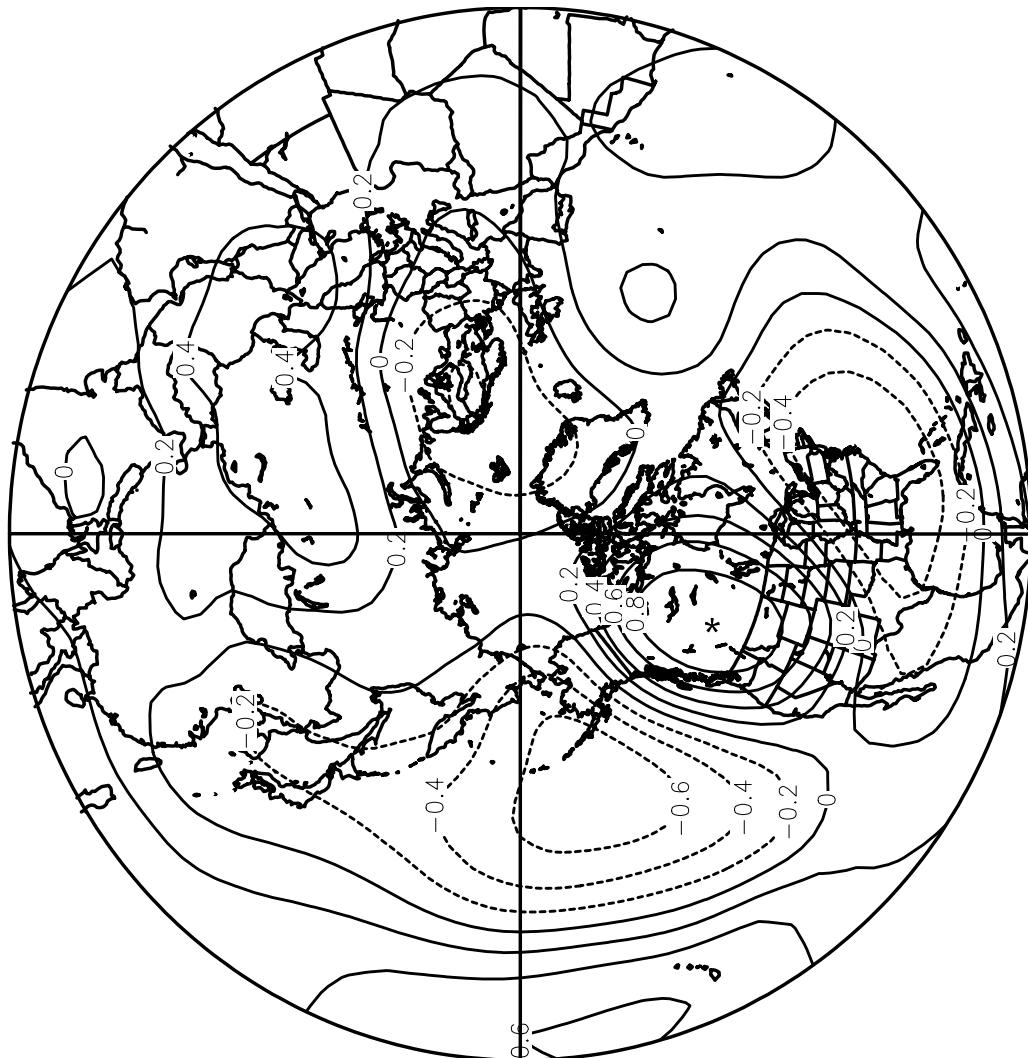

Figure T3 One-point linear correlations between average January 500-hPa geopotential heights at 55°N, 115°W (shown by an asterisk in North America) and January 500-hPa heights for the northern hemisphere (1949–2002). Data were obtained from the National Centers for Environmental Prediction/National Center for Atmospheric Research (NCEP/NCAR) reanalysis dataset.

Figure T4, which shows a map of correlations between January 500-hPa heights near Iceland and locations over the northern hemisphere, highlights the NAO teleconnection. Additional information on the PNA and NAO, including a description of all major northern hemisphere extratropical teleconnections can be found on the United States Climate Prediction Center (CPC) website (<http://www.cpc.ncep.noaa.gov/>). The CPC teleconnections are based on a rotated principal components analysis (RPCA) of 700-hPa geopotential heights, similar to that used by Barnston and Livezey (1987).

Temporal variability

The use of RPCA to examine teleconnections also yields important insight into the temporal variation of the major patterns. Certain patterns emerge as leading modes of circulation during particular months. For example, the CPC reports that the PNA pattern is the leading mode of northern hemisphere

700-hPa circulation during January. By contrast, the PNA is not among the leading modes of variability during June and July (<http://www.cpc.ncep.noaa.gov/>). The NAO is most dominant during March, April, October, and November.

Interannual variations in the strength of teleconnection patterns can be determined through the use of teleconnection indices. Different techniques have been used to create these indices. Yarnal and Leathers (1988) used standardized 700-hPa geopotential heights at three locations nearest the wave centers of the PNA pattern to develop a PNA index. Rogers (1984) calculated the difference in mean sea-level pressure between the Azores and Iceland to characterize the NAO. An alternative method of index development uses RPCA to statistically isolate the teleconnections and to calculate factor scores for each pattern (Barnston and Livezey, 1987). These scores provide an amplitude time-series for each pattern. Figure T5 shows the factor score time-series for January NAO (<http://www.cpc.ncep.noaa.gov/>). As can be seen in Figure T5, the NAO index exhibits a considerable

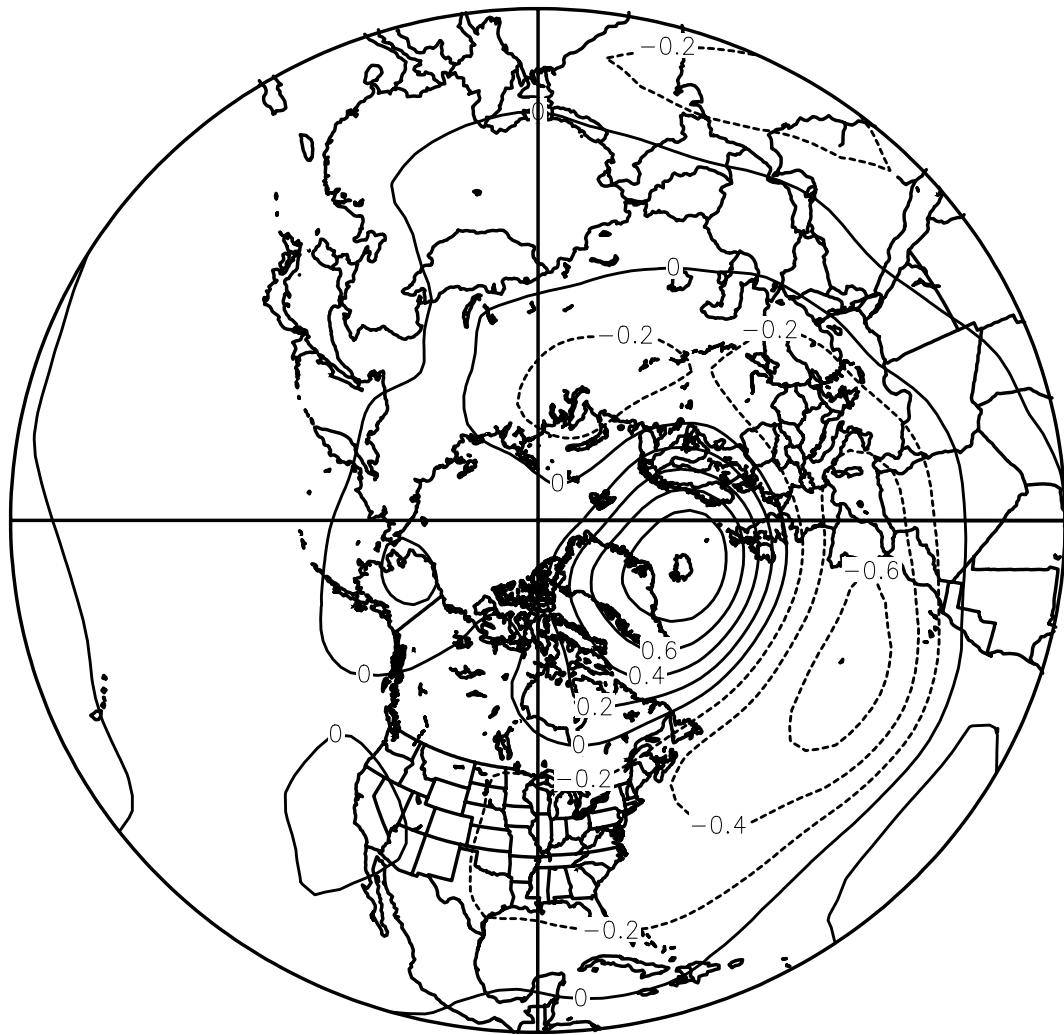

Figure T4 One-point linear correlations between average January 500-hPa geopotential heights near Iceland (shown by an asterisk) and January 500-hPa heights for the northern hemisphere (1949–2002). Figure T5 January NAO index for 1950–2003 as derived by the Climate Prediction Center using a rotated principal components analysis of 700-hPa geopotential height data.

amount of interannual variability. However, also apparent in the NAO record is a first-order trend toward a more positive NAO in recent decades. Temporal variability in the NAO, as with other teleconnections, exerts a strong influence on regional surface climate via its impact on airmass advective frequencies and storm track (Hurrell, 1995, 1996; Hurrell and van Loon, 1997).

Teleconnective processes

As described by Harman (1991), teleconnected wave trains result from the tendency for air flow to follow trajectories that conserve absolute vorticity. Under conditions of non-divergent flow, absolute vorticity is conserved through compensating changes in Earth vorticity (f) and relative vorticity (ζ_R). This relationship is captured in equation (1):

$$\frac{d}{dt}(\zeta_R + f) = 0 \quad (1)$$

The relative vorticity term can be broken into vorticity associated with wind shear (ζ_s) and that caused by flow curvature (ζ_k). Shear vorticity contributions are typically much smaller in spatial extent than that caused by flow curvature. As such, ζ_s can be disregarded. The conservation of absolute vorticity relationship can now be expressed by equation (2):

$$\frac{d}{dt}(\zeta_k + f) = 0 \quad (2)$$

Variations in Earth vorticity (f) are driven by latitudinal changes in Coriolis; therefore, any change in the latitude of the flow will produce a change in f and a compensating change in ζ_k . Figure T6 shows a simplified example of northern hemisphere circulation in which the flow is initially moving poleward. Under such conditions, f will increase and require a decrease in ζ_k . As ζ_k decreases, curvature will become increasingly anticyclonic and ultimately produce a ridge axis and equatorward flow. As flow moves south, f will decrease and force a compensating increase in ζ_k and the development of a trough. This relationship, which is referred to as the conservation of absolute vorticity trajectory (CAVT), yields a series of teleconnected waves.

Forcing mechanisms

A full discussion of the mechanisms through which teleconnected circulation patterns are forced is beyond the scope of this discussion. However, central among these mechanisms are the influences of diabatic heating and orography (see Barry and Carleton (2001) for a detailed description of these processes). A central component of orographic forcing involves the vertical compression of the air column as it moves over a mountain barrier. As described by Harman (1991), this vertical compression is compensated by a horizontal expansion of the column and a decrease in absolute vorticity. This decrease in vorticity occurs primarily through changes in ζ_k and a redirection of the flow. As the air flows past the orographic barrier, vertical expansion and horizontal contraction produce an increase in ζ_k . In this fashion orographic features can create geographically fixed waves that are then teleconnected downstream via CAVT processes.

The role of diabatic heating in planetary wave forcing involves a number of processes, including sensible and latent heat exchanges and radiative transfer (Barry and Carleton, 2001). For example, during winter the sea surface temperatures off the east coasts of Asia and North America are significantly warmer than the adjacent land areas. Cold airmasses flowing eastward over this warm sea surface are destabilized. The resultant instability produces vertical air motion, horizontal compression of the air column, and increased ζ_k . Changes in ζ_k , associated flow directional change and CAVT can yield a wave train geographically fixed to the surface heat source. Forcing of this type tends to vary seasonally as the strength and location of the diabatic heat source changes. Trenberth et al. (1998) provide a thorough review of the role that tropical sea surface temperature (SST) variability, such as that associated with El Niño/Southern Oscillation, plays in driving extratropical teleconnections. Of the dominant midlatitude teleconnection patterns, only a few exhibit strong linkages with tropical SST variability. Of these, the PNA pattern appears particularly sensitive to SST variations in the tropical Pacific. Ultimately, these tropical–extratropical connections rely on Rossby wave propagation. However, this process can be complicated by midlatitude influences, thus clouding the exact mechanisms through which extratropical modes of circulation are driven by tropical SST variation.

TEMPERATURE DISTRIBUTION

Each day Earth receives energy in the form of incoming solar radiation from the sun. This shortwave solar radiation ranges mostly from ultraviolet ($0.2\text{ }\mu\text{m}$ wavelength) to the near-infrared ($2.0\text{ }\mu\text{m}$ wavelength), but reaches its maximum at around $0.5\text{ }\mu\text{m}$ wavelength (blue–green visible light). This insolation is absorbed by Earth's surface and is converted to heat (longwave radiation). Earth's (terrestrial) longwave radiation reaches its peak intensity at the $10\text{ }\mu\text{m}$ wavelength (thermal infrared) and is responsible for heating the lower atmosphere.

Temperature is represented by a human-invented quantitative measure of heat energy emitted by or contained within a surface or material. As such, these numerical temperature values can be used to differentiate one climatic region from another. Spatial variations in temperatures (i.e. temperature distributions) occur both vertically and horizontally within the Earth's atmospheric envelope. These temperature distributions, their causes and variations, are discussed below.

Vertical distributions

The atmosphere can be divided into four distinct layers based on characteristic temperature distributions (see Figure T7). The

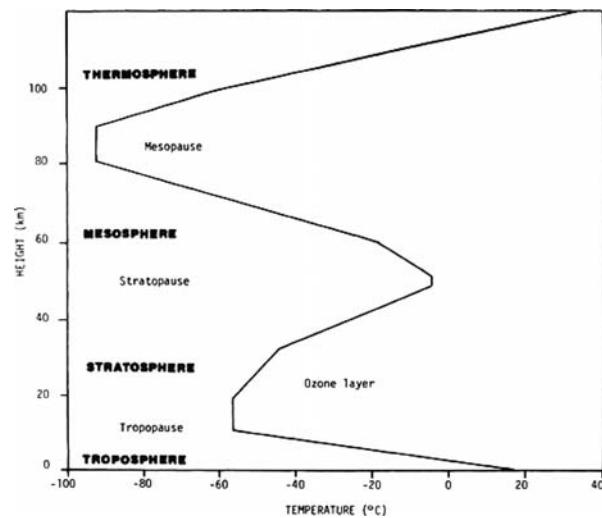

Figure T7 Vertical temperature structure of the atmosphere.

layer closest to the Earth's surface is called the *troposphere*. Almost all atmospheric water vapor and turbulent mixing exist within this layer, thus it is here that virtually all phenomena related to weather or climate take place. Temperatures tend to decrease with increasing altitude above Earth's surface (the source of terrestrial heat radiation). Cold temperatures observed at high elevations and snowcapped mountains are physical manifestations of this tropospheric temperature trend. On the average, temperatures in the troposphere will decrease at the *normal* or *environmental lapse rate* of $6.5^\circ\text{C}/1000\text{ m}$ of rise.

The troposphere ends at a boundary layer called the *tropopause*. The tropopause is at its highest elevation over the tropics (approximately 16 km) but decreases in elevation poleward (9 km or less at the poles; Lutgens and Tarbuck, 2001). Temperatures in the tropopause remain constant with height and this layer is *isothermal* (same temperature) in nature.

Temperatures tend to increase with height within the *stratosphere*. This increasing temperature trend is caused by heat released during the interaction between incoming ultraviolet radiation and the ozone (O_3) layer (ozoneosphere) nested within the stratosphere. It is the formation, the destruction (into molecular and atomic oxygen, O_2 and O , respectively), and the reformation ($\text{O}_2 + \text{O} \rightarrow \text{O}_3$) of ozone that shields the Earth from the harmful effects of ultraviolet radiation and, at the same time, adds heat energy to the stratosphere. The upper limit of the stratosphere is bounded by another isothermal layer called the *stratopause*.

Above the stratopause lies the next layer of the atmosphere called the *mesosphere*. The temperatures in this atmospheric shell decrease with an increase in altitude. The mesosphere (middle sphere) ascends to an elevation of around 80 km where it ends at the last isothermal layer called the *mesopause*.

Extending from the mesopause to the outer limits of the atmosphere lies the final layer, the *thermosphere*, which accounts for a minute fraction of the atmosphere's total mass. The particles (mostly ions) in this uppermost layer are energized by incoming solar radiation and move at very fast speeds, thus causing heat sensors to register an increasing temperature with height.

Factors influencing the horizontal distribution

Though it has been shown that temperatures vary vertically from the surface of the planet to the outer limits of the atmosphere, horizontal temperature distributions and the mechanisms that create them are of greater importance to climatologists and meteorologists. The causative factors and resulting temperature distributions on the surface of Earth are discussed in further detail.

Latitude and sun angle

Latitude is the single most important factor determining planetary temperature distributions. In general, as one traverses from the equator (0° latitude) to either pole (90° latitude) temperatures decrease. This equator-to-pole temperature gradient is directly related to the angle at which the sun's rays strike Earth's surface.

Solar radiation, having traveled some 150 million km, reaches Earth's spheroid surface in essentially parallel lines (see Figure T8). As such, there can be only one latitude where the sun's rays intersect the surface at a direct (90°) angle. A displacement north or south from this line of direct (maximum) radiation must result in an incident sun angle less than 90° ; thus the intensity of the radiation decreases (Figure T9).

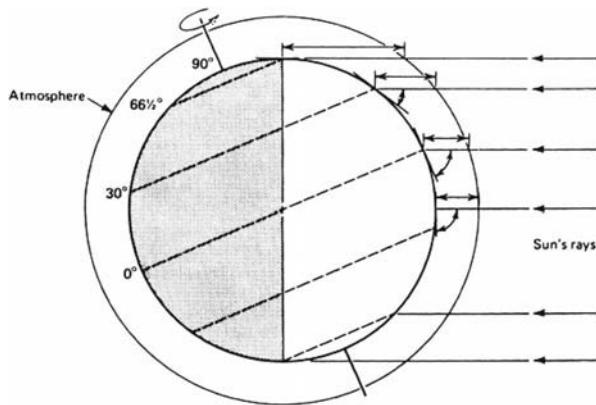

Figure T8 The Earth in the December solstice position. Parallel sun rays strike the Earth at a variety of sun angles. Rays striking the Earth at low angles, must traverse more of the atmosphere than rays striking at a high angle, and are thus subject to greater depletion by reflection and absorption (Lutgens and Tarbuck, 2001).

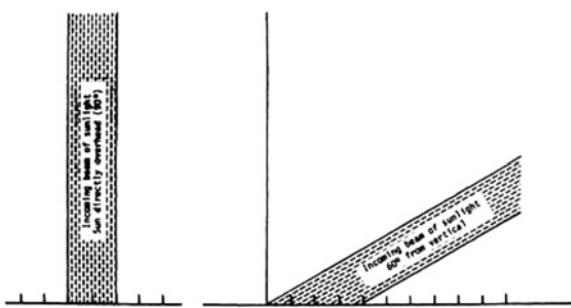

Figure T9 The sun rays intersecting Earth's surface at 60° (right) will cover twice the ground surface but with only half the intensity of a direct 90° angle (left).

The relationship between the intensity of solar radiation and sun angle is described by *Lambert's Cosine Law*: $I = I_0 (\cos \gamma)$, where I = radiant intensity of radiation reaching some point on the surface, I_0 = radiant intensity at maximum (where sun angle is 90° overhead) and γ = angle from the vertical to the direction of the radiation (zenith angle; Rosenberg, 1974). For example, when γ equals 60° from vertical, the intensity of solar radiation is half of its maximum ($\cos 60^\circ = 0.5000$; Figure T9).

The thickness of the atmosphere through which insolation must pass is also affected by sun angle. Low-latitude high-sun angles pass through a shorter distance of atmosphere as opposed to high-latitude oblique sun angles, which must traverse a much greater distance (see Figure T8). By traveling through a greater distance of atmospheric gases, the intensity of the solar radiation is partially extinguished by the gas molecules. This relationship is best described by *Beer's Law*:

$$I = I_0 e^{-ax}$$

where I_0 is the initial radiant intensity and I is the radiant intensity after passing through a depth x of a medium (i.e. the atmosphere) with extinction coefficient a . Extinction of radiant intensity can occur by absorption and scattering of the solar radiation (Rosenberg, 1974). Again, the low sun angles in polar regions are less intense than the tropical high sun angles.

Seasons

The migration of the maximum sun angle north and south of the equator is responsible for seasonal variations on the Earth. On 21–22 December the most direct (90°) sun angle contacts $23\frac{1}{2}^\circ\text{S}$ latitude (the Tropic of Capricorn). In this orbital position – the *December Solstice* – the northern hemisphere is tilted its farthest back ($23\frac{1}{2}^\circ$) from the sun and experiences the winter season. This represents the shortest day of the year in the northern hemisphere, and the North Pole is in total darkness (see Figure T8). In the southern hemisphere this is the longest day of the year, the first day of summer and the sun is visible above horizon 24 hours a day at the South Pole. During 21–22 June, radiation strikes directly upon $23\frac{1}{2}^\circ\text{N}$ latitude (Tropic of Cancer). The *June Solstice* marks the first day of summer in the northern hemisphere and winter in the southern hemisphere.

The vernal and autumnal equinoxes (21–22 March and September, respectively) are the days when the sun's rays hit directly on the equator. Earth experiences 12 hours of daylight and 12 hours of darkness on these equinox dates.

During the course of a year the direct and most intense rays of the sun will migrate from $23\frac{1}{2}^\circ\text{N}$ to $23\frac{1}{2}^\circ\text{S}$ and back again. For this reason the tropics are always warm, energy-rich areas of the world, whereas the poles are always cold, energy-poor regions of the world. Again, the angle of incoming solar radiation will cause an equator to pole (latitude-dependent) temperature gradient found on the Earth.

Air mass circulation

As stated above, incident sun angles cause the tropics to be energy-rich, and the poles energy-deficient. This imbalance of energy has not, however, caused the tropics to become warmer nor the poles to become colder through time. The tropics and the poles maintain their climatic characteristics by exchanging

energy, mass, and momentum through the middle latitudes ($23\frac{1}{2}^{\circ}$ to $66\frac{1}{2}^{\circ}$ N or S). The weather and climates in the middle latitudes are variable in nature due to the invasion of large air masses poleward from the tropics and equatorward from Arctic and Antarctic regions.

An *air mass* is a large body of air measuring hundreds to thousands of kilometers in length and breadth, and may extend from the surface to the tropopause. Air masses have definable characteristics of temperature and humidity derived from their *source regions*; that is, the region from which the air mass originates.

The circulation of these air masses, and more importantly the frequency with which an air mass type dominates an area, will affect the temperature distribution and the climate of that area (Oliver, 1970). For example, if the midwestern United States experiences invasions of continental arctic (CA) air from northern Canada during a winter season, it may become a record cold winter. In contrast, if that same region during the winter is frequented by maritime tropical (mT) air from the Gulf of Mexico, a mild season would result. Air mass movements are variable and their variations are reflected in the temperature distributions.

Cloud cover

The effects of cloud cover on temperature are most evident in the diurnal temperature cycle (Figure T10). Cloud cover during daylight hours prevents some incoming solar radiation from reaching Earth's surface by reflecting it back to space. Thus temperatures may be cooler on cloudy days. Cloud cover at night causes overnight low temperatures to be warmer. The clouds act like a blanket, keeping longwave

terrestrial (heat) radiation close to Earth's surface. This heat radiation would otherwise be lost to space by escaping through a cloudless sky.

Excessive cloud cover may cause variances in annual temperature cycles as well. Monsoonal regions are particularly susceptible. During the wet monsoon, long periods of heavy cloud cover will cause temperature values to be depressed. Temperature data for Calcutta, India (Table T1), shows April, May, and June to have the highest temperatures, whereas July and August (considered months with the highest temperatures) are cooler beneath the monsoonal cloud cover (beginning in June and extending through August).

On a global scale, areas of persistent cloud cover or clear skies will cause alterations in temperature distributions. The equatorial region of the Earth is one with abundant cloud cover. The perennial high sun angles of the tropics warm the moist equatorial air, causing it to become buoyant and rise (equatorial low pressure) and cool aloft to form ample cloud cover. By contrast, subtropical regions (30 – 35 °N or S latitudes) are regions of stable, descending air (subtropical high pressure), which is conducive to the formation and maintenance of clear skies. Subtropical high-pressure systems and their associated clear skies are responsible for many of the world's large deserts (e.g. North Africa and Saudi Arabia).

Though the highest sun angles occur in the tropics, the clear skies and abundant solar radiation of the subtropics allow these regions to yield higher temperatures. Many all-time record high temperatures were observed at stations located between 30 ° and 40 ° latitude. Some examples are Azizia, Libya (57.8°C); Death Valley, California (56.7°C); Seville, Spain (50°C); and Tirat Tsvi, Israel (53.4°C) (National Climatic Data Center). From the microscale to the global scale, and within diurnal as well as annual temperature cycles, cloud cover remains a factor that affects temperature distributions.

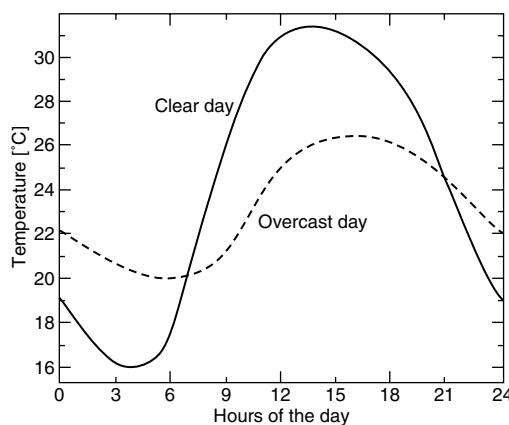

Figure T10 The daily temperature cycle on a clear day versus a cloudy day. Cloud cover will depress the daily maximum while raising the daily minimum temperature (after Lutgens and Tarbuck, 2001).

Distribution of land and sea

The surface of Earth is covered by a wide range of materials. The character of these surfaces will affect the way they accept solar radiation and emit terrestrial radiation. The largest division of surface materials lies between land and water. These two substances react differently to incoming and outgoing radiation. In general, land heats and cools considerably faster than water. This difference in the rate of their temperature gain or loss is caused primarily by their different specific heat values. *Specific heat* is the amount of heat necessary to raise the temperature of a material 1°C. Water has a specific heat of 1 calorie per gram °C, whereas most earthen materials range between 0.3 and 0.5 calories per gram °C. Thus land masses can heat and cool two to three times faster than water bodies.

Water is also transparent (or translucent) and accepts sunlight into its upper layers. In addition, water has the ability to circulate the heat energy. Unlike water, an opaque and rigid

Table T1 Mean monthly temperatures (°C), Calcutta, India

Month	J	F	M	A	M	J	J	A	S	O	N	D
	18	21	27	30	31	30	28	27	28	27	22	18

land surface reacts more quickly to heat energy exchanges with the atmosphere.

Surface temperature characteristics vary with distance from large bodies of water (e.g. large lakes or oceans). Proximity to a large body of water tends to moderate extreme temperatures. This effect is clearly demonstrated in annual temperature range value (i.e. the difference between the highest mean monthly temperature in summer and the lowest mean monthly temperature in winter). For example, choosing three stations of approximately equal latitude (32°N), we find Bermuda (surrounded by water) has a temperature range of $9\text{--}10^{\circ}\text{C}$. By comparison, Charleston, South Carolina (a coastal station), has an annual temperature range of 17°C . Further inland, Pine Bluff, Arkansas (a landlocked station), has an annual temperature range of $23\text{--}24^{\circ}\text{C}$ (Tanner, 1964). Therefore, the *continentality* of a location (the degree to which the interior of a continent affects the climate) will have an influence on temperature distributions.

Albedo

Land surfaces are composed of many different materials, each with its own set of characteristics that may affect Earth's energy balance and temperature distributions. Albedo is one such characteristic and is defined as the amount of solar radiation reflected by a surface to the amount incident upon it; it is commonly expressed as a percentage (Huschke, 1959). Surfaces with high albedo (e.g. snow and ice) reflect 80–85% of the incoming solar radiation and express lower temperatures than surfaces of low albedo (e.g. green forest, albedo = 3–10%).

Cloud cover has the most variable albedo, which changes with the type and thickness of clouds (ranges from negligible values to 80%). In summary, the changing colors, textures, and substances of surface materials will determine albedo values and thus affect surface temperature distributions.

Ocean drifts and currents

Ocean water is transported by two major mechanisms: (1) frictional drag of prevailing winds on the ocean surface; and

(2) differences in water density (density currents) with varying heat and salt concentrations. A slow, inconspicuous movement ($3\text{--}4\text{ km/h}$) over broad areas are called *drifts*, as opposed to *currents*, which are narrower, extend to greater depths and move faster (10 km/h).

If a drift or current originates in tropical (low-latitude) regions and migrates poleward, it will invade colder ocean waters and by comparison to its surroundings would appear as a warm current. Conversely, drifts and currents that stem from the higher latitudes and advect equatorward are perceived as cold (or cool) currents.

Where they exist, warm and cold currents will influence surface temperature distributions, especially along coastal regions. For instance, if we examine the mean annual temperatures of the two South American coastal locations at the same latitude, the effect of ocean currents is clearly visible. Lima, Peru, is under the dominance of the cold Peruvian current moving equatorward and has a mean annual temperature of 19°C , whereas Salvador, Brazil, under the influence of the poleward-flowing, warm Brazilian current, has a mean annual temperature of 26°C (National Climatic Data Center). Though all the atmosphere–ocean interrelationships are not fully understood, the consequences of ocean movements and climate (and more specifically temperature distributions) cannot be ignored.

Urban–rural temperatures

Surface temperature distributions tend to take on distinctive patterns in and around urban areas, designating what is called an urban heat island. In general, temperatures tend to increase as one traverses from the rural surroundings to the center of an urban area.

Observed horizontal distribution

The actual horizontal distribution of temperatures are shown in Figures T11 and T12. These maps depict mean global

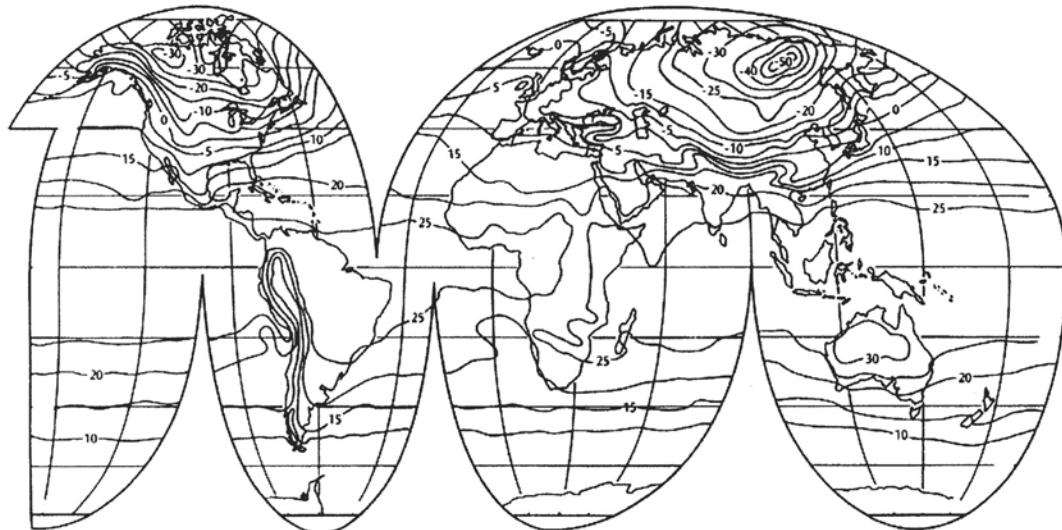

Figure T11 Map showing global distributions of mean January temperatures. The isotherm line patterns reflect some of the controls on surface temperatures.

isotherms (lines of equal temperature value) for January and July. The patterns of the isotherms tend to confirm some of the influencing factors previously mentioned.

Equator to pole gradient

The first noteworthy pattern can be seen on both figures (regardless of season). The east–west arrangement of isotherms mimics the orientation of latitude lines and reflects a changing sun angle. Here, the effects of Lambert's Cosine Law and Beer's Law work together to create an obvious equator-to-pole temper-

ature gradient. The isotherms will deviate from their east–west alignment when passing from sea to land and back again. These disruptions in the continuity of the isotherms demonstrate the way land and sea accept solar radiation and emit terrestrial radiation. During the same season, and at comparable latitudes, land and adjacent sea may not maintain the same temperature.

Maximums and minimums

The maximum temperatures are observed in the high sun hemisphere (hemisphere that is experiencing its summer season).

Figure T12 Map showing global distributions of mean July temperatures. The isotherm line patterns reflect some of the controls on surface temperatures.

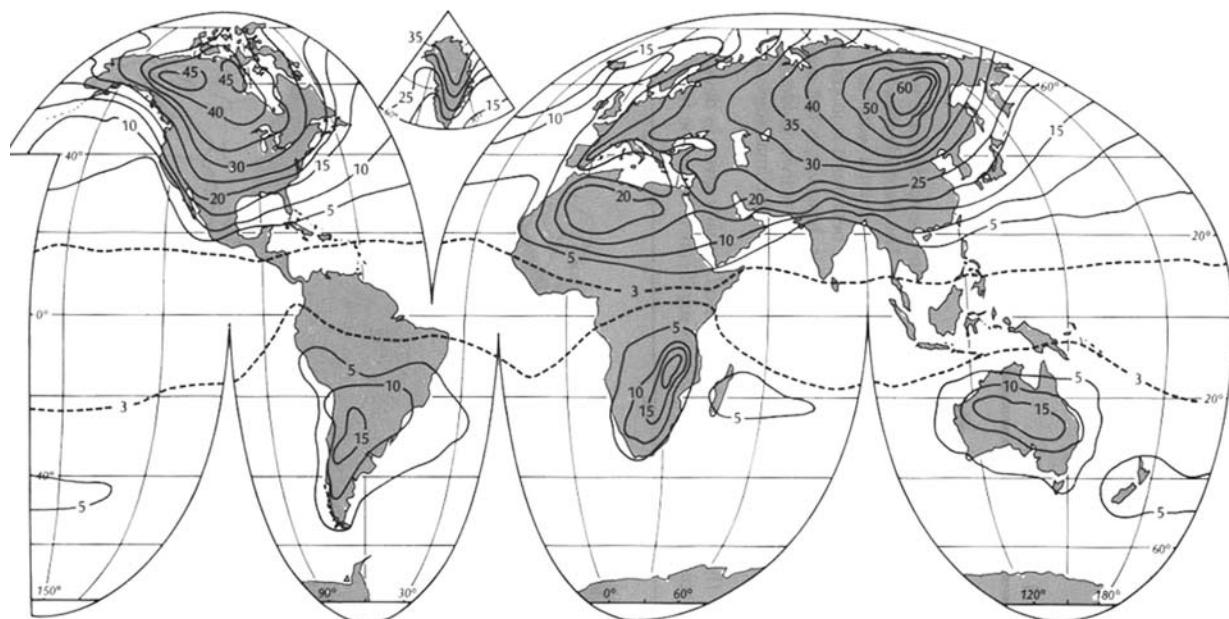

Figure T13 Map depicting global distributions of temperature range. The difference between mean January and mean July temperatures constitutes useful information to the climatologist.

This shifting of maximum temperatures from the northern hemisphere (in July) to the southern hemisphere (in January) follows the migration of the direct (90°) incident sun angle from the June solstice position ($23\frac{1}{2}^\circ\text{N}$ latitude) to the December solstice position ($23\frac{1}{2}^\circ\text{S}$ latitude). Further note that the maximum temperatures are found in the subtropical regions (approximately 30°N or S latitude) where clear skies dominate, and not in the tropics where a cloud cover prevails much of the time. Finally, maximum temperature (e.g. over North Africa) and the minimum temperatures (e.g. over Antarctica and northern Siberia) are found over land bodies. Here again, a low specific heat value and other factors mentioned earlier allow land bodies to respond more rapidly to seasonal changes. This is further exemplified in Figure T13, which displays average annual temperature ranges (the difference in temperature between January and July averages). In this figure, small temperature ranges are found over the oceans where temperature changes are less dramatic and large temperature ranges (i.e. closed isotherms) are found over continental regions (effects of continentality).

Ranges and seasonality

The temperature range isoline map (Figure T13) is useful in demonstrating more than just the continentality of a particular region. Temperature ranges can further indicate the degree to which a region is affected by the seasonal changes. The small temperature range isolines that straddle the equator are showing that the tropics experience no appreciable seasonal changes. The highest sun angles within the tropics year-round; therefore the climate remains essentially the same. Near the poles, low sun angles and periods of total darkness account for seasonal variation. However, the middle-latitude temperature ranges are much higher (seasonal changes are more prominent). This is an area where sun angles, air masses, ocean currents, surface albedo, and cloud cover vary through time and space. With alterations in these and other factors come changes in temperature across the surface.

TERRESTRIAL RADIATION

Electromagnetic radiation emitted by the Earth's surface and atmosphere is called *terrestrial* or *longwave* radiation (the latter being the preference of the World Meteorological Organization). Since these bodies exhibit temperatures in the range 200–300 K, terrestrial radiation lies in the infrared portion of the electromagnetic spectrum. At mean Earth surface temperature (288 K), nearly all the emission from a black body occurs between the wavelength limits of 4 and 100 μm , with peak monochromatic emittance at 10 μm .

The spectral distribution of emission from the Earth's surface generally approximates that from a black body. Emissivities for natural surfaces mainly lie in the range 0.90–0.97, although fresh snow exhibits very high values (>0.99) and smaller ones are associated with dry, mineral materials such as desert soils, dry rocks and building materials (0.7–0.9).

Both the amount and spectral distribution of emission by the atmosphere primarily depend on the vertical profiles of temperature and emitting gases and the presence, type, and location of clouds and aerosols. A cloudless atmosphere emits in the characteristic fashion of a gas, with prominent emission lines and bands. The major constituents of the Earth's atmosphere responsible for emission are water vapor (bands from 5–7 μm and beyond 15 μm), carbon dioxide (13–17 μm and at wavelengths <5 μm) and ozone (a strong, narrow band centered on 9.6 μm , with minor ones at 4.7 and 14.1 μm), although other gases (the so-called "greenhouse gases") also play a part (e.g. nitrous oxide, methane, carbon monoxide and chlorofluorocarbons). In the approximate wavelength range 8–13 μm (the *atmospheric window*) emission is small in the troposphere and may be attributable to water vapor *dimers*. Clouds radiate at all wavelengths, although only thick low clouds can be approximated as black bodies. Middle-layer clouds possess emissivities near 0.9, whereas cirriform clouds may have emissivities as low as 0.3. Emission of terrestrial radiation from the atmosphere is hence increased by the presence of clouds due to enhanced radiation in the window region. The role of aerosols is

controversial but is probably significant in increasing emission in the window.

Following Kirchoff's Law, the atmosphere's constituents absorb terrestrial radiation in the same wavelength regions in which they emit.

At the Earth's surface, upward emission generally exceeds the irradiance from the atmosphere (the *counter-radiation*), although the difference is smaller with the presence of clouds or fog. On an annual, global basis, the counter-radiation is about 85% of the surface emittance.

Within the atmosphere, complex exchanges of terrestrial radiation occur, depending on the vertical distributions of temperature and emitting and/or absorbing constituents. Such exchanges generally result in radiative cooling of the air (up to approximately 3 K/day). The radiation emerging from the top of the atmosphere averages about 63% of that emitted by the surface.. Highest terrestrial radiation losses occur in the subtropics (where a warm surface is overlain by a relatively cloudless atmosphere), with lower values associated with the high, cold cloud tops of the *intertropical convergence zone* and with the colder regions of the high latitudes. Annually and globally averaged terrestrial radiation losses roughly balance absorbed *solar radiation* to maintain the planetary equilibrium climate.

THORNTWHAITE, CHARLES W. (1899–1963)

Charles Warren Thornthwaite was born in 1899, on a small farm outside of Pinconning, in central Michigan, the first of four children. His family realized that the only escape from the back-breaking farm work was through education, an understanding that drove Warren, as he preferred to be called, the rest of his life.

With no high school in Pinconning, Warren left home after grade school to attend high school and college in Mount Pleasant, Michigan. He graduated from Central Michigan Normal School (now Central Michigan University) in 1922 with a teacher's certificate and accepted a job teaching high

school in Owosso, Michigan. For two summers he registered for geography courses at the University of Michigan and was then persuaded to enter into the geography graduate program at the University of California at Berkeley under the guidance of Carl Sauer.

Upon finishing his dissertation research in 1927, Thornthwaite accepted a teaching position in the Department of Geography at the University of Oklahoma where he realized that there was a need for a more rational understanding of the moisture factor in climate, long ignored by earlier climatologists. He immediately began work on what was to become one of his most significant contributions to climatology, the development of a new and more rational classification of world climates. His first attempts, published in 1931 and 1933, left Thornthwaite unsatisfied with his expression for the climatic demands for water and, over the next 11 years, he developed his concept of potential evapotranspiration (the water loss from a uniform, closed cover of vegetation that never suffers from a lack of water). This led to his expression for potential evapotranspiration in 1944 and its use, along with precipitation, in a climatic water budget in 1946. It served as the basis for his seminal paper in 1948 entitled "An approach toward a rational classification of climate".

Thornthwaite left Oklahoma in 1934 to work on a government-sponsored study of the Great Plains and, in the following year, to become Chief of the Climatic and Physiographic Division of the Soil Conservation Service in the Department of Agriculture, a position he held for the next 11 years.

Thornthwaite took a leave of absence from government service in 1946 to explore opportunities as a consulting agricultural climatologist at Seabrook Farms in southern New Jersey. During the next two years he completed his work on the climatic water budget and his new climatic classification, developed a significant improvement in the field of phenology (the relationship of climate to periodic biological activity) permitting the scheduling of planting and harvesting of crops, used his climatic water budget to develop a simple bookkeeping approach to scientific irrigation, undertook a multi-year research study of microclimatology for the US Air Force, and established a Laboratory of Climatology for the training of climatologists. The success of these activities encouraged him to resign from his government position and to undertake a new career as a private consulting climatologist.

Scientists from all over the world came to visit the Laboratory and to work with the students in training there. During the 1950s he used his climatic water budget approach to solve practical problems in soil tractionability (the movement of humans and vehicles over unpaved surfaces), the leaching of radioactive strontium through the soil, and the disposal of factory effluent by spray irrigation. He also directed the development of a series of sensitive micrometeorological instruments – both horizontal and vertical wind anemometers, net radiometers, soil heat flux transducers, and dewpoint hygrometers.

Thornthwaite was elected the first president of the UN World Meteorologic Organization Commission for Climatology in 1951 and re-elected in 1953. This provided the opportunity for world travel to attend Commission activities and to represent the US at various other UN organizational meetings. He easily became the best-known climatologist of his day and his

reputation was international. He received many honors including the Cullum Medal of the American Geographical Society, the Outstanding Achievement Award from the Association of American Geographers (he was Honorary President in 1960–1961), and an Honorary Doctorate from Central Michigan University. He died of cancer at the height of his career in 1963.

Thornthwaite possessed that rare spark of genius that allowed him to rise from a poor rural farm background to become a world-renowned climatologist and geographer. Without question, he was the most outstanding American climatologist of the twentieth century and his work in applied climatology and the water budget profoundly influenced the development and direction of the modern field of climatology.

THUNDER

Thunder is the sound that accompanies and follows immediately after the passage of a lightning flash or thunderbolt. We consider the sound of thunder to include its infrasonic (inaudible) components as well as the familiar audible loud noise. A flash of lightning heats a long column of air, averaging about 6 km in length and about 15 cm in diameter. The heating is to a temperature of 12 000 K and is practically instantaneous, at least as far as the generation of sound is concerned. Shock waves start to travel radially outward from the long irregular column that makes up the air heated by the flash. The shock wave is a sharp wave front of sound pressure that gives rise to the familiar “crack” sound of a nearby thunderbolt. At distances of about 10 m or so, the shock waves change into sound waves. The listener hears the sound waves arriving at varying times from the various parts of the thunderbolt, giving rise to the familiar prolonged duration of the sound. Reflections from both the ground and the inhomogeneities in the atmosphere contribute substantially to the prolongation.

The greatest distance of audibility for thunder heard by a casual observer is about 25 km. But thunder has been heard at distances of the order of 100 km when the listener is in a quiet location out of doors. The total acoustical energy radiated by a typical thunderbolt is approximately 10^8 joules. Near the flash, the distribution of energy at various frequencies includes both ultrasonic and infrasonic components. The ultrasonic components are rapidly attenuated with distance from the lightning flash, then the audible components are attenuated although less rapidly, leaving finally only the infrasonic components at large distances. The infrasonic sound energy per unit frequency (i.e. the power spectrum), at an average distance of about 5 km from thunderbolts, is inversely proportional to frequency in the spectral range between about 1.0 and 10 hertz. The propagation of the audible parts of the sound wave is strongly influenced by the temperature of the atmosphere and by the winds between the thunderbolt and the listener. In an upwind direction from the source of sound, and with the temperature falling rapidly with altitude, a listener can be in the shadow zone and hear nothing from a thunderbolt only a few km away.

Lightning
Thunderstorms

THUNDERSTORMS

A thunderstorm is a deep convective cloud (cumulonimbus) that produces lightning and thunder, heavy rain, strong surface outflow of cool air, hail and, on rare occasions, a tornado. A characteristic feature of the thunderstorm, viewed from a distance, is its cylindrical or slightly hourglass shape capped by an anvil-shaped top; the anvil is caused by air diverging from the upper portions of the storm's updraft (Figure T14).

The vertical extent of thunderstorms varies from one climatological region to another. In moist regions, cloud base can be several hundred meters above the ground, whereas in more arid regions, cloud base can be at a height of several kilometers. Storm tops typically vary from 9 to 18 km above the ground. Within a given region, the taller the storm, the stronger is the updraft and the more severe is the surface weather associated with it.

Formation mechanisms

A thunderstorm can be thought of as a thermodynamic machine driven by the release of latent heat of condensation (water vapor converted into cloud droplets) and, to a lesser extent, latent heat of freezing (water droplets converted into ice particles) and latent heat of deposition (water vapor converted into ice crystals). When a convective cloud develops in an unstable environment (that is, one where a rising parcel of air is buoyant – warmer than its surroundings), the potential energy of latent heat is converted into kinetic energy of vertical air motion. As long as the rising mass of air remains buoyant, it accelerates upward. After passing through the equilibrium level (where the temperature of the rising air is equal to that of its surroundings), the air becomes colder than its surroundings and rapidly decelerates.

If the storm is of the ordinary type (see discussion below), it will rain out and die soon after reaching its maximum vertical extent. However, when the environmental winds exhibit a great deal of vertical shear – marked change in wind direction and increase of wind speed with height – longer-lived severe storms can occur. Another important factor is dry midlevel environmental air that helps to promote downdraft formation. In a severe thunderstorm the updraft continues to be vigorous with horizontally diverging air above the equilibrium level producing an expanding anvil cloud (Figure T14). The top of the updraft is characterized by a convective turret (overshooting top) that can extend a kilometer or two above the top of the anvil into the lower stratosphere.

How does the thermodynamic engine get started? In other words, what causes the air to rise so condensation can begin to occur? The primary mechanisms might be called buoyant lifting and dynamic lifting.

Buoyant lifting occurs when air above a warm surface (land or water) is heated until it becomes warmer than its surroundings.

Figure T14 A severe thunderstorm near Topeka, Kansas, at 1750 CST on 21 April 1961. Photographed from the US Weather Bureau's DC-6B aircraft at 6 km height by T. Fujita, University of Chicago (courtesy of the late Professor Fujita).

Successive thermals of heated air develop into cumulus clouds that grow higher and higher until a full-fledged thunderstorm forms. Through the solar heating process, this type of storm reaches maturity in the late afternoon and early evening.

Geographic features that encourage buoyant lifting are isolated mountain peaks or mountainous terrain in general. Thunderstorms typically develop in these areas during the late morning and early afternoon. These storms begin earlier than those over flatter terrain because the southeastward- and southward-facing (northeastward- and northward-facing in the southern hemisphere) slopes are more perpendicular to the morning sun's rays.

Another important geographic feature is the land–water boundary. On a summer day the heated land becomes warmer than the water, and a lake breeze or sea breeze develops with a localized circulation of air flow from water to land at low levels and return flow aloft from land to water. Through dynamic lifting, the lake or sea breeze front (leading edge of the advancing circulation) favors thunderstorm development over land. If the land cools sufficiently during the night, a land breeze can develop with thunderstorms occurring just offshore. In the fall and early winter seasons, thunderstorms or thunder-snowstorms can form over warm lakes during cold air outbreaks.

Dynamic lifting plays a major role in those thunderstorms that develop along a convergence line (e.g. cold front, mesoscale pressure trough, dry line). These storms can become organized into a squall line. The leading edge of a squall line is characterized by strong winds and heavy rain, often followed by a wide area of stratiform precipitation. Such lines develop their own propagating mechanism and live on through the night, occasionally having an overall lifetime of more than 24 hours.

Global and seasonal distribution

In general, thunderstorms occur most frequently in the tropics and somewhat less frequently in the middle latitudes. Occurrence drops off rapidly in the poleward direction with thunderstorms rarely observed beyond the Arctic and Antarctic circles. The worldwide distribution of thunderstorms by season is shown in Figure T15.

The overall distribution pattern is influenced by three primary elements: (1) the intertropical convergence zone (ITCZ); (2) solar heating of landmasses; and (3) warm ocean currents. The presence of the ITCZ in the vicinity of the equator provides a favored environment for thunderstorm development during the entire year. Most activity is over land and warm (shallow) tropical water. Since the ITCZ is located within the prevailing easterlies, thunderstorms extend to the west of the landmasses. Note that thunderstorm maximums in this zone move northward and southward with the sun.

Outside the tropics, terrestrial thunderstorm activity also follows the sun. Pronounced thunderstorm maximums occur in the summer hemisphere and minimums in the winter hemisphere. Since South America and Africa are the only continents that straddle the equator, the presence of the ITCZ and solar heating provides these two continents with the greatest thunderstorm activity.

Ocean currents also play an important role in the global distribution of thunderstorms. Generally, warm ocean currents flow poleward along the east coasts of continents and cold equatorward-moving currents flow along the west coasts. Therefore, during most seasons it is not surprising to see local thunderstorm maximums over the Brazil current east of South America, the

Agulhas current east of the tip of Africa, and the East Australia current between Australia and New Zealand. Likewise, but less spectacular, there is enhanced activity over the Gulf Stream from the east coast of North America toward Europe and the Kuroshio along the east coast of Asia. Pronounced thunderstorm minimums are found along continental west coasts outside the tropics where colder ocean currents occur.

Thunderstorm structure

The following discussion is based on studies of northern hemisphere midlatitude thunderstorms. Discussed are the single cell (“ordinary”) thunderstorm, the multicell thunderstorm, and the supercell thunderstorm.

Ordinary thunderstorm

The ordinary type of thunderstorm over land is one that develops owing to solar heating. It frequently is called an airmass thunderstorm because it forms within a uniform airmass far from fronts or other large-scale lifting mechanisms. The environmental wind field in which it forms does not contain marked change of wind speed or direction with height. The storm moves in the direction of, and at a slightly slower speed than, the average wind throughout storm depth.

During the roughly 1 hour of the storm’s existence, it passes through three distinct stages: cumulus (growing) stage, mature stage, and dissipating stage (Figure T16). During the cumulus stage, water vapor in the rising updraft condenses on microscopic particles (that are plentiful in the atmosphere) to form cloud droplets. As condensation forms, latent heat is released to fuel the buoyancy of the cloud. When cloud droplets collide with each other and coalesce, raindrops form. Raindrops continue to grow by colliding with cloud droplets and other raindrops within the updraft.

At temperatures below freezing, water vapor within the updraft is converted directly to ice crystals through the deposition of water vapor on microscopic particles (another source of buoyant energy for the cloud). However, cloud droplets that rise above the freezing height remain in liquid form (supercooled) down to temperatures of -20°C or less before they freeze. The presence of these supercooled cloud droplets plays an important role in the formation of graupel (snow pellets), hail, and electrical discharges in the cloud.

When an ice crystal intercepts a supercooled cloud droplet, the droplet immediately freezes on the crystal; this process is called riming. As the process continues, the crystal becomes completely rimed, and then it is called graupel. If air entering the updraft is extremely moist, there will be an abundance of supercooled cloud droplets such that the graupel and coexisting frozen raindrops continue to accumulate rime ice. If the riming particles remain at midaltitudes in the updraft, where temperatures are -10°C to -30°C , the particles serve as embryos that eventually grow into hailstones.

It appears that the presence of ice crystals and riming graupel at midaltitudes within the growing storm leads to the development of an electric field. The most prevalent hypothesis is that the electric field arises owing to noninductive charging; that is, charging in the absence of a surrounding electric field. Laboratory experiments show that, under typical midaltitude within-storm conditions, when an ice crystal hits and bounces off a riming graupel particle, the ice crystal acquires a positive charge and the graupel acquires a negative charge. The

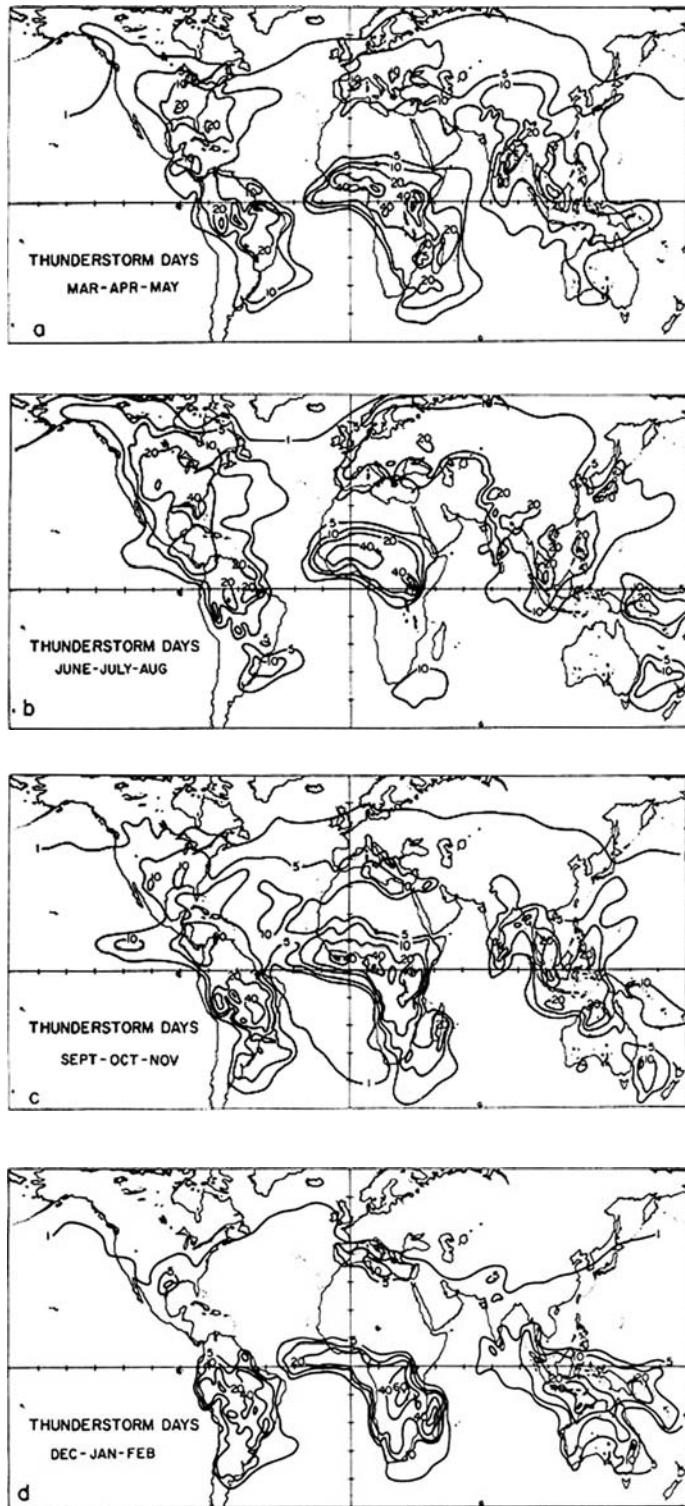

Figure T15 Geographical distribution of the average number of days on which thunderstorms occur during each season of the year. Isobronts are drawn for frequencies of 1, 5, 10, 20, 40, and 60 thunderstorm days per season (after World Meteorological Organization, 1953, 1956).

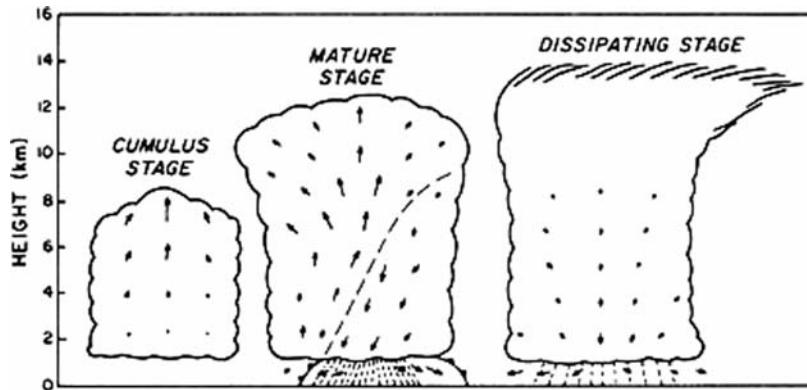

Figure T16 Vertical cross-section of three stages in the life cycle of an ordinary thunderstorm. Gust front boundaries beneath mature stage indicate leading edges of cold-air flow. Time increases as successive stages occur from left to right (after Byers and Braham, 1948).

hypothesis specifies that the lighter ice crystals are carried to the top of the cloud, while the heavier graupel particles remain suspended at midaltitudes. As a consequence of this differential transport, a positive electric field is found in the upper portions of the cloud and a negative field is found at midaltitudes, leading to the development of electrical discharges (lightning).

The beginning of the mature stage is marked by vigorous updrafts ($15\text{--}25 \text{ m s}^{-1}$) and the start of precipitation particles (rain, graupel, hail) falling toward the ground. It is during this stage that the electric field attains its maximum strength, with frequent in-cloud and cloud-to-ground lightning. The descending precipitation particles are accompanied by a strong downdraft of air (reaching strengths of $10\text{--}15 \text{ m s}^{-1}$). When the evaporatively cooled air reaches the surface, it diverges outward producing a strong expanding gust front.

As the surface gust front expands, it cuts off the supply of moist air to the updraft and the updraft dies. Without an updraft available to produce more precipitation and the corresponding release of latent heat, the storm enters the dissipating stage. The downdraft weakens as precipitation decreases and consequently the storm dies.

Multicell thunderstorm

In addition to the single thunderstorm cell, as depicted in Figure T16, thunderstorms also organize themselves into a group of cells where each one is at a different developmental stage at a specific instant. This multicell thunderstorm can become severe and produce surface damage due to strong winds and hail. In Figure T17, cells 1 and 2 are in the cumulus stage, cell 3 is at the beginning of the mature stage and cell 4 is in the dissipating stage. Precipitation falling beneath cell 4 and a portion of 3 consists of both rain and hail.

The vertical cross-section in Figure T17 is perpendicular to cell motion, with the cells moving away from the viewer directly into the page. Moist low-altitude air approaching the storm from the right side (when looking in the direction of cell motion) is lifted by the outflowing cold air. Thus, the storm continues to evolve by producing its own lifting mechanism.

Although the individual cells of a multicell thunderstorm generally move with the mean wind, the cell ensemble does not move in that direction. With new cells developing at periodic intervals to the right of the existing cells, and old cells dying on

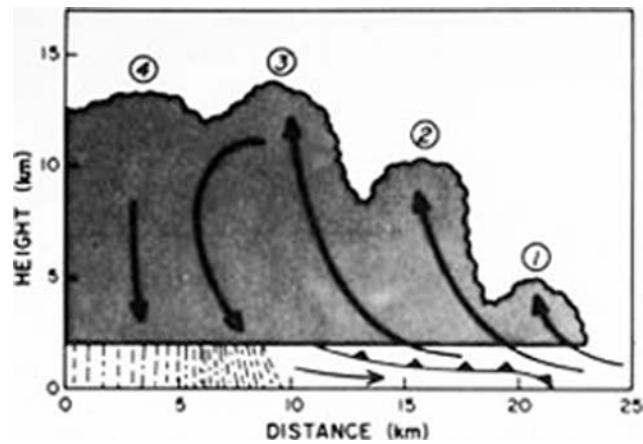

Figure T17 Vertical cross-section through a multicell storm, perpendicular to cell motion and mean environmental wind. Cell motion is away from the observer into the page; storm motion is at an angle to the right of cell motion. The gust front boundary is indicated with black triangles (modified after Kessler, 1985, p. 147).

the left flank, the storm as a whole moves (propagates in discrete steps) at an angle to the right of individual cell motion. This process of discrete propagation can last for hours, even though the lifetime of individual cells is about 1 hour.

Supercell thunderstorm

Severe thunderstorms that are capable of producing tornadoes develop an extraordinary structure during the mature stage. This "supercell" thunderstorm typically is an isolated storm that develops in an environment marked by extreme wind shear with height. However, not all supercell storms are isolated; some can be part of a squall line. The supercell storm differs from the ordinary storm because wind variation with height enables the precipitation downdraft to form adjacent to, and coexist with, the updraft. This feature permits the storm to have a quasi-steady mature stage that can persist for hours.

A notable characteristic of the supercell storm is its strong, rotating updraft (Figure T18); the rotating column is called the

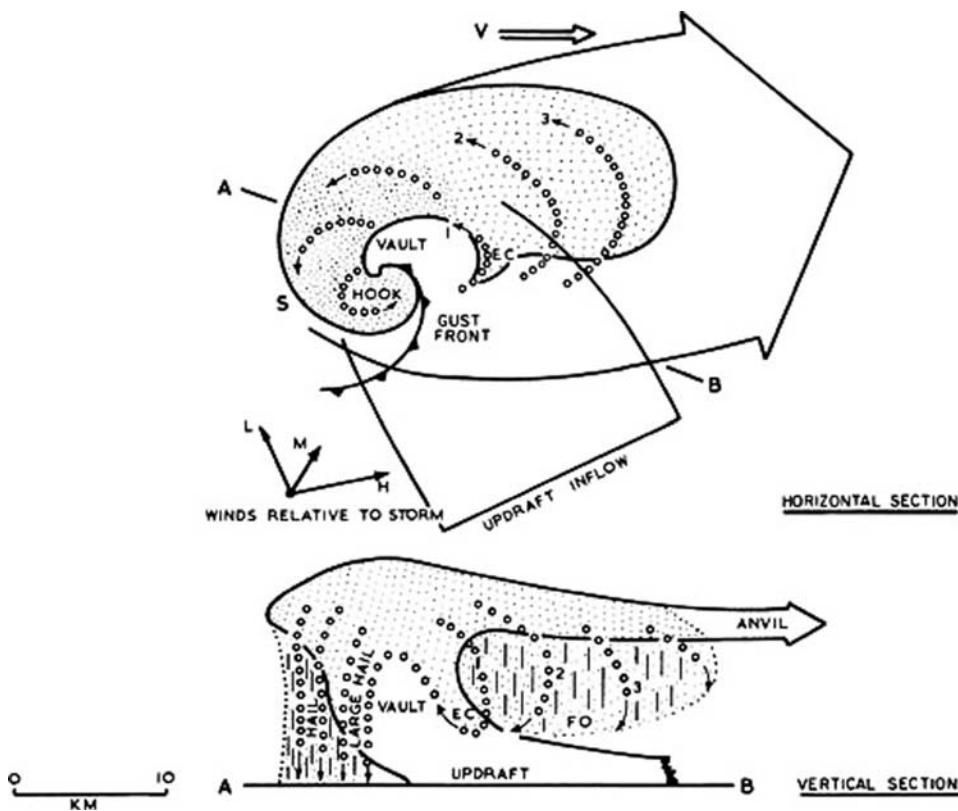

Figure T18 Horizontal and vertical cross-sections through the Browning model of a supercell thunderstorm. Stipple shading indicates the radar echo portion of the storm. (See Figure T14 for a visualization of this storm type.) Vertical section AB (lower panel) is oriented in the direction of the mean wind shear (indicated in upper panel). Environmental winds relative to the moving storm (V) are indicated at low (L), middle (M) and high (H) altitudes. The broad arrow represents low-altitude air entering the updraft, rising, and then flowing downstream with the high-altitude winds. The dotted (open circle) curves are precipitation trajectories. In horizontal section (upper panel), light and heavy stippling denotes areas of rain and hail, respectively, near the ground. Broken vertical hatching in the forward overhand (FO) and hailfall area indicates downdrafts with strong flow normal to the vertical section. Hail embryos are found in the embryo curtain (EC) (after Kessler, 1985, p. 152).

thunderstorm mesocyclone. Low-altitude air (*L*) enters the updraft, turns cyclonically (counterclockwise in the northern hemisphere) as it rises and exits through the anvil with the high-altitude storm-relative winds (*H*). Due to the updraft's strength ($30\text{--}50\text{ m s}^{-1}$), cloud droplets do not have time to grow into radar-detectable precipitation particles until they have risen high in the storm. Consequently, the updraft is marked by a pronounced weak-echo vault that forms within the storm's radar echo. The fact that the updraft is rotating is indicated by descending precipitation being drawn around in the hook-shaped radar pattern in the storm's right rear quadrant. The low-altitude weak-echo inflow air beneath the vault forms the other part of the mesocyclone's circulation. Doppler radar measurements, which show the component of precipitation motion toward or away from the radar, indicate that the mesocyclone is typically about 10 km in diameter and extends vertically throughout much of the storm's depth; peak rotational velocities of $20\text{--}25\text{ m s}^{-1}$ are found at an average radius of 2.5 km. If the storm produces a tornado, the tornado usually forms within the mesocyclone.

Being continuously fed with low-altitude moist air along its right flank, the storm appears to propagate continuously toward the right; this process is in contrast with the marked discrete

propagation of multicell storms. The updraft within the supercell storm begins to die when there no longer is a balance of forces across the gust front. As low-altitude outflow air behind the gust front increases in relative strength, the gust front accelerates around the mesocyclone center, choking off the low-altitude moisture source that is vital for sustaining the updraft. In some supercell storms a new updraft forms along the gust front near the dying one. Since the new updraft grows in the cyclonically rotating portion of the storm, the rotation is concentrated by the updraft and it starts to rotate, producing a new mesocyclone center. On rare occasions this process can continue with the production of a series of mesocyclones over a period of several hours. This appears to be the process that takes place in storms that produce a family of sequential tornadoes, with each new tornado being associated with a new mesocyclone center.

Improving understanding of thunderstorm processes

Even though the basic characteristics of severe storms are known, complete understanding of the processes taking place within the storms is lacking. Use of conventional radars since the mid-1940s has increased our understanding of thunderstorms.

Starting in the early 1970s, Doppler radars and three-dimensional computer modeling of the thunderstorm life cycle have provided new insights into the workings of severe storms. During the 1990s, meteorologists began to use mobile instrumentation (Doppler radars, balloon launch equipment, lightning sensors, surface weather instruments) to follow thunderstorms in order to systematically measure hitherto-unknown details of the within-storm and near-storm conditions. More recently, dual-polarization Doppler radars permit discrimination among raindrops, hail, and ice crystals within evolving storms. Three-dimensional lightning detectors, that allow one to track in-cloud lightning discharges, are helping to understand the electrical component of storms. All of these facilities hold promise for solving many of the remaining mysteries about severe thunderstorms.

Tornadoes

TORNADOES

Tornadoes are zones of extremely rapid, rotating winds beneath the base of cumulonimbus clouds. Though the overwhelming majority of tornadoes rotate cyclonically (counterclockwise in the northern hemisphere), a few spin in the opposite direction. Strong tornadic winds result from extraordinarily large differences in atmospheric pressure over short distances. Over just a few tenths of a kilometer, the pressure difference between the core of a tornado and the area immediately outside the funnel can be as great as 100 mb. In what follows we adopt a northern hemisphere perspective, where “counterclockwise” is cyclonic.

Tornado characteristics and dimensions

It is difficult to generalize about tornadoes because they occur in a wide variety of shapes and sizes. While the majority have diameters of about 50 meters or so, some may extend as much as a kilometer in diameter or more. Usually they last no longer than a few minutes, but some have endured for several hours. Tornadoes normally move across the surface at speeds of about 50–65 km/h; so a typical tornado normally covers no more than a couple of kilometers from the time it touches the ground to when it dies out.

Estimates of wind speeds within tornadoes have historically been based primarily on the damage produced, and it was once believed that velocities could approach 800 km/h. The advent of weather radar has allowed meteorologists to make far more accurate estimates, and it is now understood that the weakest have wind speeds as low as 65 km/h and the most severe in excess of about 450 km/h.

Tornado formation

Tornadoes can develop in any situation that produces severe weather – frontal boundaries, squall lines, mesoscale convective complexes, supercells, and tropical cyclones. The processes that lead to their formation are not very well understood. Typically, the most intense and destructive tornadoes are those that arise from supercells.

Supercell tornado development

In a supercell storm, the first observable step in tornado formation is the slow rotation of a large segment of the cloud (up to 10 km (6 miles) in diameter). Such rotation begins deep within the cloud interior, several kilometers above the surface. The resulting large vortices, called *mesocyclones*, often precede the formation of the actual tornado by some 30 minutes or so.

The initiation of a mesocyclone depends on the presence of vertical wind shear near the surface. Figure T19 illustrates this process. Moving upward from the surface, the wind direction shifts from an easterly to westerly direction as the wind speed increases. This wind shear causes a horizontal vortex to develop. Under the right conditions, strong updrafts in the storm lift the middle of the vortex so that it bends upward with both a counterclockwise and clockwise limb. The counterclockwise rotating vortex provides the rotation needed for the development of the mesocyclone.

Intensification of the mesocyclone requires that the area of rotation decrease, which leads to an increase in wind speed. The narrowing column of counterclockwise rotating air stretches downward, and a portion of the cloud base protrudes downward to form a *wall cloud* (Figure T20). Wall clouds form where cool, humid air from zones of precipitation is drawn into the updraft feeding the main cloud. The humid air condenses at a lower height than does the air feeding into the rest of the cloud. Wall clouds most often occur on the southern or southwestern portions of supercells, near areas of large hail and heavy rainfall. *Funnel clouds* form when a narrow, rapidly rotating vortex emerges from the base of the wall cloud. A funnel cloud has all the characteristics and intensity of a true tornado; the only difference between the two is that a funnel cloud has yet to touch the ground. Funnel clouds and tornadoes are visible as the condensation that occurs as rising air cools adiabatically around the vortex. In some instances the tornado occurs without the accompanying condensation, and the vortex is not visually evident

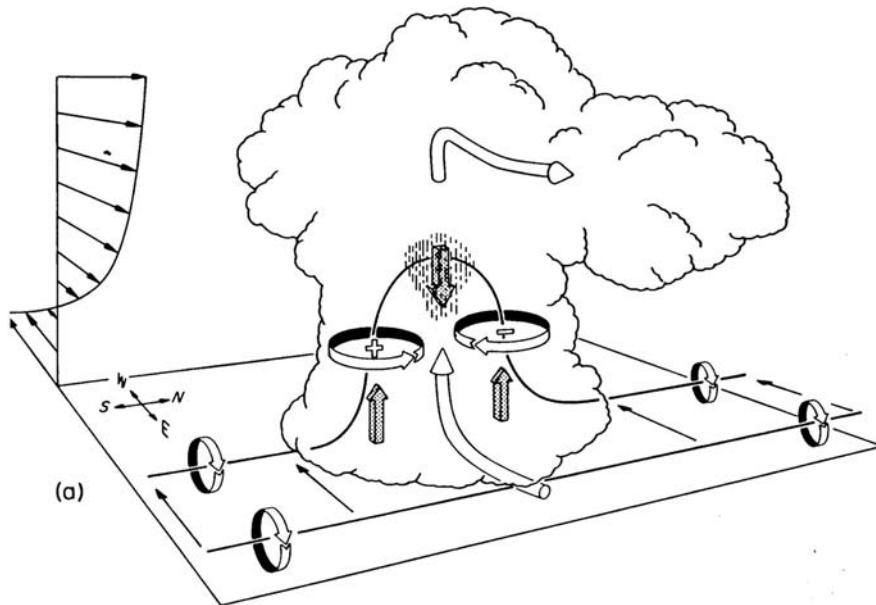

Figure T19 The development of a mesocyclone. Mesocyclones begin with the development of a horizontally rotating tube of air due to wind shear. Convection can then lift the vortex along the middle, creating clockwise and counterclockwise vortices. The counterclockwise vortex grows into a mesocyclone. (From Klemp, 1987, Dynamics of tornadic thunderstorms, *Annual Review of Fluid Dynamics*, **19**: 369–402.)

except for the dust that is entrained from below. At other times condensation may cause the visual appearance of the tornado, but nearby rain obscures the event to people some distance away.

Because Doppler radar enables forecasters to observe the rotating winds of mesocyclones, the network of these radars has greatly increased lead times in the issuance of tornado warnings. Only about 50% of all mesocyclones actually spawn tornadoes, however. Exactly why some mesocyclones produce tornadoes and others do not is unknown, and for that reason

forecasters cannot tell in advance which mesocyclones will produce tornadoes. Despite these uncertainties, Doppler radar has already proven itself to be the most important tool yet developed in “nowcasting” (making short-term predictions) the formation of tornadoes.

Nonsupercell tornado development

The exact mechanisms that lead to nonsupercell tornadoes are also poorly understood, though recent research indicates that

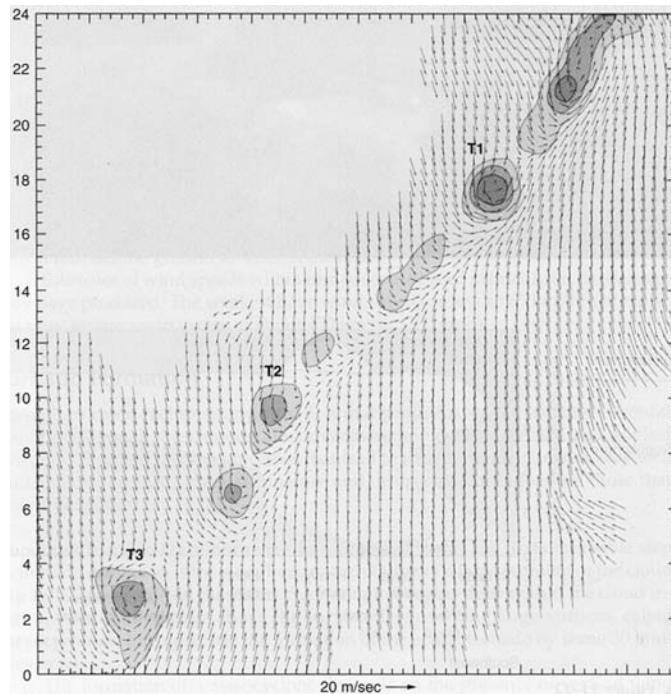

Figure T21 Convergence of two outflow boundaries can sometimes lead to the formation of tornadoes, as in this example. The vectors represent wind velocities. (From Aguado and Burt, 2002. *Understanding Weather and Climate*. Used with permission of Prentice-Hall.)

such tornadoes have their origins nearer to the surface than do those that begin as mesocyclones. Figure T21 illustrates one situation that may lead to nonsupercell tornadoes. The arrows show the outflow of air from two thunderstorm regions: at the top left and bottom right of the figure. From the bottom left to the top right of the figure is a zone of convergence between the two masses of air. At certain areas along the convergence zone (the circled areas), strong rotation develops. Another possible mechanism is shown in Figure T22, where strong convection along the convergence zone causes uplift and the formation of a cumulus cloud. In Figure T22c the cloud develops into a cumulonimbus, and the strong rotation stretches down from the cloud base to form a funnel cloud.

The location and timing of North American tornadoes

Though tornadoes occur over much of the world, no other country in the world has nearly as many as does the United States. Other areas in which tornadoes are fairly common include Japan, Australia, western Europe, South Africa and northern Argentina, but several factors combine to make North America a haven for tornadoes. First, the continent covers a wide range of latitudes; its southeastern portion borders the warm Gulf of Mexico, while the northernmost portion extends into the Arctic. Furthermore, much of the eastern portion of the continent is relatively flat and, in particular, there is no major mountain range extending in an east–west direction. Together, these features allow for a collision of northward-moving maritime tropical air from the Gulf of Mexico with southward-moving continental polar air along the polar front. This setting, coupled with the frequent presence of potential instability,

provides a favorable situation for tornado development. The frequent occurrence of dry lines also contributes to the high incidence of tornadoes across much of southern Plains. Tornadoes occur at least occasionally in almost all 50 states. A great many tornadoes touch down along a wide strip running southwest to northeast between the southern Plains and the lower Great Lakes region, commonly called *Tornado Alley*.

Texas easily leads the United States in total number of tornadoes, with well over 100 annually. But when the large size of that state is accounted for, it ranks only ninth in number of tornadoes per unit area. Interestingly, the state with the greatest number of tornadoes per unit area is Florida, which lies altogether outside Tornado Alley. Unlike the twisters in Tornado Alley, many of Florida's tornadoes are embedded in passing hurricanes and tropical storms. Oklahoma is a close second to Florida in tornado density, but has about twice as many strong or violent tornadoes.

Tornadoes can occur at any time of the year; however, as shown in Figure T23, there is a strong concentration of tornadoes during the spring, when airmass contrasts are especially strong. May has the greatest number of tornadoes, with June a close second. The peak tornado season is not uniform throughout the country, because spring does not arrive everywhere at once. Louisiana and Arkansas have the greatest number of tornadoes in April, but Illinois, Wisconsin, and Nebraska are most apt to have them in June. Farther to the west, the Plains states of Texas, Oklahoma, and Kansas all share May as the peak month.

Tornadoes are far less common in Canada, with an annual average of only about 100. The greatest concentration is in the extreme southern part of Ontario, between Lake Huron and Lake Erie. The majority of Canadian tornadoes outside Ontario occur in the southern region of the Prairie provinces and southwestern

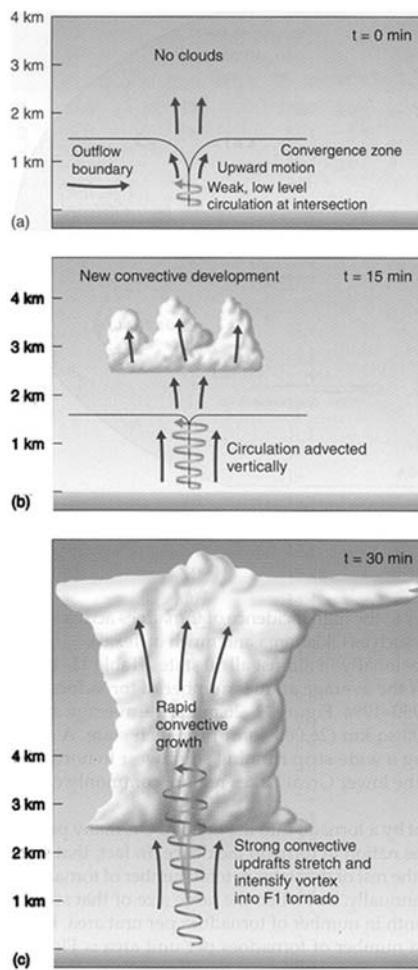

Figure T22 The development of a tornado along a convergent boundary. Spinning motions along the boundary (a) can be carried upward if there is sufficient convection (b). Once the cumulonimbus develops (c), the downward movement of the strong rotation can lead to tornadoes. (From Aguado and Burt, 2002. *Understanding Weather and Climate*. Used with permission of Prentice-Hall.)

Quebec. The Canadian tornado season extends from April through October, with the greatest frequency in June and July. Despite the fact that the greatest concentration of tornadoes in general, and of very strong tornadoes in particular, occurs in Ontario, it is interesting to note that the worst Canadian tornado outbreak in recent decades occurred in 1987 in Edmonton, Alberta, where the tornadoes of 31 July left 27 people dead, more than 300 injured, and thousands homeless. Total damages were estimated at \$300 million.

Trends in US tornado occurrence

Tornado occurrences in the US, based on a log of events collected by the Storm Prediction Center of NOAA, shows a dramatic rise in tornado frequency from 1950 to the present (Figure T24). However, the same log suggests that intense storms (F2 or greater) have decreased since the 1970s, which implies that any increase in total storms has resulted from much higher frequency of moderate and weak events.

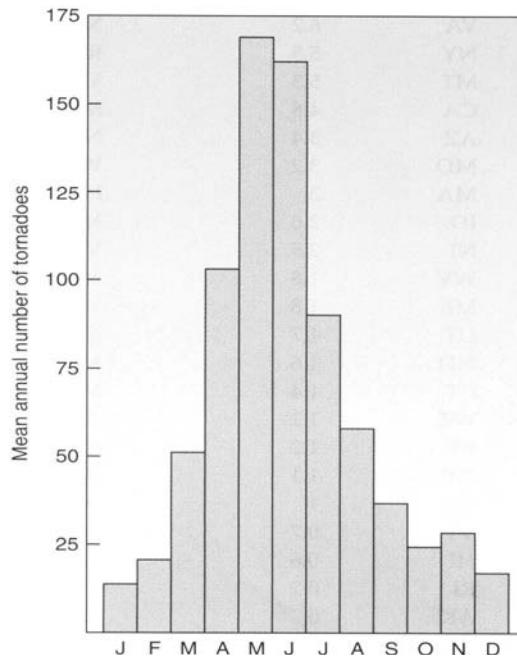

Figure T23 The monthly distribution of tornadoes in the United States, from 1950 to 1995. (From Aguado and Burt, 2002. *Understanding Weather and Climate*. Used with permission of Prentice-Hall.)

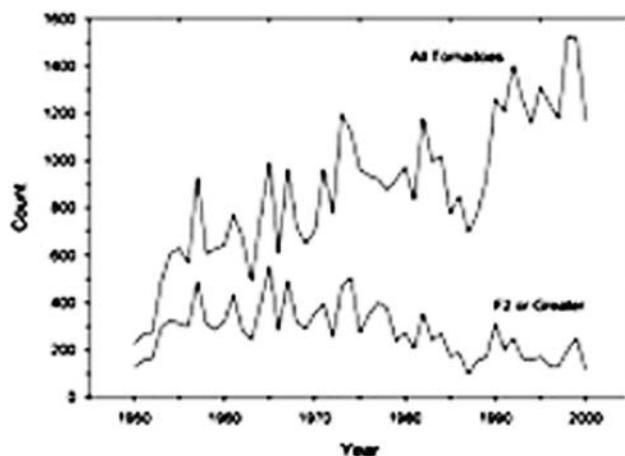

Figure T24 Observed counts of US tornadoes by year as recorded by the Storm Prediction Center. Data courtesy of Dr Matthew Menne, Climatic Data Center, NOAA.

However, there is good reason to doubt the accuracy of this figure as an indicator of occurrence, because the official log does not account for increasing population (more “observers”), improved methods of detection (including Doppler radar), nor changes in the way tornadoes are classified. In contrast to Figure T24, a recent reconstruction assembled from objective evaluation of tornado environments (i.e. atmospheric conditions suitable for tornadoes) suggests a rather different trend. According to the reconstruction, strong-to-violent tornado

frequency was relatively constant from 1950 through the early 1990s, then increased dramatically, roughly doubling in the ensuing 10 years.

Tornado damage

Most of the structural damage from tornadoes results from their extreme winds. It was once believed that homes were destroyed mostly by the pressure differences associated with a tornado's passage, which supposedly caused the air to push outward against the walls so violently that the house would explode. For this reason, people were advised to open their windows if they saw an approaching tornado, so that the pressure within the house could be reduced.

We now know that this was not good advice, in part because few homes actually explode. Moreover, though winds are the major factor in tornado damage, flying debris is the primary cause of tornado injuries, and opening a window increases the risk of personal injury from flying debris. (We must also suspect that opening the windows is useless in any case, because they are likely to be "opened" anyway by flying objects.)

Although most tornadoes rotate around a single, central core, some of the most violent ones have relatively small zones of intense rotations (about 10 m (30 ft) in diameter) called *suction vortices*. It is these small vortices that probably allow the familiar phenomenon of one home being totally destroyed while the one next door remains relatively unscathed.

Except for those rare times when tornado-chasers make first-hand observations of passing tornadoes, it is impossible to get a precise reading on their pressure changes and wind speeds. But it is possible to classify them according to the magnitude of the damage they cause. The *Fujita scale* (named for the eminent tornado specialist Theodore Fujita) provides a widely used system for ranking tornado intensity. As shown in Table T2, documented tornadoes fall into seven levels of intensity, with each assigned a particular F-value ranging from 0 to 6 (F6 tornadoes are theoretical and have not been observed in nature). In the US the majority (69%) fall into the *weak* category, which includes F0 and F1 tornadoes. Twenty-nine percent of tornadoes are classified as *strong* (F2 and F3), which makes them capable of causing major structural damage even to well-constructed homes. Fortunately, only 2% of tornadoes are *violent* (F4 and

F5). Those tornadoes are capable of wreaking incredible destruction. Cars can be picked up and carried tens of meters, pieces of straw can be driven into wooden beams, and freight cars can be carried off their tracks. Indeed, these storms are the true stars in all the movies and videos about tornadoes.

Between 1950 and 1999 there were 51 F5 tornadoes in the US and none in Canada. Thus they occur about once a year in all of North America. Texas holds the lead for the greatest number of F5 tornadoes (six) over that period, while Alabama, Iowa, Kansas, and Oklahoma each had five.

Fatalities

Because they are small and last for such a short time, the overwhelming majority of tornadoes do not inflict fatalities. Consider the fact that, between 1950 and 1994, an average of 91 people died in 760 reported tornadoes each year. This means that at least 88% of all tornadoes did not kill anybody, and the actual proportion of fatality-free tornadoes is even higher than 88%, for at least two reasons. First, tornadoes in which no one dies are preferentially undercounted, because a storm that kills is almost certain to be reported. Second, most fatalities result from a few very large storms that kill up to dozens of people. According to the National Severe Storms Laboratory (NSSL), fewer than 5% of all US tornado deaths are associated with weak (F0 or F1) tornadoes, nearly 30% with strong tornadoes (F2 and F3), and about 70% with violent tornadoes (F4 and F5). Thus, only 2% of all tornadoes are responsible for more than two-thirds of all fatalities.

A disproportionately large percentage of tornado-related deaths occur in mobile homes, which offer little protection to their occupants because they are easily blown off their foundations and tossed about by strong winds. During the 1985–2003 period there were a reported 997 tornado fatalities in the US. Of those, 403 (40%) occurred in mobile homes, in contrast to the 313 (31%) in regular residential structures.

Ten percent of the tornado fatalities during the 1985–2003 period were passengers and drivers of trucks and automobiles. Such victims often panic and make the fatal mistake of leaving the relative safety of their homes to outrun the storm in their vehicles. By far the safest place you can be when a tornado threatens is inside a well-constructed building, preferably in the

Table T2 The Fujita scale

Intensity	Wind speed (km/h)	Wind speed (mph)	Typical amount of damage
F0	<116	<72	Light: broken branches, shallow trees uprooted, damaged signs and chimneys.
F1	116–180	72–112	Moderate: damage to roofs, moving autos swept off road, mobile homes overturned.
F2	181–253	113–157	Considerable: roofs torn off homes, mobile homes completely destroyed, large trees uprooted.
F3	254–332	158–206	Severe: trains overturned, roofs and walls torn off well-constructed houses.
F4	333–419	207–260	Devastating: frame houses completely destroyed, cars picked up and blown downwind.
F5	420–512	261–318	Incredible: steel-reinforced concrete structures badly damaged.
F6	>513	>319	Inconceivable: might possibly occur in a small part of an F4 or F5 tornado. It would be difficult to identify damage done specifically by these winds, as it would be indistinguishable from that of the main body of the tornado.

F0 and F1 tornadoes are collectively called weak; F2 and F3 strong; and F4 and F5 violent.

basement and away from the windows. The notion that the southwest corner of a building offers additional protection is a commonly heard myth.

Experts cite the following safety rules for tornado safety:

1. Stay indoors and seek shelter in a basement.
2. If you are in a building with no basement, move to an interior portion of the lowest floor and crouch to the floor. If possible, cover yourself with a mattress or some other form of padding to protect you from falling or flying debris.
3. If you are in a mobile home, evacuate. If no fixed building is nearby, move away from all mobile homes and lie flat on low ground.
4. If driving a car or truck, you might be able to avoid the path of a tornado by driving at right angles to its path. Remember that most tornadoes move from southwest to northeast in the US and Canada. If you cannot avoid the tornado's path, pull off the road and seek shelter. If none is available, run to low ground away from the road.

Watches and warnings

Without question one of the most important responsibilities of the National Weather Service is to issue severe weather advisories. These take two forms: *watches* and *warnings*, either of which can be issued for severe storms or tornadoes. The declaration of a watch does not mean that severe weather has developed or is imminent; it simply tells the public that the weather situation is conducive to the formation of such activity. Most watches are issued for a period of 4–6 h, and for an area that normally encompasses several counties – about 50 000–100 000 sq km (20 000–40 000 sq miles).

The Storm Prediction Center (SPC) of the US Weather Service in Norman, Oklahoma, has responsibility for putting out severe storm and tornado watches for the entire country. Operating 24 hours a day, every day, the center constantly monitors surface weather station data, information from weather balloons and wide-bodied commercial aircraft, and satellite data for all of the US. If any particular part of the country appears vulnerable to impending severe storm activity, SPC issues a severe storm or tornado watch. The advisory then goes to the local office of the National Weather Service, which notifies local television and radio stations. The broadcast media then relay the information to the public. Watches for the entire country are also available from a number of sources, many of which are on the Worldwide Web.

Tornado warnings alert the public to the observation of an actual tornado (usually by a trained weather spotter) or the detection of tornado precursors on Doppler radar. Unlike watches, which are issued by the SPC, warnings are given by local weather forecast offices. They warn the public to take immediate safety precautions, such as finding shelter in a basement. The information is broadcast immediately by television and radio stations, and civil defense sirens are sounded.

Tornado research

Despite the inherent difficulty of studying something as complex, violent, and short-lived as a tornado, scientists can peer into their structure using a number of research tools. For many years, much of the information was obtained by films and pictures of tornadoes. Unfortunately, dust and debris kicked up by a tornado, as well as screening by trees and buildings, often

made it impossible to observe the part of the tornado nearest to the ground (and of most concern to people).

In 1980 scientists developed the Totable Tornado Observatory, better known by its acronym, "Toto" (an intentional reference to the dog in *The Wizard of Oz*). Toto was a lightweight package that could be carried in the back of a pickup truck and set up by storm-chasers in 30 seconds or less. Ideally, the instrument would be placed in the path of a tornado where it could make observations of temperature, wind, and pressure. Unfortunately, getting Toto in the path of a tornado proved exceedingly difficult. Moreover, wind tunnel tests have shown that it tends to tip over at wind speeds near 50 m/s, well below those that can occur in a tornado. For these reasons storm-chasers no longer use Toto.

More recently, scientists from the University of Oklahoma have begun placing a network of smaller instruments called "turtles" in the paths of tornadoes. Though they only record temperature and pressure, turtles have an advantage in that they can be laid out in series across a road, crossing the path of a tornado. They remain a potentially useful tool for examining the environment of a tornado.

Other methods have been attempted for making direct observations within a tornado or mesocyclone. One is to release portable weather balloons with radiosonde instruments in the near-storm environment. If they are released from the right location, the wind can carry the balloons right into the heart of a severe storm. Less successfully, researchers have attempted to fire light instrument-carrying rockets (on the order of 1 kg) into severe storms from small aircraft. Unfortunately, the measurement devices have proven to be too fragile to survive the turbulence of the storm and are no longer used.

By far the most useful instrument for studying the winds of tornado-producing storms has been Doppler radar. The NEXRAD network of Doppler radar units has yielded a marked improvement in the issuance of tornado warnings. A recent study has shown that installation of the first six Doppler radar units in the heart of Tornado Alley has improved forecasters' ability to predict tornadoes. Prior to the radar deployment, 33% of the tornadoes in the study area occurred without a tornado warning; afterward, the figure dropped to 13%.

The biggest limitation of the Doppler radar network is that the farther a storm is from the transmitter/receiver unit, the less detailed is the information about its internal winds. Because tornadoes are usually quite small, they must pass within a few kilometers of the radar if precise wind information is to be obtained. For this reason, tornado researchers also use portable Doppler radar units carried on research vehicles and aircraft.

The tornado outbreak of 3–6 May 1999

In May of 1999 a devastating series of large tornadoes reminded the world of just how devastating tornadoes can be. Hardest hit was central Oklahoma, where a series of tornadoes on the first day of the outbreak killed 44 people and destroyed 2600 homes and businesses. On the same day, tornadoes killed another five people and destroyed 1100 buildings in the Wichita, Kansas area; and on 5 and 6 May the storms claimed another five lives in Texas and Tennessee. This was the deadliest outbreak of tornadoes since the record-breaking "Xenia Tornado Outbreak" of 3–4 April 1974, which spawned a total of 148 tornadoes (seven of which were rated as F5) from northern Alabama and Georgia to Windsor, Ontario, in Canada, and killed over 300 people.

Many factors contribute to the loss of life inflicted by tornadoes, including their maximum wind speed and their paths relative to large populations. In this case extremely powerful winds descended upon large population centers. However, the effectiveness of the warning system also impacts the death total and, fortunately, the system was at its very best during the 1999 outbreak. Field crews observed and reported the early development of conditions favorable for tornadoes, which complemented the forecasting efforts of meteorologists at the respective Weather Service offices. Meteorologists issued public advisories a full 2 hours in advance of the tornadoes, television and radio news crews disseminated the information, and the public generally responded wisely. Many residents sought shelter in basements, and others living in homes without basements took cover in interior hallways in time to save their lives. (People living in mobile homes received no protection at all from the storms; in the town of Bridge Creek every one of the 11 people who died were in trailers. Likewise, many fatalities occurred on highways – three of which were of people taking shelter under freeway overpasses!) Experts at the National Oceanographic and Atmospheric Agency estimate that the warning system saved as many as 7000 lives.

Waterspouts

So far we have discussed tornadoes over land. Similar features, called *waterspouts*, occur over warm-water bodies. Waterspouts are typically smaller than tornadoes, having diameters between about 5 and 100 m (17–330 ft). Though they are generally weaker than tornadoes, they can have wind speeds of up to 150 km/h (90 mph), which makes them strong enough to damage boats.

Some waterspouts originate when land-based tornadoes move offshore. The majority, however, are formed over the water itself. These “fair-weather” waterspouts develop as the warm water heats the air from below and causes it to become unstable. As the air rises within the unstable atmosphere, adiabatic cooling lowers the air temperature to the dewpoint, and the resultant condensation gives the waterspout its ropelike appearance. Waterspouts form in conjunction with cumulus congestus clouds, those having strong vertical development but not enough to form the anvil that characterizes cumulonimbus.

Contrary to what we might assume, the visible water in the waterspout is not sucked up from the ocean below; it actually comes from the water vapor in the air. Waterspouts are particularly common in the area around the Florida Keys, where they can occur several times each day during the summer.

TOURISM AND CLIMATE

Tourism is the world’s fastest-growing industry and in many countries it is a major and rapidly developing economic sector of the economy. Climate constitutes an important part of the environmental context in which recreation and tourism takes place, and climate is a resource exploited by tourism (Perry, 1997). Because tourism is a voluntary and discretionary activity, participation will often depend on perceived favorable climatic conditions. The betterment of health has been a strong motive for travel since the taking of waters at mineral and hot springs was fashionable in the seventeenth and eighteenth centuries. In the twentieth century a holiday in the sun is still perceived by many people as vital to their well-being, despite concerns over the links between skin cancer and UV-B radiation. The search for a salubrious, amenable climate was once the prerogative of the wealthy, but has now become a mass phenomenon. Leisure time is a scarce resource and spending time in a climate perceived by the individual as being most ideal has become of great importance to many people. Weather can ruin a holiday, but climate can ruin a holiday destination. Climate is a major component of the tourist destination image and the weather conditions anticipated by the holidaymaker are one of the major influences on holiday destination decisions. The Mediterranean, with its hot dry summer, is currently the world’s most popular and successful tourist destinations, with 120 million visitors every year, many of them from the tourist-exporting countries of northern Europe, and 25% of the world’s hotel accommodation is found in this area. This area may become less attractive to tourists in high summer in the future as it becomes too hot for comfort in the peak season with a much higher frequency of severe heat waves. (Perry, 2000). This is an example of a change in the seasonality of a tourist destination, and might have the effect of changing the length of the operating season of tourist facilities and infrastructure with implications for profitability. In northern latitudes of Europe and North America warmer weather in the future may produce a longer tourist season and encourage more people to take their holidays at home.

Areas of study

Three main areas of study have emerged in climate-tourism studies:-

1. Forecasting how weather and climate affects participation rates for different types of leisure activities and the levels of personal safety, comfort and satisfaction that ensue.
2. Improving the range and provision of weather and climate information for the leisure industry.
3. Investigating the likely impacts of climate change, particularly projected global warming, on tourism and recreational activities and enterprises.

Smith (1993) has drawn a distinction between weather-sensitive tourism, where the climate is insufficiently reliable to attract mass leisure participation, but good weather can stimulate tourist activity, and climate-dependent tourism where travel to the destination is based on the reliability of the climatic conditions. Climate as a motivating factor in holiday destination choice has been examined by Maddison (2001) and Giles and Perry (1998). Predicting both spectator and participant numbers at outdoor recreational sites is important for implementing effective visitor management strategies. Activity choice, for example whether to play golf, swim or go hill-walking, is in large measure determined by perceived weather conditions. For many activities there are critical thresholds beyond which participation and enjoyment levels fall and safety may be endangered.

Tourism and leisure activities generate a large percentage of the total demand for weather information from meteorological services. However, portraying the suitability of the climatic environment for different types of leisure activity and for different groups of potential customers is a difficult task. Easily available information in holiday brochures is often misleading, incomplete, and may be distorted by commercial interests.

To present the totality of the climatic environment for tourists it is necessary to develop indices that integrate a number of climatic parameters. A tourism climate index is a useful concept but there are various facets to tourism climate, e.g. aesthetic (sunshine hours), physical (rain and wind) and thermal (combined metabolic effect), which make an effective and simple descriptive index difficult to devise. Whilst climatologists use various standard measures of comfort and discomfort these are little known or understood by the general public, and there remains the challenge of developing indices of holiday climate that can be widely used and understood by the traveling public.

Climate change

Climate change will impact upon tourism and in turn impacts, through growing greenhouse gas emissions, on the climate. Impacts may be direct, e.g. changing the environment of resorts as a result of sea-level rise, or indirect, for example raising conflicts over water resources. Tourism has a strong international dimension and is sensitive to any change of climate that alters the competitive balance of holiday destinations. Tourism is vulnerable to natural disasters and extreme events such as hurricanes, avalanches, heatwaves and droughts, whose frequency and distribution may change in the future. Infrastructure developments such as campsites are often placed in hazard-prone sites such as flood plains, to take advantage of scenic attractiveness, but are then prone to sudden-onset disasters such as flash floods.

Winter sports centers, especially those at lower altitudes, will be increasingly at risk from shorter seasons, higher temperatures (making adaptation strategies such as artificial snowmaking difficult to implement) and unreliable natural snow cover. The most vulnerable tourist resorts are a function of the likely magnitude and extent of the climate impact, the importance of tourism to the local economy and the capacity to adapt (Agnew and Viner 2001). The primary resources of sun, sea and beaches are likely to be re-evaluated in the light of expected climate change, but tourism is a continuously adapting industry and climate change will present new challenges that could lead to opportunities for tourist investment to capitalize on the changed environmental conditions.

TRADE WINDS AND THE TRADE WIND INVERSION

Easterly winds of the tropical oceans, both north and south of the equator, have long been known as trade winds. Here, “trade” comes from a now-obsolete form, meaning “track”, and refers the persistent direction of these winds. The trades are among the most important features of the atmospheric circulation, gathering energy from the ocean surface and transporting it toward the equator and controlling the climate of nearly half the Earth’s surface.

The trade winds form the equatorward limb of the Hadley circulation in each hemisphere. They flow out of the subtropical high-pressure cells as northeasterlies in the northern hemisphere, and southeasterlies in the southern hemisphere. They meet at the near-equatorial convergence zone (CZ, see Ramage et al., 1981), often referred to as the intertropical convergence zone (ITCZ). The CZ is a zone of frequent convection that migrates north and south with changing sun angle, but remains in the northern hemisphere over the oceans. Tropical winds are dominantly easterly throughout the lower and middle troposphere. Rising air along the CZ begins to diverge in the upper troposphere. As this flow moves poleward in each hemisphere, Coriolis causes it to become a westerly wind. The poleward flow

descends at about 30°–35°N and S, forming the subtropical high-pressure belt and completing the Hadley cell circulation.

Observations indicate that the trades accumulate both latent and sensible heat as they flow across the ocean surface. The trades transport most of this energy to the CZ area, where it contributes to the massive convection there, which in turn sets in motion the Hadley cells. In this respect the trades are seen as drivers of the atmospheric general circulation.

Trade winds form the equatorward sides of the subtropical anticyclones. The preferred positions of these large, semipermanent high-pressure systems are in the eastern portions of the ocean basins. The highs shift with the seasons, affecting the location of the trade wind zone. In each hemisphere, subtropical anticyclones shift equatorward during winter, relative to their summer positions. In the northern hemisphere, with its relatively large continents, they also shift landward (east) during winter.

Over continental areas, especially Asia, the annual cycle of heating and cooling strongly influences the patterns of tropical winds. For example, while easterlies are found across the entire tropical north Pacific in January, the Asian monsoon disrupts this pattern in summer, resulting in southwesterly winds in the sector from East Africa all the way to the western Pacific. Similarly, the monsoon trough over northern Australia during the Austral summer limits the trades of the south Pacific to the eastern two-thirds of the basin.

Trade wind inversion

Throughout much of the trade wind zone, subsidence in the subtropical anticyclones produces a persistent temperature inversion. This so-called trade wind inversion (TWI) originates on the eastern sides of the oceans, and steadily increases in height and decreases in strength moving westward and equatorward. Like any temperature inversion, the TWI is a highly stable layer which effectively caps vertical motion from below. This tends to prevent deep convection and makes thunderstorm development rather rare. The inversion also isolates the air above it from the oceanic moisture source. This upper air has been desiccated by its descent in the downward limb of the Hadley cell, and therefore air above the TWI is generally very arid. Despite inhibiting vertical exchange in the mean, Riehl (1979) has shown that the TWI is not a material boundary. There are exchanges of air across the boundary, which certainly contributes to the downstream weakening of the TWI. The TWI does not represent the upper limit of the trades, but rather separates well-mixed, humid marine air from an arid upper air. Riehl (1979) defines four layers in the trade flow, going from the surface upward: subcloud layer, cloud layer, inversion layer, and free atmosphere.

Many of the important characteristics of the TWI have been known since the Atlantic Meteor Expedition of 1925–1927, which focused on observations within the North and South Atlantic trade winds zones. In general, the strong subsidence and cold ocean currents along the eastern margins of the oceans favor the maintenance of an inversion at 500 m altitude or lower. As air flowing out of this zone moves westward and equatorward, convection in subcloud and cloud layers deepens. As a result the height of the inversion increases. In the North Pacific, for example, the inversion rises from less than 500 m at the California coast to over 2000 m at Hawaii. At the same time the strength of the TWI decreases with distance downstream. The temperature difference from the bottom to the top of the inversion layer is a good measure of its strength. An 8–10° temperature difference at the California coast weakens to about 3°C over Hawaii.

Climate of the trade wind zone

The climate of the trade wind zone is remarkably consistent, in large part due to the persistence of the trade winds. In Hawaii, trades occur approximately 90% of the time during summer, and 50% of the time during winter (Blumentock and Price, 1967). The consistent direction and intensity of the winds, and their long trajectory over ocean, are responsible for Hawaii's agreeable climate (Giambellucca and Schroeder, 1998). The TWI strongly affects weather in Hawaii and other similarly positioned oceanic island groups. The inversion limits rainfall in the region near Hawaii to around 700 mm per year. Because of the persistent orographic lifting of trade winds on the windward slopes, some spots in Hawaii receive spectacular amounts. Mount Waialeale on Kauai averages around 11 m of rainfall annually (Giambellucca et al., 1986), making it a candidate for the wettest spot on earth. The TWI, however, inhibits upward flow beyond about 2000 m. Therefore, the upper slopes of Hawaii's highest mountains, including Haleakala on Maui, and Mauna Loa and Mauna Kea on Hawaii Island, are quite dry. This juxtaposition of persistent orographic lift and the capping effect of the TWI give rise to incredibly steep gradients in rainfall and other climatic variables, along Hawaii's upper mountain slopes.

TREE-RING ANALYSIS

Well-defined annual-growth rings can be observed in the wood (xylem) from many species of temperate forest trees throughout the world. The rings are formed by cell division of the cambium, which lies along the inner portion of the surrounding bark (Figure T25). In certain circumstances these growth rings contain useful information about varying environmental conditions affecting their growth. Dendroclimatology involves the study and use of these growth rings to reconstruct past variations in climate.

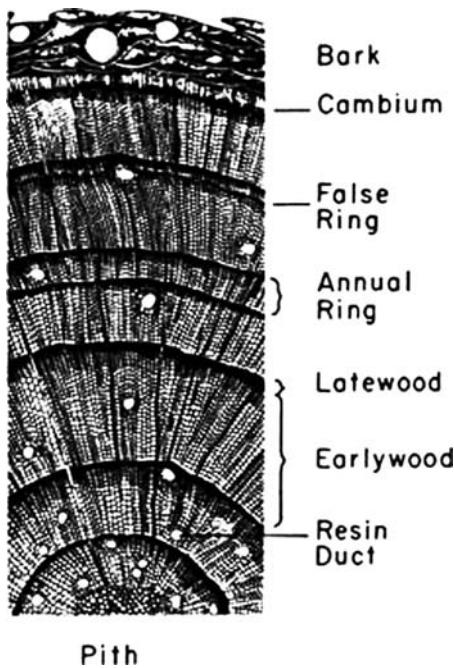

Figure T25 Drawing of cell structure along a cross-section of a young conifer stem. The earlywood consists of large and relatively thin-walled cells and the latewood is composed of small, thick-walled cells. Variations in cell size and thickness within the ring can produce false rings in either earlywood or latewood. The large circular openings are resin ducts, which form a complex system of tubes throughout a coniferous tree. Note the variability in width from one ring to the next and in the proportion of earlywood versus latewood, which can be used for crossdating and reconstruction of climate.

Growth-ring formation

Initiation of cell division generally occurs throughout the cambium in the spring. The newly formed xylem cells lying inside the cambium expand into large thin-walled cells. In conifers this earlywood appears as light-colored tissue on the inside of the annual ring (Figure T25). As the season progresses, the growth slows down, the latewood cells do not expand as much as those in the earlywood and the cell walls become thicker. This forms denser, darker wood in conifers with the last-formed cells of the year usually becoming the smallest with the thickest walls. The abrupt change in color and structure between these cells and the lighter-colored earlywood of the next ring forms a distinct boundary between annual rings.

Sometimes the growing season is interrupted and more than one growth layer is apparent within the annual ring. These are referred to as intra-annual growth bands, multiple rings, or false rings (Figure T25). The outer margins of false rings are usually, but not always, less distinct than the outer margins of true annual rings. At other times the environment can be so harsh that no ring is formed in certain portions of the tree. These are called locally absent or missing rings and can usually be found elsewhere in the tree or in other nearby trees. Because of false and missing rings, the annual growth layers and thus the age of the tree cannot be reliably determined from simple counting of rings. This information must be obtained by using a dendrochronological procedure called *crossdating*.

Dendrochronology

The early Greeks were the first to note that trees form more or less annual layers and that the widths of these layers can vary as a function of local environmental conditions. Two French naturalists, Duhamel and Buffon, noted in 1737 that a frost-damaged layer occurred 20 rings in from the bark on each of several newly felled trees. A.C. Twining in 1827 was the first to grasp the possible use of tree-ring matching to establish the dates of the rings. According to Russian workers, in 1892 F.N. Shvedov was not only the first to crossdate tree rings but also the first to use variations in ring structure to infer the past history of climate.

A.E. Douglass is generally recognized as the first American worker to utilize crossdating in a systematic fashion. He is the acknowledged founder of the discipline of dendrochronology, which can be succinctly defined as the field of *systematic dating* of tree rings and their application to environmental problems, the dating of structures, or past events. He attracted international attention when he dendrochronologically dated the prehistoric pueblo dwellings of the southwestern United States (Douglass, 1936).

The crossdating procedure utilizes similarities in ring width or other morphological ring features that vary as a function of time (Figure T26). The pattern of variation is similar among trees growing throughout the same region for the same time period, presumably due to variations in macroclimatic factors affecting the trees' growing conditions. The crossdating procedure is described most fully by Stokes and Smiley (1996) and is summarized by Fritts (1976).

Crossdating includes the comparison of specimens by: (1) visual and statistical matching of features, such as width or earlywood-latewood color and thickness, which vary from one ring to the next; (2) examining these features for the presence or absence of synchrony over time; (3) identifying any inconsistent features not coinciding on all available specimens; (4) interpreting from the differences in ring structure what was the most probable cause of each discrepancy (such as failure of cambial initiation causing missing rings or interruption of cambial activity causing multiple growth layers); (5) establishing the validity of the interpretation by finding consistent structural features in the rings of different trees; and (6) finally arriving at a corrected chronological sequence that is consistent on all dated annual rings.

There is a lower limit in the number of rings (years) that must overlap in time and the number of trees (samples) necessary to establish accurate dating. Many workers would like at least 100 years of overlap and samples from ten or more trees, depending on the difficulty encountered in dating the ring sequences from the site. The majority of dendroclimatic studies incorporate two radii from at least 20 trees of the same species that are affected by similar climatic conditions.

If crossdating is done properly and carefully, with a sufficient number of suitable specimens, the troublesome ring features causing possible counting errors can be identified and corrected, and no further discrepancies will be detected no matter how many additional tree-ring materials are dated against the chronology. Literally hundreds of independently dated chronologies from southwestern North America follow the same general ring-width pattern. If there were even one error in these well-dated chronologies, the same dating error would have to have occurred in all samples of the southwestern collections, which, of course, is extremely unlikely. Because of the high accuracy of the crossdating methods, a tree-ring date can be

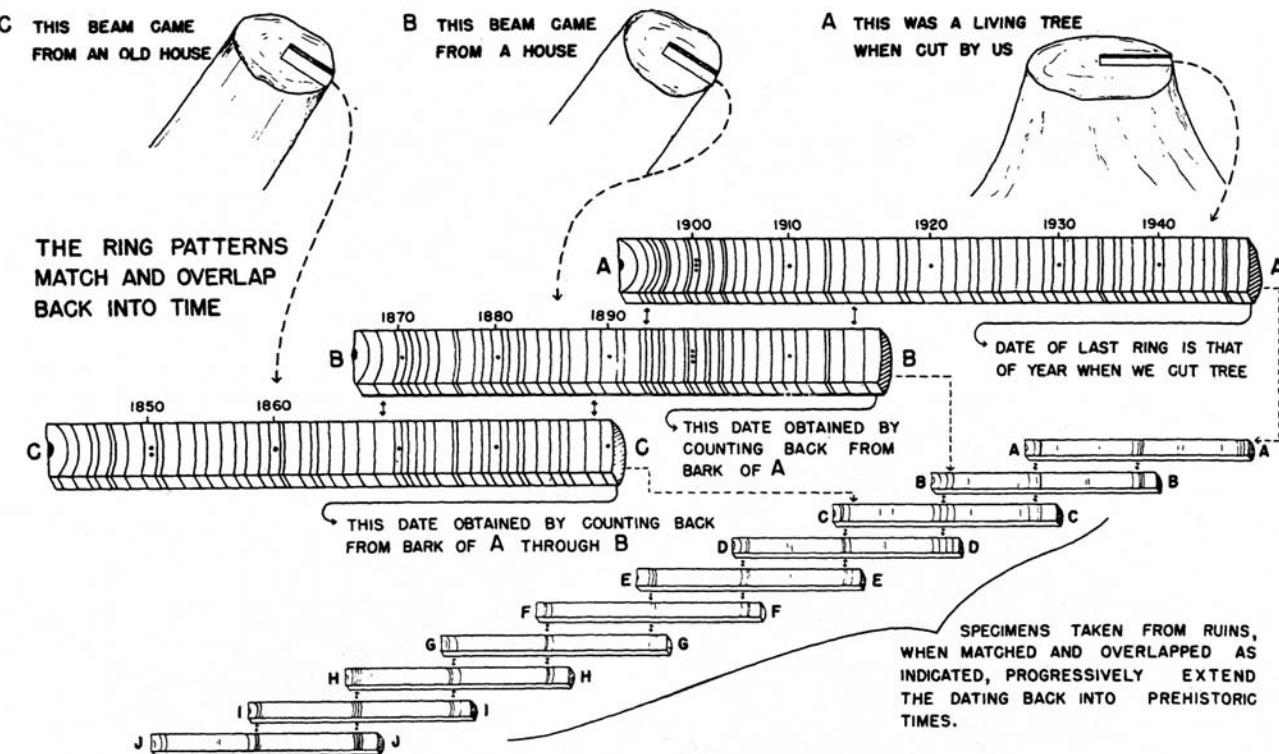

Figure T26 Crossdating is the basic principle of dendrochronology that provides annual resolution and the ability to date samples from dead wood. (Reprinted with permission from the University of Arizona Press, modified from Stokes and Smiley, 1996.)

considered for all intents and purposes absolute (Douglass, 1946; LaMarche and Harlan, 1973; Baillie, 1982). The certainty of crossdating allows one to average the measurements of the dated growth rings from many trees to obtain an important indicator of the relative effect of yearly climate on the mean yearly growth of the sampled trees.

However, tree-ring dating cannot be applied to all wood materials. Some tree species, particularly those from the tropics or subtropics, may have rings too poorly defined for crossdating. Other species may have distinct growth rings, but their ring features do not exhibit sufficient variation in common among trees to enable one to crossdate them. Still others have so many complications with both false and missing rings that synchrony of ring features is not certain, and thus dating is impossible. In addition, there are some trees that are too short-lived and have an insufficient number of rings overlapping in time to allow accurate crossdating. Therefore, in the past, dendrochronology has been applied to a restricted number of species and sites in temperate regions, but increasingly more species are being examined for their dendrochronological potential and researchers are finding unique sites in the tropics with trees that produce annual growth. Gymnosperms include the most favored species for dendrochronological investigation because they generally have the least ambiguous ring structure and most datable ring characteristics.

Dendroclimatology is considered a subfield of dendrochronology because dendrochronological procedures must be applied to date the ring materials. This assures that measurements such as ring widths from different trees of the same species are properly placed in time and can safely be averaged

to produce a single chronology for the sampled site. This chronology is the time series that is used to reconstruct past climatic variations.

Tree-ring parameters reflecting variations in climate

Until recently dendroclimatic studies were largely confined to analyses of ring widths. Sometimes earlywood and latewood widths were considered, but the exact boundary between the two layers within the same ring was difficult to measure optically. There are new developments that now make these and other ring measurements practical. Wood density changes revealed by optical film density after exposure of the wood to X-rays provide information on intraseasonal climatic variations not contained in simple ring-width measurements. Also a specific density value can be chosen and used to determine the exact position of the earlywood–latewood boundary within each ring.

The area occupied by vessels in the ring can be measured optically and related to temperature and precipitation. Isotopes such as ^{18}O , deuterium, and ^{13}C in the cellulose of the ring also appear to contain a signal of past climatic conditions (Long, 1982; Wigley, 1982; Leavitt, 2002). For example, Feng and Epstein (1996) found a worldwide warming trend over the past 100 years using deuterium isotopes.

Some of these parameters offer considerably more promise than others, especially maximum wood density of the ring (Briffa et al., 1992; D'Arrigo et al., 1992; Luckman et al., 1997). Briffa et al., (1992) used a network of densitometric data from tree rings to reconstruct summer temperature across western North America. They found in their particular case that

maximum latewood density was more adept at reconstructing summer temperature than was ring width.

For many of the less promising procedures the relationships to climatic variables are still not well understood. At present most of them involve more costly equipment and time-consuming procedures than the collection and processing of ring widths. However, these new parameters provide new options for dendroclimatic research. They can furnish considerably more information than ring-width analysis, especially for species on moist temperate sites where the ring widths are more complacent and contain less variation related to climatic conditions than growth rings from stressed trees in the American southwest.

The growth response to climate

The climatic signal in a tree-ring record arises from a variety of limiting environmental conditions occurring throughout the calendar year. The most obvious are those conditions affecting the rate and duration of cambial cell division during the growing period. Trees growing at high altitudes, near their polar limits, or on very arid sites may have very short growing seasons lasting for only a few weeks. Under less limiting conditions the cambium can remain active longer and growth can sometimes continue into early fall.

At other times in the year the growing tissue usually remains dormant. However, many plant processes such as photosynthesis, food storage and consumption, respiration, water uptake and loss, root growth, and ion absorption continue even through midwinter (Fritts, 1976). Whenever environmental conditions limit these processes, conditions may change within the plant that can alter the rate and timing of cambial division, the amount of cell enlargement, and cell-wall thickness in one or more of the growing seasons that follow.

The ring widths of trees growing on predominantly arid sites, for example, can be limited chiefly by conditions linked to low precipitation and high temperatures during the growing season, but at certain times during the year other factors such as low temperatures, excess moisture, heavy snow pack, and cloud cover can be limiting. Low temperatures can markedly reduce the ring widths in trees growing near their upper altitudinal limits, but low moisture and high wind also can be important limiting factors.

Different factors become limiting at different times during the year. There are also differences in response attributable to species, topography of the site, altitude, and a variety of other characteristics such as soil drainage, soil color, mineral nutrition, or shading from neighboring trees (Fritts, 1976). Any of these, as well as other factors, can modify the action of macroclimatic factors on the microenvironments of the trees and ultimately affect the tree's growth.

Modeling the climate response

Some dendroclimatological studies, especially the earlier works, assume a simple linear climate response developed in an *a-priori* fashion or inferred from a simple correlation analysis. The appropriate climatic conditions were then deduced from the associated variations in the past growth record (Schulman, 1956; Fritts, 1976). As dendroclimatological technology advanced, one type of multivariate technique called a response function (Fritts et al., 1971; Fritts, 1974) was developed to determine the overall tree-ring response to climatic factors. The generalized results of the response function were then used to infer the climatic conditions indicated by the tree-ring record.

We now know that it usually is too simplistic to assume growth is a linear response to a single climatic factor such as precipitation or temperature, even for trees growing in extremely arid or cold sites. On the other hand, the physiological processes behind the tree-growth and climate linkages are too poorly understood to construct equations for a mechanistic growth model. The only feasible approach at present is to model ring width as a lagging and autoregressive, as well as direct, response to a climate input (Figure T27) of factors that can vary throughout the year. Then one can apply a multivariate statistical model (Figure T28) to calibrate the ring-width variation with all significantly correlated climatic factors and apply calibration equations to past tree growth to reconstruct past climate.

Climate factors correlated with ring width

The most common climatic variables that have been considered are those that can be reasonably associated with environmental conditions that can limit processes affecting tree growth. Monthly mean, mean maximum or mean minimum temperature, or total monthly precipitation have been correlated or calibrated most often with ring width simply because long homogeneous records of these variables are readily available from weather stations near the tree sites. Relative humidity, sunshine, snowfall, dates of freezing as well as first and last frost, and other related measurements have also been considered (Fritts, 1976). However, the records of these types of measurements frequently are too short and are less commonly available from stations near the tree sites.

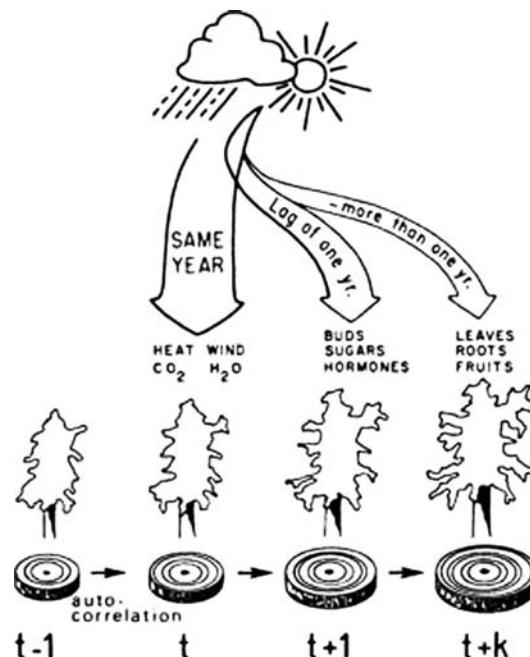

Figure T27 Climate of a given year t affects ring width for the same year through heat, wind, carbon dioxide, water, and other factors that ultimately impinge on tree growth. However, climate can also affect the width of rings formed in succeeding years, $t + 1$ up to $t + k$, through its effects on buds, sugar, hormones, and the amounts of leaves, roots, and fruits that in turn can influence growth. The width of the ring in year $t - 1$ is also statistically related to the ring width in year t . This can be modeled as autocorrelation.

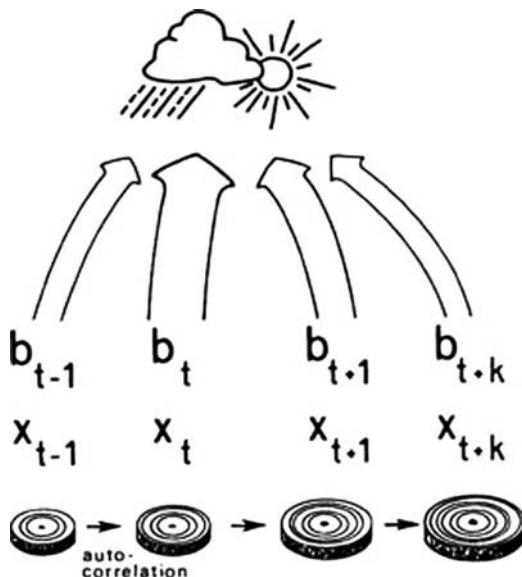

Figure T28 A multivariate transfer function can be applied to the growth model in Figure T27 to calibrate measurements of growth with measurements of climatic factors. Partial regression coefficients, or scaling factors, b_i are obtained, which are multiplied by the corresponding ring-width indices, x_i , and their products added to obtain an estimate or the calibrated variable of year t climate. The scaling factors are then applied to ring-width indices for early time periods to reconstruct the corresponding past climate. The scaling factor b_{t-1} is included in the model to correct the causal linkages for any autocorrelated effects.

There are some types of climatic variables such as sea-level pressure and sea-surface temperature that are known not to impinge directly on any physiological processes important to tree growth but that have been found to be significantly correlated with ring width. Apparently these variables are so closely linked with other climatic variables such as cloud cover, light levels, soil moisture, temperature, and wind, which all can influence physiological conditions affecting tree growth (Brubaker, 1980) that the linked variable can be calibrated with and reliably reconstructed from ring widths (Fritts, 1976; D'Arrigo et al., 1993).

Two or more variables such as temperature and precipitation are sometimes combined into a single drought index that appears better related to growth than either temperature or precipitation alone. Palmer Drought Severity Index (PDSI; Palmer, 1965) is the most frequently used composite variable that seems to affect tree growth (Meko et al., 1993; Cook et al., 1999; Stahle et al., 2000).

Measured stream flow can be calibrated with and reconstructed from tree growth because it is correlated with watershed soil moisture, which affects growth (Stockton and Jacoby, 1976; Stockton et al., 1985; Holmes et al., 1982). Fluctuating lake levels, affecting soil moisture and soil oxygen available to trees along the shore, have been successfully calibrated with ring width. The recorded annual catch of albacore tuna north of San Francisco has also been calibrated with and reconstructed from tree growth in western North America (Clark et al., 1975). This was possible because the schools of fish respond to sea-surface temperatures, which are in turn linked with the variations in the prevailing winds, surface pressure, and movement

of storms inland, all of which influence the climatic factors impinging on tree growth.

El Niño and the Southern Oscillation (ENSO) affect tree growth in many places around the world through climatic teleconnections. Because of the annual resolution and millennial length of chronologies, tree rings are an excellent tool for reconstructing past ENSO events. Sites in the southwestern United States that are sensitive to winter precipitation have correlated significantly with ENSO events (D'Arrigo and Jacoby, 1991). This association is so robust that southwestern fire occurrence decreases following strong El Niño events (Swetnam and Betancourt, 1990; Grissino-Mayer and Swetnam, 2000).

Douglass was the first to propose that sunspots may be recorded in tree rings through a climatic influence. Since that time many researchers have pursued and identified significant association between the sunspot cycle (11 years) or the double sunspot cycle (22 years) and tree-ring width (Mitchell et al., 1979; Murphy et al., 1996; Cook et al., 1997). Although others have not found significant sunspot cycles recorded in trees rings, which has led to some discussion in the literature (LaMarche and Fritts, 1972; Briffa, 1994).

Chronology development

Modern dendroclimatologists have learned not to use ring measurements from a single tree to deduce past variations in climate because the climatic signal in a single tree's ring-width variance is too small. The measurements can be corrected for nonclimatic influences, such as changes in tree age, by indexing procedures. The indices for many trees from a given locale can be average together to form a mean chronology for the site. The more-or-less random nonclimatic noise found in different trees, including any measurement errors, cancel one another so the yearly mean index values have a much-reduced variance. The climatic signal represented by the variance common in all trees, on the other hand, is not reduced. Thus in the averaging process the ratio of signal to noise is enhanced. Using these techniques, chronologies can be developed that are responding to forcing factors at different spatial scales. By grouping trees together into stand chronologies, then aggregating stands into watershed-level chronologies, and finally combining watershed-level chronologies into regional chronologies, dendrochronologists can explore these forcing factors at multiple spatial scales (Figure T29; Swetnam and Baisan, 1996).

Other dendroclimatic practices and procedures have been developed to facilitate data acquisition and assure that the common signal is largely attributable to macroclimatic linkages. First, a site is carefully selected to maximize the amount of climatic variance in the sampled ring widths. The more climate has been the dominant limiting factor, the greater the common variation in the ring-width variable due to the climatic signal, and the smaller the number of cores needed to obtain a given ratio of signal-to-noise. Then, so as not to harm the living tree, cylinders of wood about 4–5 mm in diameter are extracted from two or more sides of at least 10 trees growing on the same kind of site. Trees are selected that show no evidence of major nonclimatic influences such as fire, insect damage, or forest cutting.

In the laboratory the samples are mounted and the cross-section surface prepared so that the rings are clearly visible. The ring structures in the different cores are carefully crossdated to determine the exact year of ring formation (Stokes and Smiley, 1996). This technique uses the pattern of wide and narrow rings to visually determine where two samples of wood date against

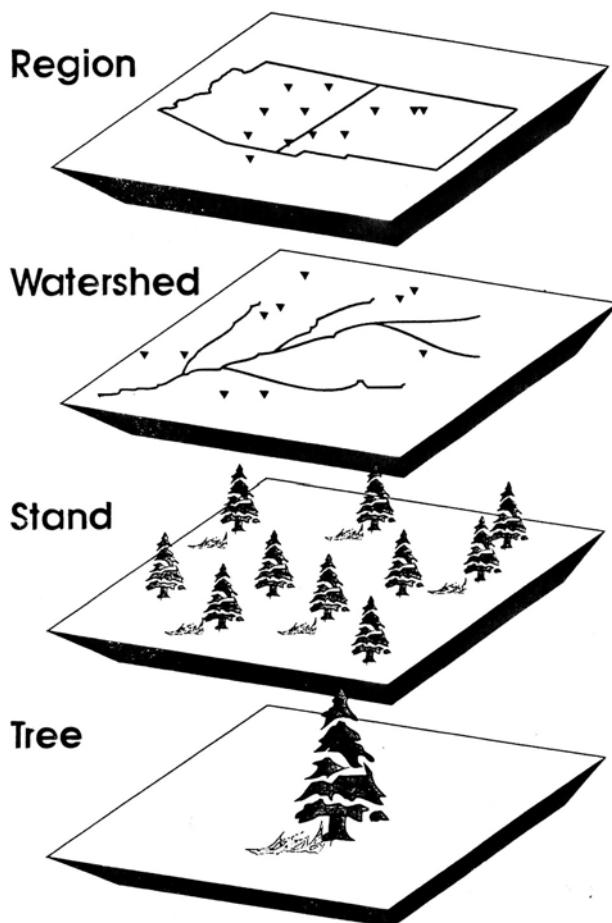

Figure T29 By collecting samples over a broad area and aggregating those samples based on topographic breaks or air mass boundaries, we can reconstruct environmental variables at multiple spatial scales. (Reprinted with permission from USDA Forest Service Swetnam and Baisan 1996.)

each other. This is the key principle of dendrochronology and provides the annual resolution needed for comparison to climatic data. Characteristics such as ring width, earlywood and latewood width, or wood density may be used for dating purposes. These characteristics are often measured and computer programs are used to provide quality control checks of the dating accuracy (Holmes, 1983) and the precision of measurement (Fritts, 1976).

As was stated earlier, many measurement parameters have substantial trends over time associated with the changing geometry of the ring, increasing tree age, and slowly changing features of the tree's immediate environment. These very low-frequency trends and changes in growth can be approximated by an exponential or polynomial curve, cubic spline, or some other similar function. In the case of ring-width measurements, an appropriate curve is fitted to the data for each core by least-squares techniques, and the ring width for each year is divided by the value from the fitted curve for that year to obtain a relative index of growth (Fritts, 1976; Graybill, 1982). This procedure is called standardization. A slightly different procedure is sometimes needed to standardize other types of measurements

and recently Cook (1985) has developed a new procedure using time-series modeling techniques.

Since the changes associated with the growth function itself can contribute to a large percentage of the ring-width variance, the removal of this function by standardization enhances the climatic signal remaining in the indexed measurements. Some long-term climatic trends in growth may also be removed by this standardization procedure.

Both the mean and variance of the standardized indices for most ring-width time-series are relatively homogeneous over time. In a sample of chronologies from arid-site trees (Fritts and Shatz, 1975), roughly 90% approximated a normal distribution. However, the autocorrelation in standardized tree-ring indices is usually higher than it is for annual averages of most instrumental climatic measurements.

The signal-to-noise ratio in a typical sample of ring-width indices from a single core ranges from 0.1 to somewhat over 1.0. When the indexed values from all cores and trees collected and dated for a site are averaged to obtain a site chronology, the signal-to-noise ratio is increased. Arid-site chronologies developed from 10 or more trees, two cores per tree, typically have signal-to-noise ratios of 15 or higher (Graybill, 1982).

Generally the data are combined only from trees of one species growing on one site type because the measurements from these trees are likely to portray a consistent growth response. The chronology from such a group of trees will provide the clearest information on climate. If data are averaged from trees of different species or from sites with different characteristics, the chronology is more likely to contain a mixture of diverse climatic responses.

Climate also varies over space. Thus a reasonable sampling strategy is to treat collections from different localities, species, and site types as different chronologies in order to maintain the clearest tree-ring response. Instead of averaging the data from different chronologies, the chronologies can be entered into an array of m different chronologies of n years in length, each representing a particular species, type of site, and geographic area (Fritts and Shatz, 1975). The m elements of the array can be analyzed to extract the dendroclimatic information pertinent to each study of climate. Other ring parameters such as maximum and minimum wood density can be measured, standardized, and entered as additional chronologies to increase the size of the array and its information content.

There will be a variety of climatic signals in such a chronology array, but the different kinds of information can be factored out and used along with the information that is in common to reconstruct seasonal, annual, and decade-long variations in temperature, precipitation, drought, atmospheric pressure, and other climatic parameters. Some of the calibration procedures that can be used to accomplish this factoring will now be discussed.

Calibration

The complexities of autocorrelation and diversity in a tree-ring response can be approximated by a linear multiple regression model of m predictor variables applied at k lags to allow for m times k possible growth-climate linkages. The sign and magnitude of the multiple regression coefficients express the direction and magnitude of each linkage. A regression using empirical orthogonal functions (EOF) of monthly climatic variables as predictors and ring-width indices as predictands provides the equation for a response function. However, to interpret the

equation the partial regression coefficients associated with the EOF must be transformed into coefficients of the climatic variable space by multiplying them with the eigenvectors of climate (Fritts et al., 1971; Fritts, 1976).

If variables of tree growth are the statistical predictors and a variable of climate is the predictand, the multiple regression equation becomes a transfer function that transfers the tree-ring index data into estimates of climate (see Figure T29). Multivariate transfer functions of varying complexity can be used to sort out and demodulate different tree-growth and climate linkages. Unique coefficients are calculated for each variable, season, lag, and chronology. Autoregressive moving-average time-series analyses (Meko, 1981; Cook, 1985) can also be used to identify and correct each chronology for the important autoregressive and moving-average elements. The residual from the fitted model from the time-series analysis approximates a simplified nonlagging signal of the limiting conditions of climate. This simplification appears to clarify some of the higher frequency variations in reconstructions of climate.

Verification

It is possible that large and complex transfer functions provide statistically significant calibration statistics but fail when they are applied to independent data (data not used for calibration). Although the reliability of regression estimates almost always declines for such data, it is important to assess the magnitude of the decline and to test whether the independent reconstructions are likely to have arisen by chance.

Climatic data or other related information outside the calibration period can be set aside for this purpose. Figure T30 shows an example where the expected decline in the association

between the instrumental (real) data and the reconstructions from the independent compared to the dependent record is evident from the statistics. However, the first two statistics that can be tested (the correlation and the correlation of the first differences) are significantly different from random expectation ($p \leq 0.05$) for both time periods. The reduction of error terms greater than zero indicates meaningful climatic information has been reconstructed. Once the reconstructions are validated, as in the above example, the statistics from different calibration models can be compared to select the transfer function providing the most reliable climatic estimates.

Where suitable data exist, such reconstructions should be further validated for time periods outside both the calibration and verification periods. Such tests can use information from other sources such as historical data, observations on phenology, dates of lake freezing (Gordon et al., 1985) or climate reconstructions from independent proxy sources (Lough and Fritts, 1985), including independent tree-ring data. These indirect sources of paleoclimatic information must reflect climate in a similar way as the tree-ring data used in the reconstruction, have a time resolution comparable to the tree-ring data, and have a sufficiently strong signal of the reconstructed climatic variable to make an effective comparison possible. However, the inequalities between different data sources are often so great, or the errors so large in the datasets compared, that this second type of validation test can be statistically insignificant even when the climatic reconstruction is correct. For this reason, variables tightly coupled to the particular climatic variable in question and with little inherent error of their own provide the best validity checks. Much work remains to be done on finding suitable data and developing the optimum techniques for this second type of validation (see Wigley et al., 1984).

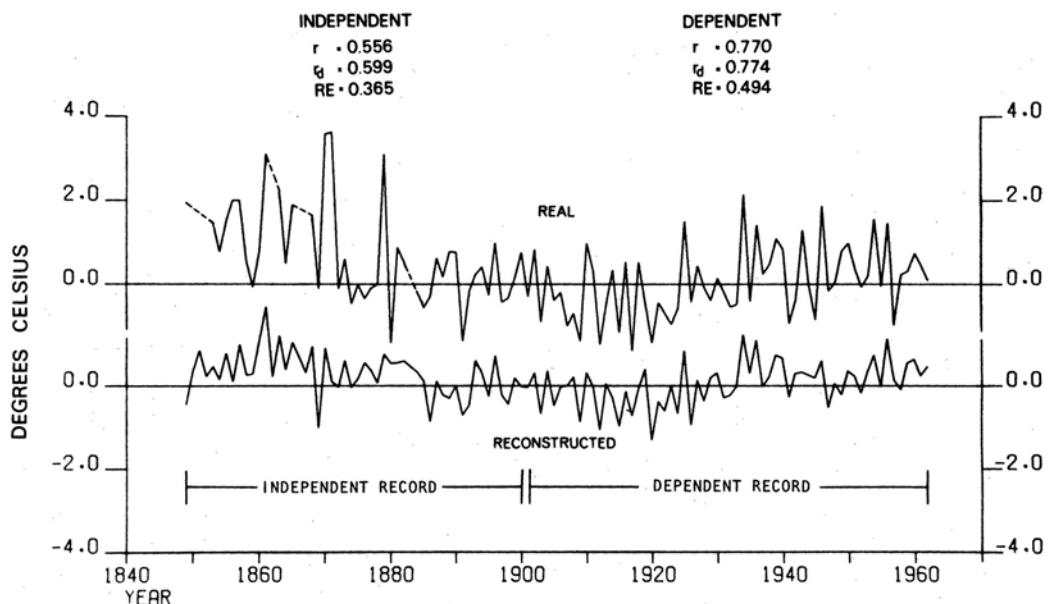

Figure T30 The mean spring temperature (real) and estimated (reconstructed) data for Santa Fe, New Mexico, plotted for the dependent record used for calibration and the independent record used for verification. Three of the six statistics of association used for verification are also shown: r = the correlation coefficient, r_d = the correlation coefficient for the first differences, and RE = the reduction of error. Temperatures and their estimates are expressed as departures from the 1901–1970 mean instrumented value.

Spatial climate reconstruction strategy

The simplest strategy is to calibrate and reconstruct one climatic record from one tree-ring chronology. However, the signal of climate in a single chronology is often too weak to obtain a reliable reconstruction. If an array of chronologies can be properly calibrated, the collective signal can be utilized while the influences of the more or less random chronology errors are averaged out. This leads to spatial reconstructions of climate on the scale of a single continent.

It has been reported (Fritts, 1982) that in some cases it may be better to calibrate climatic data for separate seasons rather than using larger intervals of time because of differences in the seasonal growth responses. Canonical regression analysis (Blasing, 1978) can be used to estimate more than one predictand. This technique has been extensively used to reconstruct the climate over different seasons and over spatial arrays of instrumented data using spatial arrays of tree-ring chronologies (Fritts et al., 1979; Fritts and Lough, 1985). Different lags in the climate response can be modeled by including tree-ring datasets at different lags as predictors and the autoregressive elements can be assessed or removed beforehand by applying time-series modeling.

Fritts (1965) first applied networks of tree-ring chronologies in climatology to reconstruct a spatial array of climate. Since that time many researchers have used a spatial array of tree-ring sites to reconstruct climate over large areas (D'Arrigo and Jacoby, 1991; Meko et al., 1993; Stahle et al. 2000). This technique has proved to be more robust than single-site climate reconstructions because the spatial continuity of the sites helps to strengthen the broad-scale climate signal (Meko et al., 1993). Stahle et al. (2000) also used a gridded network of 154 points covering a $2^\circ \times 3^\circ$ latitude/longitude grid to reconstruct drought across North America from AD 1500 to AD 1978. This work was able to put the 1950s drought and 1930s dust bowl into the perspective of the past 500 years. They found that a sixteenth-century drought was by far the most severe drought during that time period and may have contributed to the fall of early settlements such as the Jamestown and Roanoke colonies in the southeastern United States (Stahle et al., 2000).

The first high-quality grids of arid-site tree-ring chronologies were assembled for western North America by Schulman (1956), Fritts (1965), Fritts and Shatz (1975), Stockton et al. and Meko (1975), Brubaker (1982), and Stockton et al. (1985). A North American grid of high-altitude chronologies from bristlecone pine was published by LaMarche (1974). Chronology information from the eastern United States was

assembled first by Dewitt and Ames (1978) and then updated by Cook (1982). Chronology information for the American Arctic was first summarized in a systematic way by Cropper and Fritts (1981) and then updated by Jacoby (1982), Brubaker and Cook (1983), and Stockton et al. (1985).

Although the reliability of the climatic estimates generally declines with increasing distance from the tree sites, the estimates of variables such as atmospheric pressure and air temperature may remain relatively reliable at distances of 1000 km or more beyond the area covered by the tree sites (Fritts, 1991). However, the variances of the integrated climatic estimates are substantially lower than the variances of the unsmoothed instrumented data with which they were calibrated and verified, and they largely reflect conditions of climate averaged over long time scales and large regions.

Different strategies may be needed to obtain the most reliable climatic estimates over denser grids covering smaller areas in other regions of the world. In addition, the reliability of estimates will most certainly improve as tree-ring chronologies for new areas, species, and tree-ring parameters are added to the existing tree-ring chronology grids.

Multimillennial-length climate reconstructions

Over the past few decades of work, tree-ring research has expanded its temporal as well as spatial coverage. The efforts of many dendrochronologists from around the world are starting to produce multimillennial-length chronologies (Table T3). These chronologies enable us to examine today's climate and climate change from the perspective of over 2000 years of climatic history.

The long chronologies have aided our understanding of climatic trends. Mann et al. (1999) found a twentieth-century warming trend in the northern hemisphere that was anomalous over the past millennium, and were able to corroborate that the 1990s was the warmest decade and that 1998 was the warmest year in the past millennium. A distinctive warming trend was also reconstructed in New Zealand, demonstrating increased temperatures since the 1950s (D'Arrigo et al., 1998).

Worldwide interest

The first international workshop on dendroclimatology, held in 1974 at the University of Arizona, Tucson, marked the beginning of international interest and cooperation in dendroclimatology. It was convened for the purpose of sharing the new

Table T3 Multimillennial tree-ring chronologies

technology, which at that time had been largely developed at the Laboratory of Tree-Ring Research (Fritts, 1976). This was followed by the second international workshop on global dendroclimatology, held in July 1980 at the University of East Anglia, Norwich, United Kingdom. Workers from a variety of countries described new techniques developed at their laboratories, and there was much debate on the strengths, weaknesses, and suitability of some standard procedures used in dendroclimatology. Progress in the collection of new chronologies was reviewed and plans were generated for developing both regional and global tree-ring chronology networks. Soviet scientists also have held at least two all-Soviet Union conferences to stimulate similar dendroclimatological work through eastern Europe and central Asia.

These meetings led to international dendrochronology conferences which have provided a forum for the worldwide dendrochronological community to gather and exchange fresh ideas on the science. The first conference was held in Palisades, New York, in 1986 (Jacoby and Hornbeck, 1987); the second in Lund, Sweden in 1990 (Bartholin et al., 1992); then Tucson Arizona in 1994 (Dean et al., 1996); Mendoza, Argentina, in 1998; and the most recent was held in Laval, Canada, in 2002. Along with these conferences there is an International Dendroecological Fieldweek, which has been held in Europe for 19 years, and there is also a North American Dendroecological Fieldweek that is on its thirteenth annual event. These fieldweeks provide an opportunity to novice dendrochronologists and senior researchers to gather for an intensive week-long training session in dendrochronology.

The International Tree-Ring Data Bank (ITRDB) was established in 1974 at the Laboratory of Tree-Ring Research, University of Arizona, Tucson, for preserving all basic tree-ring measurements and the derived chronologies. That databank is now managed by the World Data Center-A (WDC-A) for Paleoclimatology at the National Geophysical Data Center (NGDC) in Boulder, Colorado, which is part of the National Oceanic and Atmospheric Administration (NOAA). The ITRDB now holds nearly 12 000 tree-ring chronologies representing over 150 tree and shrub species (Grissino-Mayer and Fritts, 1997).

Dendrochronologists are greatly expanding the spatial horizons of tree-ring research by examining the potential for dendrochronological research in many areas that were previously underrepresented. New chronologies have been published for the southern hemisphere from Argentina, Chile, New Zealand, Australia, and South Africa. Some of the new collection efforts in Europe have been described by Eckstein (1972, 1982). Over the past two decades tree-ring work has been expanded into tropical regions with relative success (Jacoby, 1989; Worbes, 1995; Stahle, 1999). For more information on dendroclimatology the reader should consult Schulman (1956), Fritts (1976), articles from the *Tree-Ring Research* (formerly the *Tree-Ring Bulletin*), and Hughes et al. (1982).

Climate Variation: Historical
Vegetation and Climate

TROPICAL AND EQUATORIAL CLIMATES

The tropical region of the Earth is generally defined geographically as the area between the Tropic of Cancer, situated at 23.5°N latitude, and the Tropic of Capricorn at 23.5°S. The tropics are also sometimes said to be the latitudes that lie between, and partly include, the subtropical high-pressure regions that are centered on average at about 30–35°N and S latitudes. Tropical climates are most commonly defined as those occurring between the subtropical high-pressure regions (the climatic tropics), although some suggest that tropical climates extend between 35°N and S latitudes. Included within the tropical region is the equatorial zone, which is variably defined but most often stated to be the zone extending 3° of latitude on either side of the equator, although an equatorial climate is generally stated to be the climatic type extending 10–12°N and S of the equator (and occurring on low ground–non-highlands only). Therefore, an equatorial climate is most often noted to be a subtype of the broader category of tropical climate.

More specifically, tropical climates have been defined using several climatic criteria. Supan in 1896 defined regions of tropical climates as those having average annual temperatures

exceeding 68°F (20°C), a value also adopted by Trewartha (1954). Köppen in 1918 used a criterion of all months exceeding an average temperature of 64°F (18°C), which was also adopted by Miller (1931). A classification by Trewartha in 1968 employed 65°F (18.3°C) for the average of the coolest month. Figure T31 shows the location of the 18°C isotherm for the average temperature of the coolest month. Thus the tropical and equatorial climates cover approximately half of the Earth's surface.

General characteristics

Temperatures

Tropical climates, in addition to having all months with average temperatures above about 64°F (18°C), experience no killing frosts. The terms summer and winter have essentially no meaning in terms of temperature in these climates, and these regions are sometimes described as having no winters. Greeks referred to tropical regions as the Torrid Zone. Another main temperature characteristic of tropical climates is revealed in Figure T31. Average annual temperature range is small, and day–night (diurnal) temperature ranges, although also small, often exceed the average annual range. These characteristics have led to the often-quoted statement that “night is the winter of the tropics”. Temperature range, diurnally and seasonally, is generally least in the equatorial region and increases until the poleward extent of this climatic type is reached. Temperature characteristics of tropical dry climates vary from those stated here, as discussed in the section on semiarid and arid climatic types.

Pressure and wind

As noted, the poleward border of tropical climates is situated generally at the high-pressure zones located at about 30–35°N and S latitudes. Here are located the subtropical anticyclones. Near the equator is the low-pressure zone termed the Intertropical Convergence Zone (ITCZ). This is generally considered to be the region of convergence of the northeast trade winds of the northern hemisphere with the southeast trades that are primarily in the southern hemisphere (Figure T32). However, secondary convergence areas exist, and satellite-derived wind data have confirmed the occurrence of separate northern and southern ITCZ. The northern one is created by the actual convergence of the trades, and migrates north and south of the equator with the seasons and the migration of the solar declination, whereas the southern ITCZ remains in the southern hemisphere and is produced by a

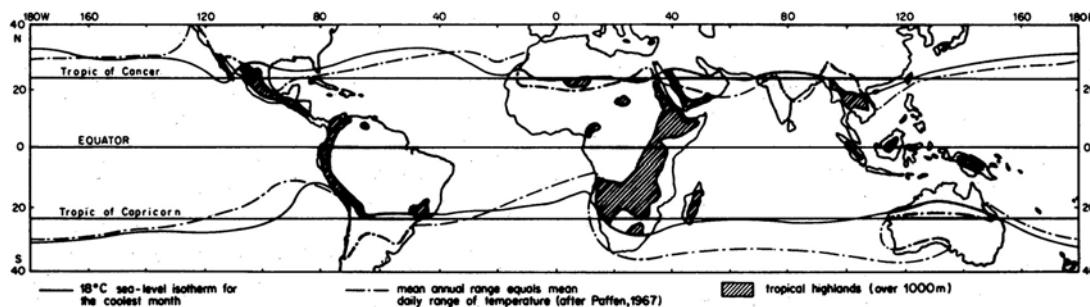

Figure T31 The 18°C sea-level isotherm and annual/daily-range isotherm (Nieuwolt, 1977).

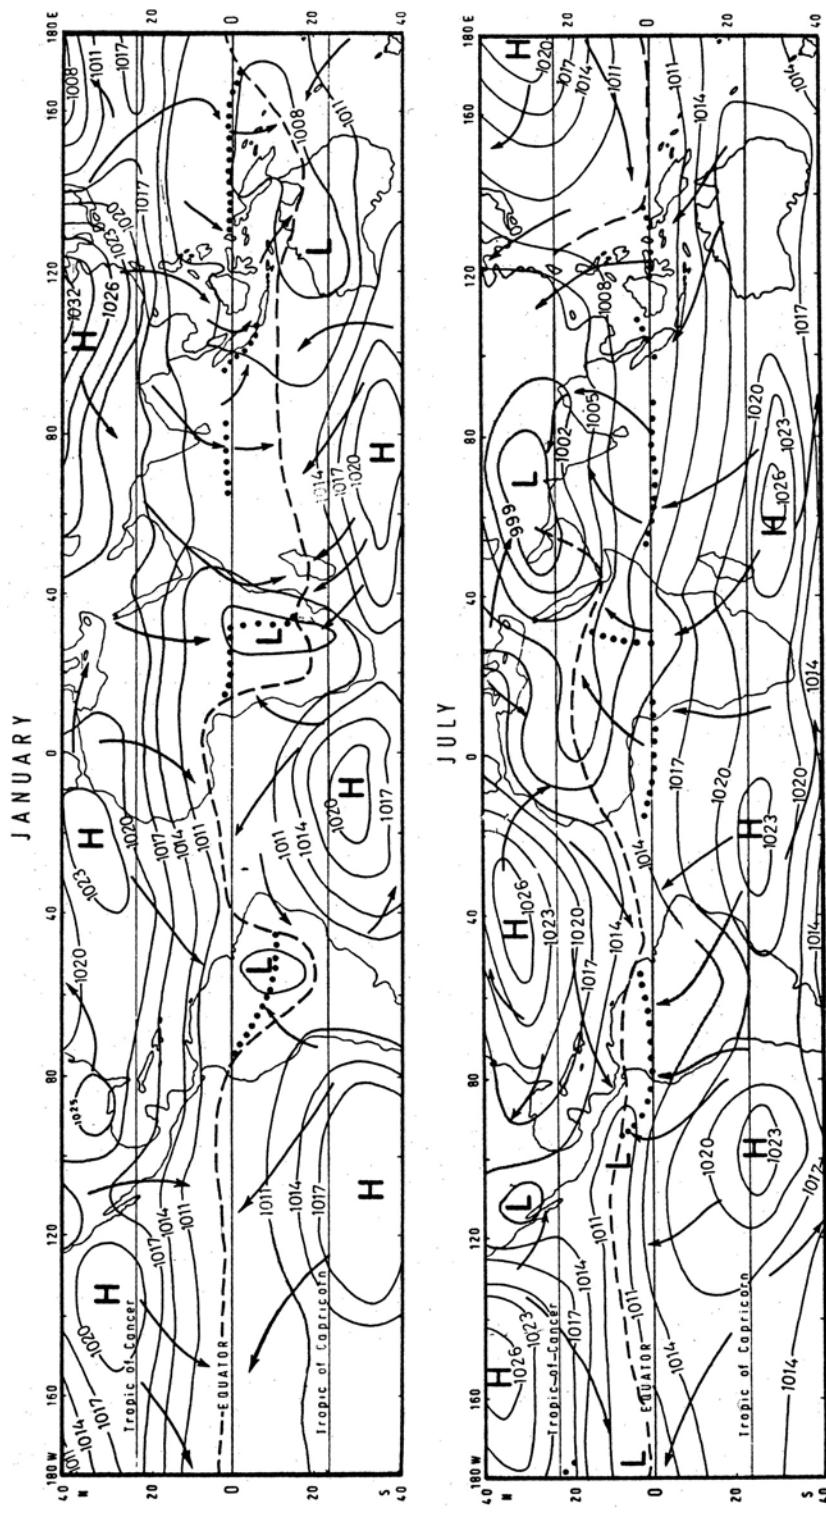

Figure T32 Average sea-level pressure and winds in the tropics. Dashed line is average position of main ITC; dotted lines indicate secondary convergence areas (Nieuwolt, 1977).

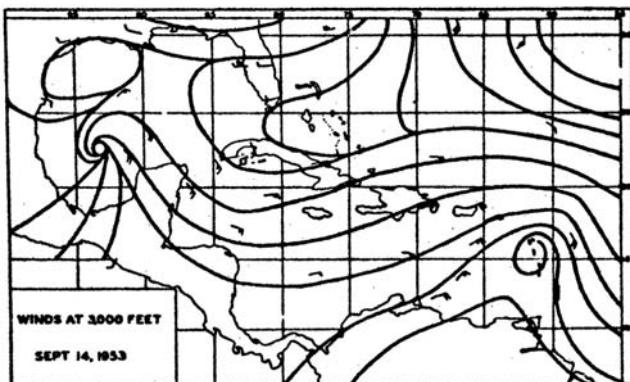

Figure T33 Representative map of streamlines in the Caribbean (after Riehl, 1954).

squeezing effect within the southeast trade winds. The southern ITCZ does not produce the significant cloud cover that is associated with its northern counterpart, nor does it produce a pronounced region of light and variable winds – the doldrums – that is characteristic of the zone of the northern ITCZ.

Pressure gradients within the tropics are relatively small, as is the Coriolis effect, which has a value of zero at the equator. For these reasons detailed pressure analysis is not as useful as wind analysis in the tropics. Instead, streamline analysis is a significant way of delineating tropical atmospheric circulation. A streamline is a line drawn parallel to the wind direction. A regional streamline chart for the Caribbean is shown in Figure T33. The streamlines indicate areas of convergence above which the air is rising and divergence above which air is subsiding. Convergent and divergent regions correspond to cyclonic and anticyclonic flow, respectively.

A surface wind characteristic that occurs with some regularity is the so-called surge of the trades, which is caused by higher-latitude disturbances, in this case Rossby waves. This leads to an acceleration of trade winds for a few days, followed by a slackening. Convergence accompanies the increase in velocity, which produces shear lines, squalls and heavy showers. Other frequent perturbations in the general surface easterly flow in the tropics are easterly waves. These are migratory wave-like disturbances that travel east to west within the trades, generally slower than the regional wind. They consist of a weak pressure trough, and are often characterized by a cluster of thunderstorms in the convergence that usually occurs east of the trough. Many originate over Africa, and usually intensify over the western portions of oceans. Several per week may influence a given location in the Caribbean from May to November.

There are several wind and related oceanic phenomena that occur periodically within the tropics that strongly influence the climate of the tropics and many parts of midlatitudes as well. El Niño/La Niña and the related Southern Oscillation (SO), together given the mnemonic ENSO, have been intensively studied and widely discussed elsewhere. Less discussed, but also an important influence on the climate of tropical regions, is the quasi-biennial oscillation (QBO). (The semiannual oscillation, abbreviated SAO, which is a tropical circulation feature that occurs in a region extending from near the stratopause to the lowermost thermosphere, i.e., primarily within the mesosphere, apparently has a less distinct influence on the surface

climatology of the tropics than the QBO, and will not be discussed here.) The QBO is a periodic oscillation of winds in the equatorial lower stratosphere. Wind here is sometimes from the east and at other times from the west. The easterlies were deduced from movement of atmospheric materials injected into the stratosphere by the eruption of Krakatau (Krakatoa) in 1883. The equatorial stratospheric westerlies were discovered by von Berson, and subsequently called the Berson (Berson's) westerlies, by launching pilot balloons above Lake Victoria in 1908. Research in the early 1960s revealed these opposite-blown winds to be the two phases of the QBO. The transition from one phase to the other, or period, varies between about 20 and 36 months, mostly 24–30 months, with an average period of 28 months, or approximately 2 years. Thus the equatorial stratospheric winds blow from the east for about 12–15 months and then reverse and blow from the west 12–15 months; another reversal occurs and the winds again blow from the east. Transition time from constant prevailing easterlies or westerlies to the opposite direction is just 2–4 months. Wind reversals occur first at higher levels in the stratosphere and descend to near the tropical tropopause. The cause(s) of the QBO are complex and not precisely known, but vertically propagating atmospheric waves and radiative diabatic cooling have been implicated. The QBO is known to be related to other atmospheric phenomena, such as high-latitude stratospheric circulation and the distribution of ozone in the stratosphere. It has an influence on surface climate, at least in the tropics, and also on the frequency of tropical cyclones.

Trade wind inversion

Riehl (1954) noted that the trade wind inversion is the most important factor about the thermal structure of the oceanic tropical atmosphere. One of the first-known accounts of the phenomenon was by Piazzi-Smyth in August 1856, when he climbed the Peak of Teneriffe in the Canary Islands, and passed from a lower region of rich agricultural slopes into an upper zone of cactus and semi-desert. The height of the base of this temperature inversion varies from about 1300 to 1650 feet (400–500 m) toward the eastern sides of the oceans, closely coinciding with the eastern extremities of the subtropical anticyclones, to about 6550–8200 feet (2000–2500 m) near the western sides and near the equator (Figure T34). However, locally the height varies due to differential surface heating and evaporation, the latter occurring from the surface and from the tops of cumulus clouds. The height of the base of the inversion has been observed to be as low as 165 feet (50 m) in the Atlantic off the coast of Africa. The strength of the inversion also varies: in the northern hemisphere it may be very weak or occasionally absent; it is usually weakest when the height of its base is highest, and vice-versa. The inversion is formed primarily by broad-scale subsidence of air from the eastern ends of the subtropical anticyclones. The subsiding air, often quite dry, is usually prevented from reaching the surface because of a surface layer of moist air. In this way the tropical troposphere is divided into an upper dry layer and a lower moist layer.

The inversion acts as a regulating valve for vertical cloud development within much of the tropics. Below the inversion there is high humidity, a steep lapse rate, and often considerable cumulus cloud cover. Above the inversion humidity values are very low and cumulus clouds seldom develop through the base of the inversion into this drier region. Only at the ITCZ does the

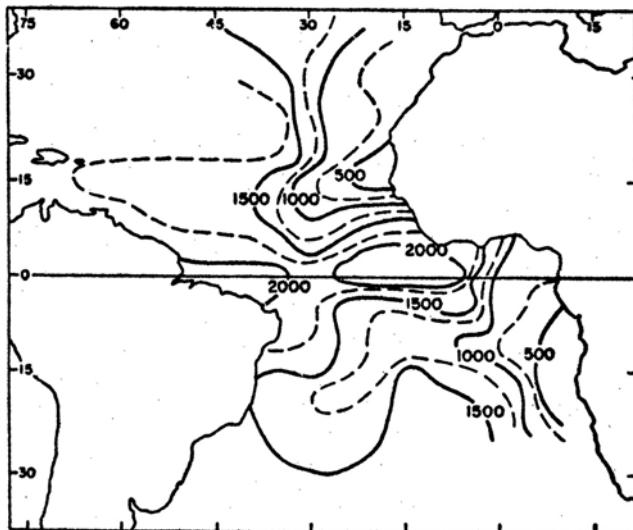

Figure T34 Height (meters) of the base of the trade wind inversion over the Atlantic Ocean.

moist air rise to great heights, accompanied by significant vertical development of cumulus clouds.

Monsoons

The monsoon is a seasonal wind reversal. Although many locations on Earth experience seasonal wind shifts, and the term monsoon has been widely applied, monsoons are best developed in southern and eastern Asia within and near the fringes of the tropics, especially over the Indian Ocean and westernmost Pacific and adjacent land. Figures T35 and T36 show that summer monsoon winds are directed from ocean to land, providing significant precipitation, and that in winter winds are the reverse direction, and usually much drier. The distribution of the major monsoon regions in the world, and a detailed discussion of the causes and characteristics of monsoons, is given in the entry on monsoon climates.

Climatic regions

Tropical and equatorial climates have been subdivided in several ways, and many names have been applied to the categories. Generally, in tropical areas climatic types are mostly determined by rainfall, especially the seasonal pattern, rather than by temperature characteristics. The simplest classification uses the following groups: (1) tropical wet, (2) tropical wet-and-dry, and (3) low-latitude dry. Most classifications employ four or five groups. A typical four-class grouping includes: (1) tropical rainforest, (2) tropical wet-and-dry, (3) tropical steppe, and (4) tropical desert. Classifications using five categories add a monsoon climatic type to the four-class grouping. A classification employing five main categories will be discussed here.

Tropical rainforest

This climatic type is also often called equatorial, humid equatorial, wet equatorial, tropical wet, and tropical rainy. It is the Af category in the Köppen classification, and Ar in Trewartha's. This climate characteristically occupies a zone extending as

Figure T35 Surface and upper-level winds during the Asian summer monsoon (Petterssen, 1958).

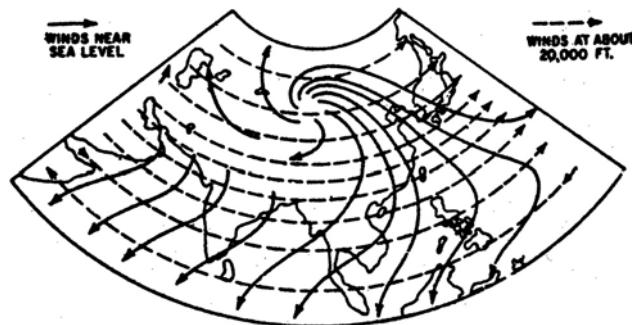

Figure T36 Surface and upper-level winds during the Asian winter monsoon (Petterssen, 1958).

much as 12° on either side of the equator, interrupted only by the monsoonal areas. It is also usually restricted to elevations less than 3300 feet (1000 m). The largest regions of this climate straddle the equator closely, coinciding with the Amazon Basin in Brazil, the Congo Basin of central Africa, and the countries of Indonesia and Malaysia.

Typically, this climatic type has consistently relatively high average monthly temperatures – about 80°F (27°C) throughout the year, although some locations have slightly lower averages. Many locations have an annual range of temperature between the month with the highest average and the month with the lowest average that is less than 8°F (4°C); such locations are designated with the letter I (for isothermal) in the Köppen system. Some locations have ranges that are less than 5°F (3°C). At these locales the monthly temperature range is often considerably less – as much as three times less – than the diurnal range, making the statement “night is the winter of the tropics” particularly *apropos*. Large annual average precipitation of about 60–100 inches (1525–2540 mm) characterizes most of this climatic type. Earth’s maximum annual average rainfall typifies many stations with this type of climate. Data for representative stations with a tropical rainforest climate are given in Table T4. These temperature and precipitation conditions support Earth’s major rainforests, or selva.

Many locations in the tropical rainforest climate experience double maximums of monthly temperature and rainfall, because the sun, and often the ITCZ, traverse each location twice per year. However, a double maximum does not occur in some places because passage of the ITCZ and its accompanying cloud

cover suppresses maximum temperatures, and because the rain-producing capacity of the ITCZ is not always geographically and temporally consistent. Also inconsistent are wind patterns. Light and variable winds associated with the ITCZ, the doldrums, predominate here, disturbed only by local winds associated with thunderstorms and by the relatively infrequent occurrence in these low latitudes of storms of tropical origin (e.g. hurricanes, typhoons, or tropical cyclones).

Tropical wet-and-dry

This climatic type is also often called tropical savanna (savannah). It is designated as Aw in the Köppen system and with the same two letters by Trewartha. It lies poleward of the tropical rainforest (equatorial) climate, quite consistently terminating near the Tropic of Cancer and Tropic of Capricorn, except north of the equator in Africa, where it extends to only about 15°N latitude, and where it extends to approximately 27°N into southern Florida. It is the primary climate of the trade wind belt. The largest occurrences of this climate are in Africa, where it covers more than one-third of the continent; South America, where it is north and south of the Amazon Basin; the Caribbean; along the west coast of Central America; India, covering much of that country; peninsular southeast Asia; and northern Australia.

The tropical wet-and-dry climate coincides closely with the occurrence of vegetation called savanna, which consists of mostly tropical grasslands, shrubs, and drought-resistant trees, the latter covering 10–40% of the land. This vegetation, and thus the climate, are transitional between the nearly constantly wet equatorial regions where the influence of the ITCZ is dominant, and the much drier regions of the subtropics. The wet-and-dry portion of the name of this climate results from its hybrid nature, being under the influence of very different climatic controls in the different seasons. Here there is no dominant double season of high insolation (high sun) and consequently no double maximums of temperature and precipitation as in the tropical rainforest climate. Instead, most regions receive significant rainfall during the high-sun season, when influenced primarily by the ITCZ coupled with rain-bearing easterly waves. Low-sun season is influenced by an equatorward shift of the subtropical high-pressure cells, which reduces rainfall, often substantially. Some areas on the eastern coasts in this climatic type have more consistent rainfall, also receiving rainfall in winter and fall from the stronger influence of the trade winds on these coastal regions.

Coastal portions of this climate typically receive 35–70 inches (890–1780 mm) of precipitation annually, most of it in the summer, and have average monthly temperatures of 65–70°F (18–21°C) during winter and 75–80°F (24–27°C) in the summer months. More continental locations generally receive 20–50 inches (510–1270 mm), with the lower amounts most commonly encountered near the poleward edges of this climatic type; much of the annual total is received in summer. Temperatures are similar to coastal locations, except that greater diurnal ranges are experienced. Data for representative stations with a tropical wet-and-dry climate are given in Table T5.

Monsoon

The monsoon climatic type is discussed in detail in the item on monsoon climates; only general characteristics will be given here. This climatic type is designated Am in the Köppen system, but is not identified as a separate climatic type in the Trewartha classification. (Am regions on maps of the Köppen system are sometimes within Ar and sometimes within Aw regions on maps depicting Trewartha's system; some consider the monsoon climate to be a variety of the tropical rainforest climate while others consider it as a subtype of tropical wet-and-dry climate.) Monsoon climates, as defined by Köppen, occur primarily in the Philippines, sections of coastal Vietnam, along the eastern coast of the Bay of Bengal, southwestern India, a small portion of western Africa (Sierra Leone and Liberia), and northeastern coast of Brazil. Some have suggested that the term monsoon climate be restricted to Asia and northern Australia, but this restriction has not been widely followed, and many consider that a true Am climate in Australia occurs in only an extremely small portion of the northeastern part of that country.

Monsoon regions are in approximately the same latitudes as the tropical rainforest (equatorial) climates, although they also extend slightly farther north in southeast Asia, and thus share some characteristics with that climatic type. Temperatures are quite similar to those of the rainforest, with all months averaging above 64°F (18°C), and average about 80°F (27°C) at many locations, but there is often a slightly greater, albeit still small, seasonal variation. Warmest conditions usually precede the arrival of the ITCZ and its associated cloud cover, and there is frequently a secondary temperature maximum following the departure of the ITCZ.

Although amount of rainfall in the monsoon regions is often similar to that in equatorial climates, the seasonal distribution is different, and it is this characteristic that primarily distinguishes

the two climatic types. Monsoon climates have at least one month that receives less than 2.4 inches (61 mm), although the so-called dry season is generally just a few months in duration. This dry season is nearly always during the winter. Often the dry period is not as distinct as the dry season of the Aw climate, and the copious rainfall of the summer is sufficient to sustain tree growth during the short dry season, and thus there are no water-balance deficits in winter in the monsoon climate, as there are in Aw climates. Data for representative stations with a monsoon climate are given in Table T6.

Tropical semiarid and arid

Many of Earth's driest areas occur within tropical/subtropical regions, and are referred to generally as low-latitude or tropical dry climates. The deserts in these latitudes, particularly those at low elevations, are often called warm deserts, to distinguish them from the so-called cold deserts of higher latitudes (and elevations), although this distinction is somewhat arbitrary, as many tropical deserts experience low nighttime temperatures and some even have relatively low summertime monthly average temperatures. Tropical dry climates are situated mostly between 12° and 35°N and S, and are most commonly divided

into two subgroups: tropical semiarid or steppe, supporting grasses, and tropical arid or desert, with xerophytic vegetation or no vegetative cover. Tropical semiarid is designated BSh in the Köppen and Trewartha classifications, and deserts are shown as BWh (interior tropical deserts) and BWk (coastal tropical deserts). (Some midlatitude deserts are also designated as BWk.) As further discussed in the item on arid climates, the main causes of dry regions in the tropics are subsidence of air in the subtropical anticyclones, cold ocean currents, which enhance the stability caused by anticyclones, topographic barriers blocking rain-bearing rains, and great distances from moist ocean winds. Often several of these mechanisms operate in conjunction to produce dryness in an area.

Semiarid regions, especially the large steppes of Africa and Australia, lie at the edges of major deserts, producing a transition from the extremely dry deserts to the more moist tropical savanna climates. (The term steppe is also used for some midlatitude grasslands, especially the extensive grasslands that extend along a significant portion of the southern edge of the Ukraine and Russia; here the climatic designation is BSk.) Much of the northern half of Africa reveals the progression equatorward of desert, centered along the Tropic of Cancer, to steppe – including much of the Sahel – to tropical savanna, and finally to tropical

rainforest at the equator. This same progression occurs in the southern half of the continent. Some of the more poleward semiarid regions have a precipitation regime that is the reverse of the adjacent tropical wet-and-dry climate. Summers, not winters, are typically dry because the subtropical highs shift over these regions, whereas in winter they are more strongly influenced by migrating storms of the westerlies. Data for representative stations with a semiarid climate are given in Table T7.

The largest and driest true arid regions, or deserts (BWh and BWk), are centered approximately on the Tropic of Cancer and Tropic of Capricorn, just poleward of the semiarid tropical steppes. Although several criteria are involved in determining aridity, and many defining schemes have been proposed, a common characteristic of all deserts is meager precipitation. Tropical deserts in the Köppen system have about 11 inches (280 mm) for maximum annual precipitation; 12 inches (305 mm) under the Thornthwaite classification; and 14 inches (355 mm) in the Miller scheme. Additionally, nearly all tropical deserts experience a large annual excess of evaporation over precipitation, with the former often 15–20 times greater than the latter. Relative humidity varies greatly, from as low as 2% in parts of the Sahara Desert to 100%, with frequent fogs, in coastal deserts.

The largest of the tropical deserts are in northern and southwestern Africa, southwestern Asia, central Australia, west-central South America, and southwestern United States/northern Mexico. Deserts are often categorized into the two broad groupings: coastal and interior.

Coastal tropical deserts include the Atacama of west-central South America, Namib of southwestern Africa, and the arid coast of Lower California, i.e. the Baja peninsula of northwestern Mexico. (The Sahara Desert of Africa and the Australian Desert extend from the interior to west coasts, but they are considered to be interior deserts.) Coastal deserts are produced mostly by a combination of dry subsiding air of the subtropical anticyclones coupled with the stabilizing influence of cool ocean currents. These effectively suppress precipitation much of the time, but relative humidity may be as high as 81% in the summer, and copious fog and dew are common in several of these deserts; fog has occurred on 200 days in 1 year in the Namib Desert. The lowest average annual precipitation on Earth, 0.03 inch (0.8 mm), also often shown as 0.02 inch, occurs in the Atacama Desert at Arica, Chile. Iquique (also Iquiqui), Chile, 120 miles (193 km) south of Arica and also in the Atacama Desert, experienced 14 consecutive years with no measurable rainfall. (In some sources this 14-year record is attributed to Arica, but most cite Iquique as the South American

record holder; some reports state that the longest rain-free period here was 20 years. There are also reports that Wadi Halfa, in the Sahara Desert, experienced a 19-year period with no precipitation.) Temperatures are relatively low in the coastal deserts partly because of the cool ocean current and sometimes-abundant cloud cover. Monthly averages range between 60°F and 70°F (15–21°C). Average annual temperature in the Atacama Desert is 66°F (19°C), and it is 63°F (17°C) in the Namib Desert. Data for representative stations with a coastal tropical desert climate are given in Table T8.

Interior tropical deserts, some of which may extend to coastal regions, are among the largest arid regions on Earth. The Sahara in northern Africa is approximately 3.5 million square miles (9.1 million square kilometers), which exceeds the area of the conterminous United States. The Australian Desert, which has many local names, covers 1.3 million square miles (3.4 million square kilometers), and covers such a large portion of Australia that the continent is sometimes called the “desert continent”. The Arabian Desert covers 1 million square miles (2.6 million square kilometers), and the Thar (Great Indian) Desert of western India and southeastern Pakistan is most frequently stated to cover 230 000 square miles (600 000 square kilometers). The desert region of northern Mexico and southwestern United States is a large contiguous region with several local names, including Chihuahuan, Sonoran and Mojave. This vast dry region is in the subtropical/midlatitude transition zone.

The aridity of these interior tropical deserts is primarily because of their location relative to the subtropical anticyclones, as was true of the coastal tropical deserts, but also because much of their areas are far removed from moist, rain-bearing oceanic winds. In the case of the Mojave Desert in California, moisture is also blocked by the tall Panamint Mountains and Sierra Nevada to the west, producing a persistent rainshadow effect. The infrequent rains usually fall from intense summer convectional storms, and occasionally from winter cyclonic storms originating in middle latitudes. The latter storms occasionally produce snow in the deserts. Precipitation is extremely variable in amount, intensity, occurrence, and distribution.

Temperatures are generally considerably higher in these deserts than in coastal tropical deserts. Average monthly temperatures are generally between 70°F and 90°F (21–32°C), and the highest temperatures on Earth, both average annual and daily maximum, have occurred in this climate, including a record-high reading of 136°F (58°C) at El Azizia, Libya – about 50 miles (80 kilometers) south of Tripoli – on 13 September 1922 (although the validity of this value has been questioned).

Death Valley, in the Mojave Desert of southeastern California, is the hottest – as well as driest and lowest – spot in North America, and experienced a temperature of 134°F (57°C) in July 1913; this still stands as the highest temperature officially recorded in the western hemisphere. In contrast, relatively low winter temperatures give these deserts the greatest annual temperature range found in tropical regions. Diurnal temperature ranges are also extreme: in the Sahara Desert in Algeria a daily range of 100°F (56°C) has been recorded, when the temperature changed in a 24-hour period from 132°F (56°C) to 32°F (0°C); this value is generally accepted as the greatest daily range of temperature to have been recorded on Earth. (Although the range – 100°F – is the same, sometimes the high and low temperatures are presented as 126°F and 26°F, respectively.) Data for representative stations with an interior tropical desert climate are given in Table T8.

High temperatures of interior tropical deserts are sometimes accompanied by hot, dry, dust-bearing winds, especially in Africa. Many of these winds have local names. The Ghibli is a hot wind in Libya, usually blowing from the Sahara; this wind in Morocco is called the Chergui. A Khamsin wind is a hot, extremely dry wind reaching into Egypt from the south and east. Another wind sweeping northward to the Mediterranean area from the Sahara or Arabian deserts is the well-known Sirocco. The Harmattan is a reverse wind from the Sirocco, blowing mostly southward from the Mediterranean or northern Africa, covering much of northern and northwestern Africa. This wind, which is usually warm rather than very hot, and extremely dry, is considered a continental part of the trade wind system.

TROPICAL CYCLONES

The term “tropical cyclone” is used to refer to warm-core, non-frontal low-pressure systems of synoptic scale that develop over tropical or subtropical oceans. This definition differentiates *tropical cyclones* from *extratropical (midlatitude) cyclones* that exhibit a cold-core in the upper troposphere and often form along fronts in higher latitudes. *Subtropical cyclones* are hybrid systems that exhibit some characteristics of tropical cyclones and some characteristics of extratropical cyclones. Tropical cyclones extract much of their energy from the upper layer of the ocean, while extratropical cyclones derive much of their energy from the baroclinic temperature gradients in which they form. This classification system differentiates cyclones based on their initial sources of energy, their thermal structure in the upper troposphere and the presence or absence of fronts. However, cyclones exhibit characteristics related to their large-scale environment, and it is possible for a cyclone to transform from one type into another type when the cyclone moves away from its genesis region. For example, many tropical cyclones undergo an *extratropical transition* into extratropical cyclones with fronts when they move into higher latitudes. Tropical cyclones are observed over the North Atlantic Ocean, the eastern, central and western North Pacific Ocean, the central and western South Pacific Ocean and the northern and southern Indian Ocean. A cyclone with some of the characteristics of a tropical cyclone was observed over the southern Atlantic Ocean in March 2004.

Tropical disturbances

A *tropical disturbance* is a discrete tropical weather system with organized convection that originates in the tropics or the subtropics. Tropical disturbances are not typically associated with fronts and they may not always exhibit a detectable perturbation in the surface wind field. A tropical weather system must maintain its identity for at least 24 hours in order to be classified as a tropical disturbance. This latter requirement makes it possible to differentiate migratory tropical disturbances from the typical diurnal convection found in tropical and subtropical regions.

Tropical disturbances originate in several regions. Tropical (easterly) waves develop over the interior of Africa and translate westward over the North Atlantic Ocean. Tropical waves are elongated troughs of low pressure with a meridional extent of hundreds of kilometers. Figure T37 is a visible satellite image of a strong tropical wave as it approaches the Caribbean Sea. Clusters of thunderstorms that originate in the Intertropical Convergence Zone (ITCZ) may become separated from the ITCZ and are classified as tropical disturbances if they maintain convection for at least 24 hours. Other tropical disturbances

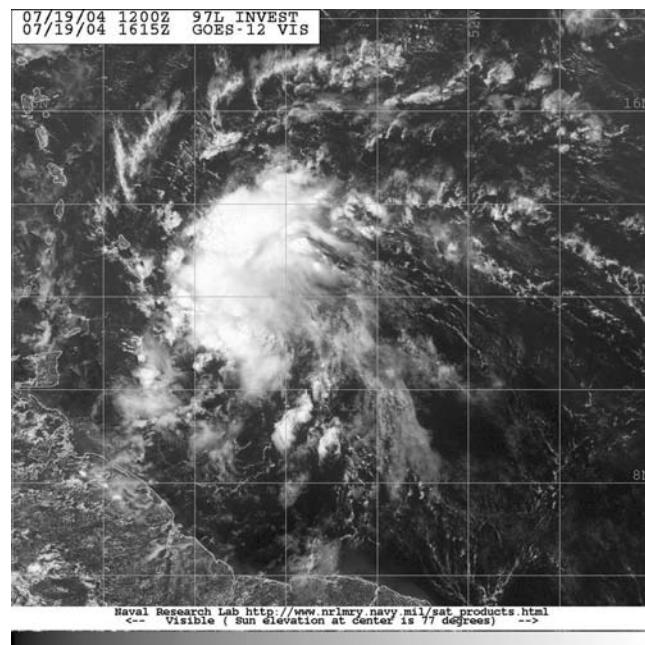

Figure T37 Visible satellite image of a strong tropical wave approaching the Caribbean Sea (from the Naval Research Laboratory's tropical cyclone web demonstration page, produced by the Marine Meteorology Division in Monterey, California).

form in the monsoon trough over the western Pacific Ocean. Tropical disturbances generally move from east to west in the prevailing flow at lower latitudes. Tropical disturbances are not tropical cyclones although the systems may evolve into tropical cyclones when certain conditions exist.

Tropical cyclogenesis

The term “*tropical cyclogenesis*” refers to the formation of a tropical cyclone. Tropical cyclogenesis occurs when an existing disturbance composed of an area of convection with embedded thunderstorms organizes into a distinct surface low-pressure system with cyclonic convergent flow. Although the precise physical processes that lead to the formation of a tropical cyclone are not known, a number of conditions seem to be necessary for tropical cyclogenesis to occur. First, a disturbance must exist with significant convection, vorticity (i.e. tendency for cyclonic rotation) and convergence near the surface. Second, the disturbance must be located over a warm ocean. The sea surface temperature (SST) needs to be warmer than 26°C and the warm water needs to extend through a sufficient depth thought to be a few tens of meters. Third, the environmental lapse rate (i.e. the rate at which the atmosphere cools with height) needs to be sufficiently large so that the atmosphere is conditionally unstable. Fourth, the middle troposphere (i.e. 3–7 km above the surface) must contain sufficient moisture to allow for the development of deep convection in thunderstorms. Fifth, the vertical wind shear (i.e. the difference in the winds between the lower troposphere and upper troposphere) must be relatively small. Sixth, the disturbance needs to be at least 500 km from the equator.

All tropical cyclones develop from existing disturbances. Most tropical cyclones develop from tropical disturbances.

However, some tropical cyclones develop from disturbances associated with dissipating frontal boundaries, subtropical cyclones and mesoscale convective systems (MCS). In order for a disturbance to develop into a tropical cyclone it must be located over a warm ocean and the flow must be convergent near the surface. As the air passes over the ocean, water evaporates from the surface into the atmosphere. Since water absorbs energy as it evaporates, this process represents a transfer of latent energy from the surface to the air. The air is usually slightly warmer than the water and there is an additional transfer of internal energy (formerly called sensible heat) into the atmosphere. The convergent flow near the surface brings the latent and internal energy into the region of convection associated with the disturbance, and the air begins to rise in thunderstorms. As the air rises, it cools until it becomes saturated and then the water vapor begins to condense. When the water vapor condenses, the latent energy is converted into internal energy and the temperatures in the middle and upper troposphere begin to increase. If sufficient condensation occurs in the upper troposphere, the temperatures will be higher near the center of the disturbance than they will be at the outer edges of the system and the system will develop a warm core.

The development of the warm core enhances the divergence of mass in the upper level of the disturbance. When the divergence of mass at the upper levels exceeds the convergence of mass in the lower levels the pressure at the surface will begin to decrease. As the pressure at the surface decreases, the horizontal pressure gradient increases and the wind speed at the surface increases. As the wind speed at the surface increases, the fluxes of latent and internal energy from the ocean to the atmosphere increase. Convergence also increases, more latent energy is drawn into the disturbance and the warm core in the upper levels becomes more pronounced. The convergence will also collect vorticity in the lower levels of the atmosphere and increase the tendency for the air to rotate cyclonically. If the surface pressure continues to fall and the flow of air at the surface develops a clearly identifiable cyclonic circulation, then the system is classified as a *tropical cyclone*.

The relative importance of the processes that produce tropical cyclogenesis has been debated by tropical meteorologists. Charney and Eliassen (1964) proposed a mechanism to explain tropical cyclogenesis called Conditional Instability of the Second Kind (CISK). CISK proposes that the convergence in the lower levels enhances convection and the release of latent energy, which further enhances the convergence. The positive feedback between the convection on the cumulus scale of motion and the larger-scale disturbance eventually produces a tropical cyclone. Emanuel (1987) proposed a mechanism called Wind Induced Surface Heat Exchange (WISHE) in which the increased convergence enhances the fluxes of latent and internal energy from the ocean to the atmosphere. The additional energy is redistributed into the upper levels of the disturbance by the convection. WISHE proposes that the increased fluxes of energy from the surface are critical to tropical cyclogenesis. Although both theories of tropical cyclogenesis include the effects of the surface fluxes of energy and convection, they assign differing levels of importance to the two processes. Convection is assumed to be the predominant factor in CISK, while the surface fluxes assume the predominant role in WISHE.

Most tropical disturbances do not develop into tropical cyclones. Numerous factors can inhibit or prevent the genesis of a tropical cyclone from a disturbance. If the SST are too cold, insufficient latent energy is transferred from the ocean to

the atmosphere to support the formation of a warm core. Even when the SST are greater than 26°C, if the layer of warm water is too shallow the winds will mix the upper layer of the ocean and cooler water will rise to the surface. The upwelling of cooler water will reduce the transfer of latent energy and inhibit the genesis of a tropical cyclone. If the environmental lapse rate is too small, the atmosphere will be stable and only shallow convection will develop. If the middle of the troposphere is too dry, the water rising in clouds will evaporate and deep convection will not be able to develop. Stability and dry air in the middle troposphere prevent the development of a warm core in the upper troposphere. If the vertical wind shear is too strong, the winds in the upper troposphere will advect (i.e. transport horizontally) the warm core away from the center of the disturbance. Strong winds aloft also inhibit upper-level divergence over part of the disturbance and prevent the decrease of pressure at the surface. When the vertical wind shear is very strong, the upper-level winds may separate the upper portion of the disturbance from the lower part of the disturbance and the system is literally blown apart.

Classification of tropical cyclones

Observation of a clearly identifiable cyclonic circulation at the surface and a warm core aloft results in the classification of a system as a tropical cyclone. If the maximum sustained wind speed at the surface is less than 17 m s^{-1} (34 knots), then the tropical cyclone is classified as a *tropical depression*. When a tropical depression forms it is given a numerical designation by the meteorological organization with responsibility for that location of the world. For example, the first tropical depression that forms over the eastern North Pacific Ocean each season is designated Tropical Depression One-E. If the maximum sustained wind speed at the surface is $18\text{--}32 \text{ m s}^{-1}$ (35–64 knots), then the tropical cyclone is classified as a *tropical storm*. When a system is classified as a tropical storm it is given a name from a list of names for that basin. If the maximum sustained winds at the surface are 33 m s^{-1} (65 knots) or greater, a tropical cyclone is classified as a *hurricane* in the western hemisphere (i.e. over the Atlantic Ocean and the eastern and central North Pacific Oceans), as a *typhoon* over the western Pacific Ocean, and as a *severe cyclone* over the Indian Ocean. A tropical cyclone in the western hemisphere with maximum sustained winds at the surface of 49 m s^{-1} (96 knots) or greater is classified as a *major hurricane*. A tropical cyclone over the western Pacific Ocean with maximum sustained winds at the surface of 66 m s^{-1} (130 knots) is classified as a *super typhoon*.

Structure

The convergent cyclonic flow in the lower atmosphere of a tropical cyclone tends to organize the convection into spiral bands. Figure T38 is a visible satellite image of Tropical Depression Three-E, which intensified into Tropical Storm Celia over the eastern North Pacific Ocean during July of 2004. The image depicts the central mass of convection over the center of the tropical depression, which is called the Central Dense Overcast (CDO). Strong rising motion near the center of the tropical cyclone transports mass upward. A primary *spiral band* of convection extends to the west and north of the center of the depression. Figure T39 is a visible image of the same tropical cyclone after it had intensified into Tropical Storm Celia. The strongest convection is still evident near the center of the

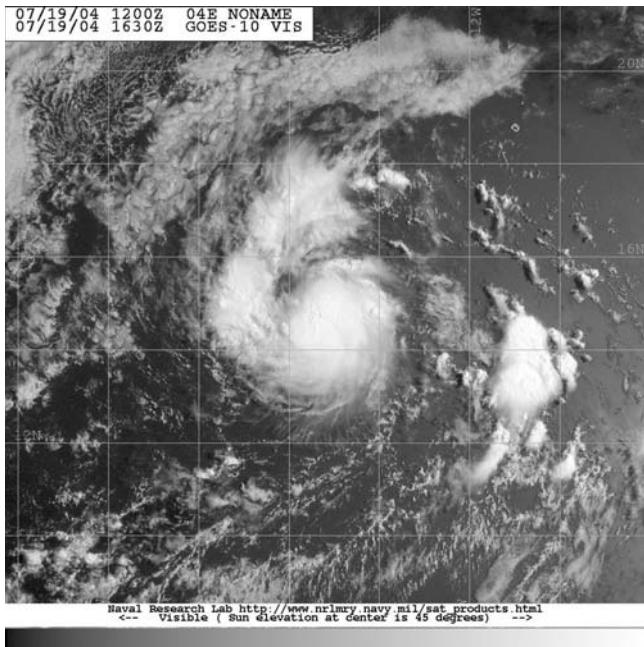

Figure T38 Visible satellite image of tropical depression Three-E (2004) (from the Naval Research Laboratory's tropical cyclone web demonstration page, produced by the Marine Meteorology Division in Monterey, California).

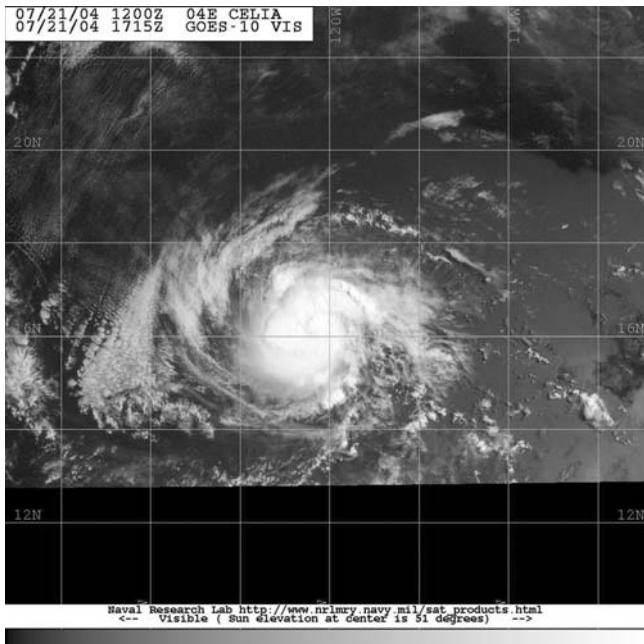

Figure T39 Visible satellite image of Tropical Storm Celia (2004) (from the Naval Research Laboratory's tropical cyclone web demonstration page, produced by the Marine Meteorology Division in Monterey, California).

system and several spiral bands are visible to the east and south of the center. The strong rising motion near the center of the tropical storm produces divergence at upper levels of the troposphere and the *cirrus canopy* spreads out over the top of the storm. Evidence of the upper-level divergence can be seen in some of the thin, wispy streamers of cirrus radiating away from the center of the storm on its northeast side.

When tropical cyclogenesis occurs, the fastest horizontal winds often are observed 100–200 km from the center of the tropical cyclone in the spiral bands. As the tropical storm intensifies, the pressure gradient increases, the low-level convergence becomes stronger, and the Radius of Maximum Winds (which is the distance from the center of the tropical cyclone at which the fastest wind speeds are found) decreases. As the intensity of the tropical storm approaches a classification of a hurricane or typhoon, the primary spiral band wraps around the center of the circulation. A clear area may begin to appear on radar and satellite imagery. The clear area at the center of the tropical cyclone is called the *eye*. Subsidence is observed in the eye in the upper and middle troposphere and the sinking motion helps account for the clearing. In the lower troposphere near the surface of the ocean the air is moister and shallow cumulus clouds may occur below the subsidence in the eye. Figure T40 is a visible satellite image of Hurricane Alex on 4 August 2004. The eye is clearly visible in the center of the storm. The diameter of the eye may be only 10 km in small intense tropical cyclones. In large tropical cyclones and those storms undergoing an extratropical transition the diameter of the eye may be 100 km. The horizontal winds are usually relatively light near the center of the eye. Wind speeds may increase toward the outer portions of the eye. Tall, vertical cumulonimbus clouds surround the eye. The inner edge of

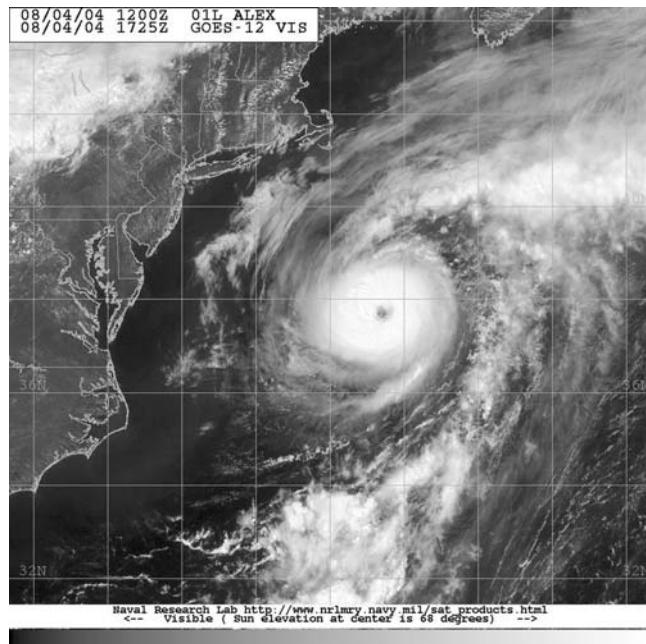

Figure T40 Visible satellite image of Hurricane Alex on 4 August 2004 (from the Naval Research Laboratory's tropical cyclone web demonstration page, produced by the Marine Meteorology Division in Monterey, California).

the vertical clouds around the eye is called the *eyewall*. The fastest horizontal winds and strongest low-level convergence in a hurricane or typhoon are often found just outside the eyewall. The highest rates of vertical motion (i.e. the strongest updrafts and downdrafts) are found in the convection that

surrounds the eye. The speed of the strongest updrafts may exceed 25 m s^{-1} in the eyewalls of intense tropical cyclones (Dodge et al., 1999). The speed of the strongest downdrafts is roughly 50–60% of the strongest updrafts in the eyewall. Aerial reconnaissance has observed that the eyewalls of some intense tropical cyclones appeared to slope outward with height in the upper levels of the storms.

Willoughby et al. (1982) documented the existence of multiple *concentric eyewalls* and an *eyewall replacement cycle* in certain hurricanes. Many times in intense tropical cyclones the convection in the eyewall moves inward as the storm intensifies and the radius of the eye becomes smaller. In some intense tropical cyclones an outer spiral band wraps completely around the center of the storm and surrounds the original eyewall. In this case the storm exhibits multiple concentric eyewalls. Figure T41 is a radar image of Hurricane Gilbert (1988) that exhibits multiple concentric eyewalls. The inner eyewall is found 10–20 km from the center of Gilbert. The edge of the outer eyewall is 50 km from the center of the storm. Figure T42 shows a cross-section of the radar reflectivity of the concentric eyewalls. The highest reflectivity, which represents the highest rainfall rate, is found in the inner eyewall. A secondary reflectivity maximum is found in the outer eyewall. Lower reflectivities, which indicate the presence of stratiform rain, are found between the regions of strong convection in the eyewalls. Most of the convergent flow in the lower levels of the atmosphere rises in the outer eyewall and convection diminishes in the inner eyewall until it eventually dissipates. The outer eyewall becomes the primary eyewall and the tropical cyclone exhibits an eye with a much larger radius. When the outer eyewall replaces the inner eyewall, the minimum surface pressure rises and the maximum sustained wind speeds may decrease. The reduction in intensity may be only temporary as the new eyewall will begin to contract if the large-scale environment is still favorable of

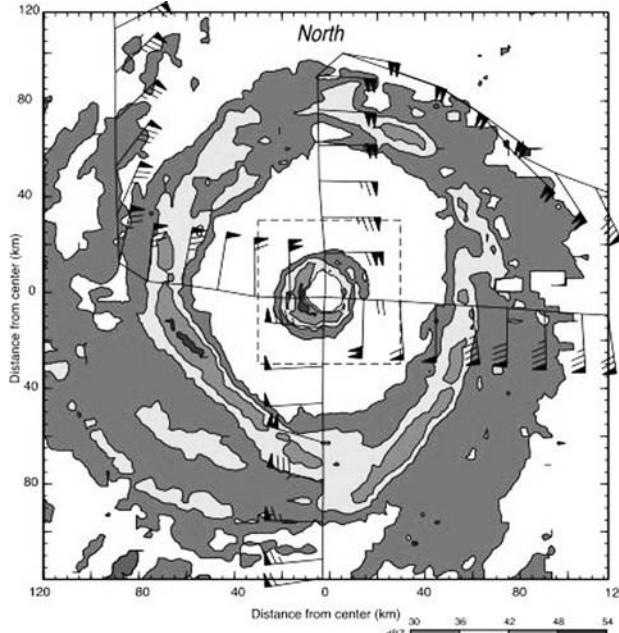

Figure T41 Radar image of concentric eyewalls in Hurricane Gilbert (1988) (from Dodge et al., 1999).

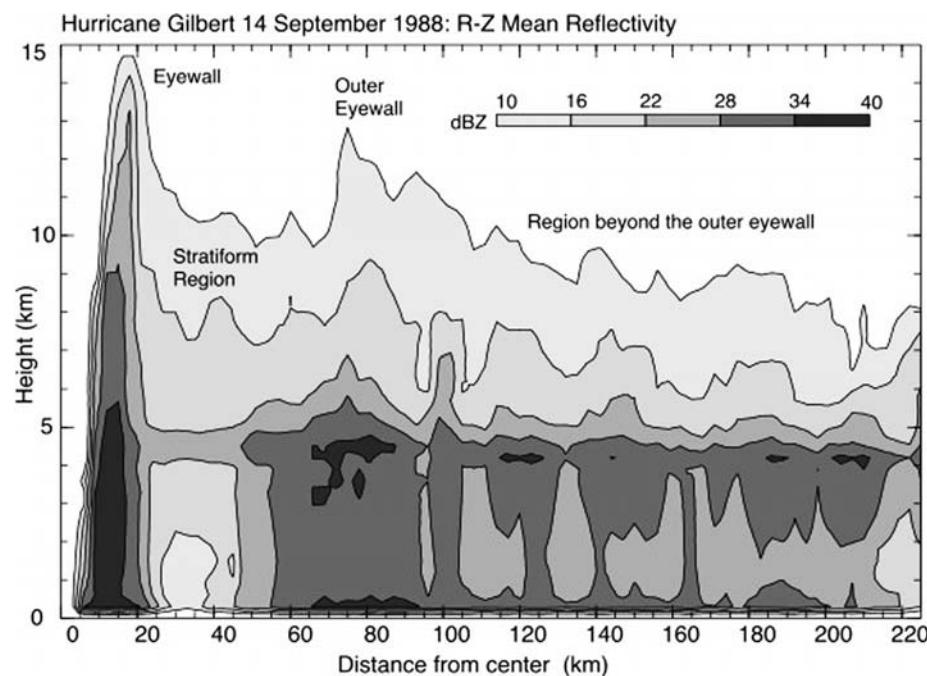

Figure T42 Radar cross-section of concentric eyewalls in Hurricane Gilbert (1988) (from Dodge et al., 1999).

intensification of the tropical cyclone. Additional spiral bands may wrap around the center of the storm and a number of eyewall replacement cycles may occur.

Tropical cyclones exhibit a wide range of sizes and their wind fields result from the interaction of the storm and its surrounding environment. For example, gale force winds (17 m s^{-1}) extended to a radius of 1100 km in Typhoon Tip over the Northwest Pacific Ocean on 12 October 1979. In contrast the radius of gale force winds was only 50 km in Tropical Cyclone Tracy on 24 December 1974.

Climatology

Approximately 90 tropical cyclones form each year. The total number of tropical cyclones is remarkably consistent from year to year, although the global distribution of the cyclones may vary significantly. Table T9 presents the monthly frequencies of tropical cyclones for six regions of the world.

The greatest number of tropical cyclones form over the western North Pacific Ocean. Approximately 32 tropical cyclones form over the western North Pacific Ocean in an average year. Tropical cyclones can form in any month, although they are relatively infrequent during the late winter and early spring. SST are warm ($>28^\circ\text{C}$) over much of the year in this region. Tropical cyclogenesis occurs most frequently during the period of July through October. During these months the monsoon trough provides a region of low-level cyclonic flow and convection favorable for the formation of tropical cyclones.

Numerous tropical cyclones also form over the southern Indian Ocean and the southwest Pacific Ocean. Although tropical cyclones may form over this region during any month, the majority of the storms occur during the austral summer. During austral summer a monsoon trough (also sometimes called the Southwest Pacific Convergence Zone) provides low-level cyclonic inflow and convection. Approximately 15 tropical cyclones form annually over the eastern North Pacific Ocean. Although this is only half the number that form over the western North Pacific Ocean, when the numbers are normalized for the size of the region the greatest frequency of tropical cyclogenesis occurs over the eastern North Pacific. In one out of every two years the first tropical cyclone occurs over the eastern North Pacific in late May. Tropical cyclogenesis is most common during July through September. Many of the tropical cyclones that form over this region appear to develop out of tropical waves that migrate across the Atlantic Ocean and central America before entering the eastern North Pacific. Abundant regions of warm SST and relatively low magnitudes of vertical wind shear create a very favorable environment for genesis of tropical cyclones from these tropical waves.

Around ten tropical storms form annually over the North Atlantic basin. Although the hurricane season in the Atlantic officially runs from the first of June through the end of November, tropical cyclogenesis occurs most frequently during August through October. Tropical cyclogenesis during the early or later part of the hurricane season often occurs along old fronts or from subtropical cyclones. Early in the hurricane season tropical cyclones most commonly form over the southern Gulf of Mexico or the western Caribbean Sea. During late summer and early autumn the SST are at their peak and wind shear is generally reduced over the lower latitudes, which allows tropical waves to develop into tropical cyclones. Tropical cyclones can form over most of the subtropical and tropical north Atlantic during this period. Toward the end of the hurricane season the preferred regions for tropical cyclogenesis move back to the southern Gulf of Mexico and the southwest Caribbean Sea.

Five tropical cyclones form on average over the northern Indian Ocean. The formation of tropical cyclones is most frequent in the fall, but there is a secondary period of formation during the early summer. Many of the tropical cyclones develop from disturbances that are associated with the monsoon trough. An average of one tropical cyclone forms each year over the central North Pacific Ocean around Hawaii. The most likely months for tropical cyclogenesis to occur are August, September and October.

The formation of tropical cyclones over ocean basins that experience relatively high frequencies of these systems is marked by periods of activity and inactivity. Maloney and Hartmann (2001) have proposed that these periods of frequent formation of tropical cyclones and quiescent periods are related to the Madden-Julian Oscillation (MJO). The MJO is associated with periods of enhanced westerly and easterly flows in the lower troposphere. It has been proposed that the enhanced westerly flows interact with the prevailing easterly winds in the tropics to generate cyclonic rotation favorable to tropical cyclogenesis. During these periods tropical cyclones form more frequently. The periods of enhanced easterly flow are thought to be associated with the periods of reduced formation of tropical cyclones.

The frequency of tropical cyclone formation also exhibits an interannual variability. Studies have examined statistical links between the frequency of tropical cyclone formation and large-scale phenomena such as El Niño–Southern Oscillation (ENSO) and the Quasi-Biennial Oscillation (QBO). Wang and Chan (2002) examined the links between ENSO and tropical cyclone activity over the western North Pacific Ocean. It was found that tropical cyclones developed farther to the south and east during an El Niño. Since the storms formed further to the

Category	Wind speed	Damage	Structures affected
One	33–42 m s ⁻¹ (64–82 knots)	Minimal	Unanchored mobile homes
Two	43–49 m s ⁻¹ (83–95 knots)	Moderate	Mobile homes, roofing, windows
Three	50–58 m s ⁻¹ (96–113 knots)	Extensive	Small residences, utility buildings
Four	59–69 m s ⁻¹ (114–135 knots)	Extreme	Residences and some commercial buildings
Five	>70 m s ⁻¹ (>135 knots)	Catastrophic	Residences and industrial buildings

south and east they typically moved further west before recurving poleward and existed for longer periods of time. Higher sea-level pressures and lower SST tend to be associated with reduced formation of tropical cyclones over the southwest Pacific Ocean around Australia during an El Niño. Although the formation of tropical cyclones over the central Pacific is relatively rare, they appear to form more frequently during an El Niño. Warmer SST and enhanced convection provide a more favorable environment during an El Niño. The frequency of the formation of the tropical cyclones over the eastern North Pacific is not strongly affected by an El Niño. The favorable conditions associated with warmer SST are somewhat offset by higher magnitudes of vertical wind shear. However, cyclones that do form over the eastern North Pacific during an El Niño exhibit higher intensities. The strongest hurricane on record in this region was hurricane Linda, which formed during the El Niño in 1997. The frequency of the formation of tropical cyclones over the Atlantic is reduced during an El Niño. The convection over the tropical Pacific Ocean generates stronger westerly winds that increase the vertical wind shear over the Atlantic Ocean and inhibit the formation of tropical cyclones.

Movement of tropical cyclones

The movement of tropical cyclones results from the interaction of the system with its surrounding environment. However, tropical cyclones over many ocean basins exhibit similar paths. Tropical cyclones often form in the lower latitudes of the tropics equatorward of the subtropical ridge. These systems are initially embedded in deep easterly flow that causes them to move generally east to west. As the systems near the western periphery of the subtropical ridge the tropical cyclones begin to experience a more poleward direction of movement. The poleward movement around the western edge of the subtropical high is called *recurvature*. Many tropical cyclones reach their peak intensity at the western edge of the subtropical high. As the tropical cyclones move poleward they begin to be more strongly affected by the mid-latitude westerly flow. Eventually many tropical cyclones recurve and move rapidly from west to east in the midlatitude flow. These tropical cyclones often experience an extratropical transition or are absorbed into the circulation of a larger extratropical cyclone.

Hazards associated with tropical cyclones

The most obvious hazard associated with a tropical cyclone is the danger posed by high wind speeds. The National Hurricane Center in Miami, Florida uses the Saffir–Simpson Hurricane

Scale to classify hurricanes (Table T10). Even a minimal hurricane can do damage to unanchored mobile homes and poorly maintained structures. A Category Two hurricane can do significant damage to mobile homes and certain types of roofing. The wind speeds associated with a Category Three hurricane can do extensive damage to any structures in their path. The winds in Category Four and Five hurricanes are capable of doing significant damage to many structures unless they are specifically constructed to withstand extremely high wind speeds.

In coastal communities the *storm surge* may pose the greatest hazard from tropical cyclones. On the side of the storm where the winds are blowing toward the coast friction between the high winds and the water will produce a flow of water toward the coast. This flow of water produces an increase in the mean elevation of the ocean at the shore that is called the *storm surge*. Strong wind speeds also produce high waves that may add to the water-level rise. The height of the storm surge is a function of the strength of the tropical cyclone, the bathymetry of the area near the shore and the shape of the coastline. Some of the deadliest tropical cyclones in history produced catastrophic storm surges. A tropical cyclone that struck Bangladesh in 1970 produced a storm surge that may have killed 300 000 people. A hurricane that hit Galveston, Texas, in 1900 produced a storm surge that killed 8000 people.

Once a tropical cyclone moves inland the greatest threat is from fresh water flooding caused by heavy rainfall. Generally, the amount of rain produced by a tropical cyclone is a function of its intensity, size and how fast it moves. Large slow-moving storms can produce up to a meter of rain in a day; while smaller, more rapidly moving systems may only produce a few centimeters of rainfall. Rainfall may be significantly enhanced in regions where topography interacts with the tropical cyclone to produce winds flowing up the slope. Flooding produced by Hurricane Mitch in 1998 over Central America produced catastrophic flooding that may have killed 20 000 people.

Tornadoes are another hazard posed by tropical cyclones after the move inland. Although the environment around a tropical cyclone is not particularly unstable, increased friction as the winds flow from the sea to over the land can create sufficient shear to generate tornadoes. The tornadoes are often associated with strong convection in the spiral bands. After a tropical cyclone moves farther inland, warming of the surface during the daytime may increase the instability. When outer spiral bands move into these more unstable regions, convection may produce additional tornadoes. Although most tropical cyclones produce relatively few tornadoes, a few hurricanes have produced over 100 tornadoes after making landfall in the United States.

TROPOSPHERE

The vertical distribution of the atmosphere traditionally has been divided up into a series of concentric layers primarily based on the thermal structure of the atmosphere. The bottom layer of the atmosphere is called the *troposphere*, and it is within this layer that we find most of the atmospheric water vapor as well as most clouds and weather phenomena. It is primarily composed of nitrogen (78%) and oxygen (21%), with only small concentrations of other trace gases. Nearly all atmospheric water vapor or moisture is found in the troposphere. The upper boundary of this layer is called the tropopause and represents the upper limit of large-scale turbulence and mixing in the atmosphere. The height of the tropopause varies with time of year and latitude, ranging from an average height of 5–6 km over the polar regions to 15–16 km over the equator, and tending to be higher in summer than in winter.

The Earth's surface is the primary absorber of incoming solar radiation therefore the warmest portion of the troposphere is normally adjacent to the surface. Temperatures decrease at an average rate of 6.5°C/km with increasing height in the troposphere; within the tropopause, temperatures remain the same with increasing elevation. Sometimes the temperature does not decrease with height in the troposphere, but increases. Such a situation is known as a temperature inversion. Temperature inversions limit or prevent the vertical mixing of air. Such atmospheric stability can lead to air pollution episodes with air pollutants emitted at ground level becoming trapped beneath the temperature inversion.

One of the most important properties of our atmosphere is its ability to be compressed due to the influence of the Earth's

TUNDRA CLIMATE

Location and definition

There are two types of polar climates that lie poleward of 70°N where the Taiga gives way to the mostly treeless landscape. The coldest of these two regions is the Ice Cap climate (EF) and the milder is the Tundra climate (ET). The word Tundra is derived from the Finnish word *tunturia* for barren land, or treeless plain (*Tundra*, 2003). While there are a few areas of Tundra in the Antarctic, as a climatic region the Tundra generally is located around the Arctic Ocean and above the timberline of high-latitude mountains (Oliver and Hidore, 2002; Figure T43).

Tundra refers to both a climate type as well as a vegetation association (Strahler and Strahler, 2002). Tundra climate is categorized as either Arctic Tundra or Alpine Tundra. The Alpine Tundra experiences a different climate than does the Arctic Tundra in terms of daylength and seasonal changes. However, the Alpine Tundra is similar in terms of the cold temperatures and poor, thin soils. Therefore, most tree species are absent from these montane regions and Tundra vegetation invades and thrives.

The Tundra biome is subdivided into the High, Middle, and Low Arctic Tundra based on latitude. The High Arctic Tundra is restricted to the islands of the Arctic Oceans. The Middle Arctic Tundra is confined to the Arctic Coastal Plain where the terrain is fairly level and the freeze/thaw cycle creates geometric rock patterns on the surface. The Low Arctic Tundra describes the vast majority of the Tundra with steeper slopes that are better drained. Along waterways, trees, such as the willow and alder, can grow to a few meters high. However, the

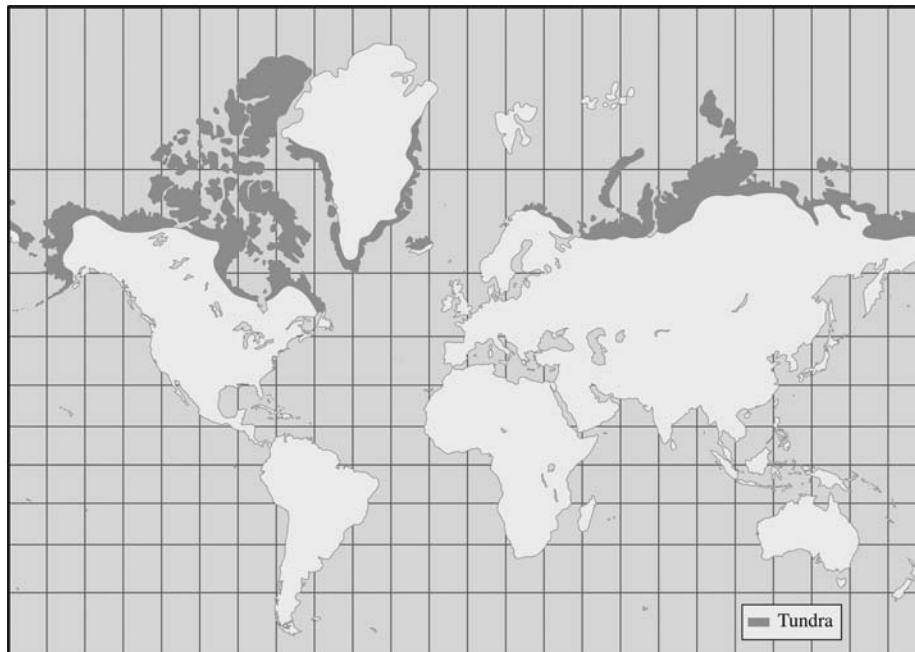

Figure T43 The Tundra; cartographer T. Truckenbrod.

Tundra climate does not favor tree growth as abrasion from wind-driven snow stunts the branches and subsurface dynamics damage the roots (*Tundra*, 1996).

Climatic characteristics

The Tundra is sometimes considered a polar desert as the precipitation is usually less than 20 cm (8 in). While at lower latitudes this scant amount of precipitation would constitute a desert, in the Tundra, evaporation rates are so low that there remains adequate moisture. In other words, the small amount of precipitation exceeds the small demand of potential evapotranspiration. According to Köppen's classification, this Tundra ET climate is under snow cover for approximately 8–10 months of the year. Snowfall actually benefits Tundra plants by providing a layer of insulation against the high-speed and desiccating winds. The amount of precipitation received by any area in the Tundra depends on proximity to large water bodies and to semi-permanent high- or low-pressure cells.

Since much of the Tundra in North America, Asia, and Greenland is located near major water bodies, there is a lesser degree of continentality than in many areas of the sub-Arctic climate region. Most of the Tundra is under the influence of high pressure; however, winter storms develop predominantly in the two areas where the barometric pressure remains low. The Aleutian Low influences the weather from eastern Siberia to the Gulf of Alaska and beyond, while the Icelandic Low generates storms from central Canada to Scandinavia and western Europe (Ritter, 2002).

The daylength of most of the Tundra, which is above the Arctic Circle, varies from 0 to 24 hours. During summer months, Tundra regions have very long days, yet the sun is never very high above the horizon. The average temperature of the warmest month in the Tundra is below 10°C and above

freezing. The warmest summers are located in the interiors of Siberia, Alaska, and Canada. Along with the high albedo of snow, this low angle of the sun contributes to a very low solar radiation receipt. Consequently, the summertime daily high temperature is mild and not much greater than the daily minimum. While the daily temperature range is low, the annual temperature range is moderately high (Figure T44).

The long, cold, dark winters of the Tundra result in 6–10 months with mean monthly temperatures below 0°C. The coldest weather occurs in northeastern Siberia (Hatter et al., 2003). There are no crops grown in the Tundra, and the short growing season for the native species is only 60–80 days. When the Tundra blooms, however, the colors are varied and the landscape is quite beautiful.

Edaphic conditions

The widespread existence of permafrost, a perennially frozen layer of soil and regolith below the surface, typifies most of the Tundra. In some locations the permafrost extends to depths of several hundred meters. During long Tundra winters the surface soil layer is thoroughly frozen. In the summer the temperatures are warm enough to thaw the upper layer of permafrost, but only to a depth of 10 cm to 1 m. Rather than the extremely cold temperatures associated with the Tundra, it is the layer of permafrost that is the primary limiting factor to tree growth as roots cannot delve deeply into the soil.

Soils of the Tundra are nutrient-poor and slow to form due to the extremely cold temperatures. In the Alpine Tundra the terrain is rugged and steep. These glacially carved areas have the distinctive U-shaped hanging valleys, talus slopes, and cirques. Where soil is present, it too tends to be poorly developed and shallow. Because thin soils of the Tundra overlie an impermeable layer of permafrost, rain and snowmelt are unable to percolate downward and the surface becomes saturated and boggy.

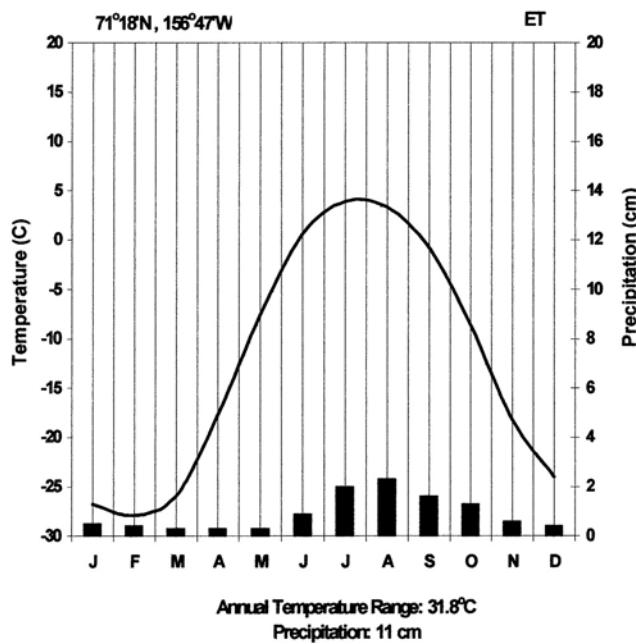

Figure T44 Climograph of Barrow, Alaska (after Eugster et al., 2000).

Mostly of the order Gelisols, Tundra soils are subject to disruption from frost churning and mixing. This freeze/thaw cycle pulls organic and partially decomposed matter from the surface down to the lower layers and brings rocky materials from the C-horizon up to the surface. This process of cryoturbation contributes to the circular, striped, and polygonal patterns of the Tundra. Together, the very thin active soil layer, the existence of permafrost, the persistent freeze/thaw cycle, and the occurrence of solifluction during warmer months create a patchwork of microhabitats and their associated plant communities on the Tundra landscape.

Vegetation

Vegetation lifeforms of the Tundra are well adapted to the soil and climate conditions and include tussock-forming graminoids; mats, or cushion plants; rosettes; and dwarf shrubs. Bunch grasses and cushion plants grow in tight clumps, enabling them to retain heat and avoid exposure to high-speed, cold winds. Many plants have dark-colored leaves that permit greater absorption of heat energy. Cotton grass has winged seeds that maximize the wind's kinetic energy to disperse offspring across the Tundra. For protection from the elements, many buds or other reproductive structures of Tundra vegetation grow close to the ground or beneath the surface as rhizomes.

On bare rock the first species to take hold are lichens. Lichens are a combination of algae and fungi and are an important food source for herbivores on the Tundra. This plant excretes an acid solution that begins the chemical dissolution of rock, and constitutes the first step in soil formation. Also present are herbaceous species such as mosses, perhaps best known is the commercially used sphagnum moss; sedges; Arctic meadow grass; perennial forbs; and members of the heath family. Dwarf shrubs and trees, such as willows and birches, are typically less than 1 m high and are found only in the most

favorable growing conditions of the Tundra. Generally the root networks of the few woody species branch out laterally just below the surface because they can only penetrate to the depth of the thawed ground.

Animals

The animal life of the Tundra demonstrates remarkable adaptive mechanisms as well. Migratory species venture south when the temperatures begin to drop. These species include caribou and birds such as ravens; snow buntings; falcons; loons; sandpipers; terns; snow birds; and various species of gulls (*Tundra Biome*, 2003). Other species migrate only when their prey population crashes. For example, the snowy owl has been seen as far south as Virginia during times when lemming populations declined drastically. The lemming is a small rodent and a major herbivore in the Tundra.

Other adaptive mechanisms include morphological characteristics. Animals which reside in the Tundra year round typically have large, compact bodies, a thick fur or covering of feathers serving as insulation, or they have a plumage or pelage that turns white in the winter and brown in the summer, like the Arctic hare. Residing year-round are the reindeer, rabbit, Arctic fox, wolf, weasel, polar bear, and musk ox. The musk ox is not a true ox, but is more closely related to goats and sheep. Insects include mosquitoes, moths, blackflies, grasshoppers and Arctic bumblebees. Fish species are cod, flatfish, trout and salmon (*Tundra Biome*, 2003). Relative to other biomes, species composition and the food chain of the Tundra are simple.

The Alpine Tundra is home to mountain goats, sheep, marmots and pikas, while the insect species include springtails, beetles, and butterflies. The vegetation of the Alpine Tundra is very similar to the Arctic Tundra as it is composed of tussock grasses, species of heath, and dwarf shrubs and trees. The Arctic Tundra is an important breeding ground for waterfowl, such as geese and swan, as well as for caribou which breed in September and October, allowing the calves to be born in the milder months of May and June. Caribou feed mostly on lichens, but they also eat shrubs, grasses, the tender shoots of trees, and mushrooms.

Concerns

The Arctic Tundra is a fragile environment. While some ecosystems take fewer than 50 years to completely return to a climax community, the slow rate of ecological processes in the Tundra causes this region to require up to centuries to recover from disturbance (Oliver and Hidore, 2002). Increased development, especially in terms of oil exploration, along with climatic change, have left their mark on portions of the Tundra.

Thermal erosion results from scraping away or destroying the upper layer of plants and organic matter in a permafrost region (Strahler and Strahler, 2002). This upper layer serves as insulation, and when it is damaged or removed the summer thaw extends further downward, enhancing the melting of ice wedges and causing general surface subsidence. Clay and silt mix with meltwater, wash downstream, and form muddy trenches to create a thermokarst landscape. The evidence of this alteration of permafrost regions became obvious during World War II when military bases with their airfields and other transportation networks caused mud basins the size of small lakes to form, that engulfed surrounding buildings. Presently, engineers are required to construct buildings on pilings in the Tundra (Strahler and Strahler, 2002).

While the Alaskan oil pipeline is supported above the ground, to minimize permafrost damage, trucks and other heavy equipment used in construction and exploration for oil in the Arctic leave behind deep trenches and a scarred landscape. The debate over drilling in the Alaskan Arctic Wildlife Refuge (ANWR) is a heated one. Proponents of drilling in this vulnerable environment point to the United States' dependence on foreign oil. Opponents to drilling in ANWR say that if the US increased fuel efficiency for cars, SUV, and light trucks from 24 to 39 miles per gallon, it would save 51 billion barrels of oil over the next 10 years. Some argue that exploration would affect only a small portion of the "adesolate tundra". Others point out that legislation was passed 30 years ago to raise the fuel standards for light trucks and cars to 27.5 mpg. In the early 1980s that standard was relaxed to 24 mpg. The difference in oil consumption for a single year between the lax legislation and the 27.5 mpg standard exceeds the most optimistic predictions of the total yield of the proposed drilling in the refuge (an estimated 5.7–16 billion barrels) (Van Deerlin, 2003).

The debate over drilling in the Arctic is related to the increasing temperatures that have been recorded in that region. Warming temperatures have been especially pronounced in the Arctic Tundra (Aleksandrova, 1980; Bliss and Matveyana, 1992; Chapman and Walsh, 1993; Keeling et al., 1996). In the last 100 years, portions of the Tundra have warmed by 10°C, which is 10 times the global average, and sea ice covers 15% less of the Arctic Ocean than it did 20 years ago (McFarling, 2002). The Tundra must be completely frozen before oil exploration can occur. On the North Slope of Alaska, the number of days that developers can venture onto the Tundra has decreased from 200 to 100 days over the past 30 years as freezing occurs later and melting begins earlier in the year (Pinsker, 2003).

Vegetation and animal communities have been monitored in the Tundra and have been shown to exhibit varying responses to the warming of that region. Browne (2002) reports that more than 75% of the Canadian Arctic Tundra is predicted to disappear, taking with it one in five of the species living there. Responses to rising temperatures at the micro-scale show changes in the vessel anatomy of Tundra plants (Gorsuch et al., 2001), and at the macro-scale the overall structure of the Taiga–Tundra ecotone has been altered (Payette et al., 2001). In an analysis of the period 1901–1995 the Tundra is a statistically significant outlier regarding the rate of warming in that region (Fraedrich et al., 2001). Species and systems alike are making manifest the substantial repercussions of climate change.

TURBULENCE AND DIFFUSION

Analysis and forecasting of meteorological motions usually is based on observations 100 miles or more apart and, therefore, only reflect the behavior of large-scale motions. However, motions exist on all scales, down to perhaps a millimeter. Further, since the basic equations of meteorology are nonlinear, the small-scale motions interact with the large-scale features of the atmosphere by their ability to mix air with different large-scale characteristics. Sometimes meteorologists define *turbulence* as small-scale motion, i.e. motion on too small a scale to be described by ordinary weather data. On the other hand, students of fluid mechanics require their turbulence to have certain definite properties, such as important nonlinear effects, large random vorticity, and the ability to diffuse contaminants. Fortunately, most of the small-scale motion is of this character; yet certain small-scale phenomena, such as internal waves, should not be classed as turbulence.

Distribution of turbulence

Most atmospheric turbulence can be ascribed to one of two causes:

1. mechanical turbulence caused by rapid change of the large-scale wind from one point to another; and

2. heat convection, caused by heating from below or cooling from above.

There are three general regions in which turbulence is important: (1) near the ground; (2) in convective clouds (cumulus type); and (3) between 25 000 ft and 40 000 ft where turbulence often occurs in clear air (clear-air turbulence, CAT).

On a windy day, turbulence is always strong near the ground, since the wind vanishes right at the surface, and we thus have a strong wind shear. Such mechanical turbulence depends on the wind speed and is especially strong over rough terrain. Convection will increase the turbulence at daytime due to solar heating and will suppress it at night.

Cumulus clouds always indicate convection cells, and some of the most destructive turbulence occurs in cumulonimbus clouds, where the upward and downward motions may reach many tens of miles per hour. Turbulence near 30 000 ft (CAT) almost certainly is due to the rapid vertical variation of wind near the jet stream. Layers of excessive shear and turbulence often are less than 1000 ft thick and often are missed by conventional meteorological observing equipment. CAT appears to be most prominent over mountainous terrain.

These three general types of regions are characterized by strong vertical turbulent motions that might be felt by aircraft. It is possible that quasihorizontal eddies of scales of tens of miles are common throughout the atmosphere.

Structure of turbulence

In general, there are eddies of all sizes. The smallest tend to be *isotropic* – equally well developed in all directions; whereas the larger ones tend to have larger horizontal than vertical dimensions. Very close to the ground, eddies tend to be small (particularly of small vertical dimensions); therefore, these eddies can produce little vertical mixing; with increasing height, vertical mixing increases. In general, turbulence caused mechanically has smaller scales than turbulence caused by heating. Thus, when convective turbulence is added to mechanical turbulence, relatively slow fluctuations are superimposed on the fast variations previously present. Particularly, the fluctuations of wind direction are greatly amplified by adding convection to mechanical turbulence. In general, mechanical eddies near the ground are elongated in the direction of the wind, whereas convective eddies have about the same dimensions in all horizontal directions.

Effects of turbulence

Turbulence alters the distribution of the mean meteorological variables by its ability to produce vertical mixing. Since this is weakest near the ground, we find the strongest gradients immediately above the surface, with weaker gradients above. Since the mean winds are nearly horizontal, most of the vertical flux of momentum, moisture, and heat is produced by turbulence. Thus, evaporation requires turbulence to carry off the vapor.

Turbulence creates irregular patches of temperature and moisture, which are able to scatter electromagnetic waves and sound waves. For example, propagation of microwaves beyond the horizon has been ascribed to turbulence.

Turbulence affects structures such as towers, planes, bridges, missiles, etc. Not only does turbulence increase the maximum wind far above the mean wind, but fluctuations within particular periods can produce resonance with certain

natural modes of vibrations of the structures, producing failure of the structures.

Turbulence produces mixing of concentrated contaminants with the surrounding air, a process called *turbulent diffusion*. This is particularly important in connection with general air pollution and with problems involving atomic debris, poisonous missile fuels, and chemical and biological warfare. The treatment of diffusion is described in the next section.

Turbulent diffusion

The coefficient of molecular diffusivity in air is so small that molecular diffusion almost always can be neglected compared to turbulent diffusion (spreading of contaminants by turbulent mixing). In most diffusion problems the source strength is given, as well as some characteristics of the atmosphere; required are either instantaneous concentrations at various points or average concentrations (dosages). Originally, this type of problem was usually attacked by writing an equation analogous to the molecular diffusion equation, but with the molecular diffusivity replaced by a much larger *turbulent* diffusivity. However, whereas the molecular diffusivity is often a constant, the turbulent diffusivity varies with height above ground and meteorological conditions. Further, the turbulent diffusivity may depend on the geometry of the contaminant (since only eddies smaller than the contaminant cloud can mix efficiently). However, the geometry of the contaminant depends on the diffusivity, so that this technique presents severe theoretical difficulties. Nevertheless, it has been used for vertical spreading from ground sources, with particular success, both in the United States and abroad. Usually, wind and diffusivity are assumed to be power laws of height so that exact mathematical solutions are possible.

Another technique of solving diffusion problems is based on the assumption that the concentration of contaminants follows a Gaussian (normal) distribution, a reasonable assumption because the turbulent wind field is very nearly Gaussian. The theoretical expressions are then made more precise by the requirement of continuity – namely, that material once emitted cannot disappear.

The resulting equations contain some unknown parameters that describe the dimensions of the cloud or plume. Usually these are related statistically to the time after emission and to the energy of the turbulence. The energy of the turbulence can be measured locally (for short-range diffusion estimates), or it can be related to the large-scale distribution of wind, temperature, and roughness in the atmosphere. Corrections have to be made for deposition rate of fall in case of large impurities, washout, and chemical interactions. In connection with air pollution regulations, a form of the Gaussian technique for pollution estimates most commonly used is the Pasquill–Gifford method. Here lateral and vertical plume spread are computed from graphs based on empirical relations between plume spread, solar radiations, and wind. Numerical approximations to these graphs are also available, which, in addition, allow for the effect of varying ground roughness on turbulent intensities.

It has been recognized that the vertical distribution of pollutants can be far from Gaussian, particularly on clear days in light winds. For example, the height of maximum concentration does not remain at the level of emission, but descends to the ground, only to rise again later. Thus, a relatively new technique has been developed for clear, convective days. New length and velocity scales are chosen: the thickness of the

mixed layer h and w^* , a velocity depending on the surface heat flux and this thickness. If all quantities are normalized by these scales, universal curves for normalized concentration as function of normalized distance and normalized height can be derived for different normalized source heights, which are equally valid in the atmosphere and in laboratory models.

A distinction must be made between continuous sources discussed so far (such as a stack) and instantaneous sources (such as an atomic bomb). In the case of a continuous source, the greatest concentration occurs along the mean wind direction. Variations of horizontal and vertical wind directions on all time scales diluted the average concentration measured at a given point. For an elevated source the greatest concentrations on the ground occur with light winds and strong vertical turbulence.

In the case of an instantaneous source, only small eddies spread the contaminant initially; the large eddies just transport the whole puff in various directions. Thus, the concentration remains high near the center of the puff, the material remains concentrated, and only a relatively small volume of air is affected

by the contamination initially. Larger eddies take over later and dilution increases.

ULTRAVIOLET RADIATION

In general scientific usage, *ultraviolet radiation* refers to radiant emissions in that portion of the electromagnetic spectrum between X-rays and visible radiation, i.e. in the wavelength range 0.01–0.4 μm approximately. However, outside the Earth's atmosphere, 99% of the solar irradiance occurs in the spectral range 0.15–4 μm; hence, climatologically significant ultraviolet radiation is that lying between 0.15 μm and 0.4 μm in the spectrum, a band containing about 9% of the radiant energy of solar origin prior to atmospheric attenuation. Solar ultraviolet radiation is conventionally subdivided into three wavelength bands, based primarily on potential biological activity: UV-A (0.32–0.4 μm), UV-B (0.28–0.32 μm), and UV-C (<0.28 μm).

Radiation with wavelengths shorter than 0.21 μm (most of the UV-C) is absorbed by oxygen and nitrogen in processes of ionization, dissociation, and heating at elevations in excess of 80 km in the thermosphere and ionosphere. However, most absorption takes place in the stratosphere, where ozone absorbs radiation in the wavelength range 0.21–0.31 μm. Collectively, these attenuation processes reduce the solar irradiance at the surface by only about 3% on a global, annual basis. Nevertheless, ozone's absorption of ultraviolet radiation to a large extent maintains the temperature structure of the stratosphere. As a result, solar radiation at the Earth's surface lacks UV-C and is deficient in UV-B, possessing little radiant energy at wavelengths shorter than 0.31 μm.

Large percentage fluctuations have been detected in the monochromatic irradiance received outside the atmosphere at ultraviolet wavelengths, primarily associated with solar activity. Because the magnitude of these fluctuations is greatest at the extreme short end of the solar ultraviolet, and decreases with increasing wavelength, the effect on the spectrally integrated solar irradiance is small (probably less than 0.1%). However, changes in stratospheric warming resulting from

irradiance fluctuations in the far ultraviolet have been linked to dynamic processes occurring in the troposphere by some authors, and speculation has ensued that longer-term variations in ultraviolet emissions by the sun may be responsible for climate changes.

Concern has been expressed about the role of stratospheric ozone depletion, brought about by the introduction of chlorofluorocarbons and other byproducts of human activity into the atmosphere, in increasing UV-B irradiances at ground level. Ultraviolet radiation, particularly at wavelengths shorter than 0.3 μm, has strong actinic effects, and excessive exposure to such radiation has been linked to sunburn, skin cancer, and eye disease in humans. Deleterious effects on terrestrial and marine ecosystems also have been suggested, as well as the potential for adverse effects on air quality. Nevertheless, this radiation possesses beneficial attributes such as forming vitamin D in the skin and devitalizing bacteria and similar microorganisms of disease.

UNITS AND CONVERSIONS

The strength and utility of a measurement system depends on the existence of a consistent set of units and standards around which a complete system can develop. These fundamental standards of weights and measures are maintained on a federal level in the United States by the National Bureau of Standards. On a worldwide level the International Bureau of Weights and Measures in Paris, which was established by the Treaty of Meter in 1875, sets the standard.

The Treaty of Meter also provided for an International Conference of Weights and Measures to meet at regular intervals. In 1957 this conference changed the world standard of length from the platinum–iridium meter bar to a multiple (1 650 763.73) of the wavelength of orange-red light of krypton 86. This new wavelength standard has several advantages over the metal one. It is indestructible, immutable, a constant of nature, and can be reproduced anywhere in the world with an accuracy of one part in one hundred million. In 1960 this same conference adopted an International System of Units (abbreviated SI for Système International). The SI is a metric system based on seven fundamental physical quantities in terms of which all others are to be defined so as to be consistent with the generally accepted equations of physics. These quantities and their units are mass (kilogram), length (meter), time (second), temperature (Kelvin), current (ampere), and luminous intensity (candela). The seventh unit, the mole, was adopted in 1971.

The SI supplants the older cgs and mks systems, although they are still the two most commonly used. In the United States the customary system still employed by established tradition uses the foot, pound, and second; these are defined in terms of the SI units by simple numerical ratios. This customary system, inherited from Britain, is widely used in industry and commerce in both the United States and much of the English-speaking world, but it is not inherently consistent and is little used for strictly scientific measurements. Certain units of measurement, e.g. the nautical mile, which is equivalent to one degree of latitude, have such obvious value that it will be difficult to replace them.

Metric units of measurement

In the metric system of measurement, designations of multiples and subdivisions of any unit may be arrived at by combining with the name of the unit the prefixes deka, hecto, and kilo meaning, respectively, 10, 100, and 1000, and deci, centi, and milli, meaning, respectively, one-tenth, one-hundredth, and one-thousandth. In certain cases, particularly in scientific usage, it becomes convenient to provide for multiples larger than 1000 and for subdivisions smaller than one-thousandth. Accordingly, the following prefixes have been introduced and these are now generally recognized:

yotta (Y), meaning 10^{24}	deci (d), meaning 10^{-1}
zetta (Z), meaning 10^{21}	centi (c), meaning 10^{-2}
exa (E), meaning 10^{18}	milli (m), meaning 10^{-3}
peta (P), meaning 10^{15}	micro (μ), meaning 10^{-6}
tera (T), meaning 10^{12}	nano (n), meaning 10^{-9}
giga (G), meaning 10^9	pico (p), meaning 10^{-12}
mega (M), meaning 10^6	femto (f), meaning 10^{-15}
kilo (k), meaning 10^3	atto (a), meaning 10^{-18}

hecto (h), meaning 10^2 zepto (z), meaning 10^{-21}
 deka (da), meaning 10^1 yocto (y), meaning 10^{-24}

These prefixes increasingly are used with data exchanges. The bit (b) and byte (B) are the standard unit of data quantity, and Gb, MB and GB are commonly used.

Time

Second: the standard unit of time. It was originally defined as 1/86400 of a mean solar day, but the standard was changed in 1960 by the Eleventh General Conference on Weights and Measures to be 1/31 556 925.9747 of the tropical year 1900. The second is the duration of 9 192 631 770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the cesium 133 atom. The present standard avoids the variability caused by changes in the Earth's period of rotation about its axis.

1 minute = 60 seconds
 1 hour = 3600 seconds
 1 sidereal month = 27.32167 days
 1 synodical month = 29.53059 days
 1 tropical (ordinary) year = 31 556 925.9747 seconds
 1 calendar year (common) = 31 536 000 seconds

Temperature

Temperature: a term used to express the relative intensity of heat. It is identified with the kinetic energy of translation of molecules and, in accordance with the kinetic theory of gases, has an absolute zero where all motion has ceased. It is also an aspect of matter that governs the ability to transfer heat from or to other matters. Heat will not transfer between two bodies if they are at the same temperature. There are three temperature scales currently employed: the Fahrenheit scale, the Centigrade (Celsius) scale, and the Kelvin scale. By international agreement, Celsius is favored over Centigrade, but the latter is still widely preferred.

Temperature scales – Centigrade (Celsius) to Fahrenheit

Equivalents
 $1\text{ C}^\circ = 1.8\text{ F}^\circ$
 $1\text{ F}^\circ = 0.5556\text{ C}^\circ$
 $1\text{ K (Kelvin)} = 1\text{ C}^\circ - 273\text{ C}^\circ = -459.4\text{ F}^\circ = 0\text{ K}$

Conversion formulas
 $\text{F}^\circ = 9/5\text{ C}^\circ + 32$
 $\text{C}^\circ = 5/9 (\text{F}^\circ - 32)$

Note: F° is read “degrees Fahrenheit”
 C° is read “Fahrenheit degrees”
 C° is read “degrees Centigrade or Celsius”
 C° is read “Centigrade or Celsius degrees”

$1\text{ F per foot} = 0.0182269\text{ C per centimeter}$
 $1\text{ C per centimeter} = 54.864\text{ F per foot}$
 $1\text{ ft per F}^\circ = 0.54864\text{ m per C}^\circ$
 $1\text{ m per C}^\circ = 1.82269\text{ ft per F}^\circ$

Mass and weight

Gram: the unit of mass in the metric system that was first defined to be equal to the mass of a cubic centimeter of pure

water at the temperature of its maximum density (4°C). A platinum cylinder was made, known as the kilogram, and declared to be the standard for 1000 grams.

Gram-atomic weight: the atomic weight of an element expressed in grams, customarily based on a scale on which the gram-atomic weight of oxygen is 16 000 grams, but more precisely, based on a scale on which the gram-atomic weight of carbon 12 is 12 000. The gram-atomic weight of all elements contains the same number of atoms. This number, called Avogadro's number, is 6.032×10^{23} and is termed a gram atom.

Gram-equivalent weight: the equivalent weight of an element or compound expressed in grams, customarily based on a scale on which the equivalent weight of oxygen is 8000 grams. It is the gram-atomic weight of an element (or formula weight of a radical) divided by the absolute value of its valence (oxidation state).

Gram-molecular weight: the molecular weight of an element or compound expressed in grams. The gram-molecular weight of all elements or compounds contains the same number of molecules, 6.032×10^{23} (Avogadro's number), and is termed one mole.

Ton: in the United States a ton is a unit of weight equal to 2000 pounds, commonly called a short ton. The long ton, more widely used in England, is equal to 2240 pounds. The metric ton is equal to 1000 kilograms.

1 short ton = 0.90718 metric ton = 0.892857 long ton
 1 long ton = 1.12 short tons = 1.016047 metric tons
 1 metric ton = 0.984207 long ton = 1.10232 short tons
 1 pound (avoirdupois) = 7000 grains = 16 ounces
 1 ounce (av.) = 437.5 grains
 1 ounce (troy) = 480 grains
 1 pound (troy) = 5760 grains
 1 ounce (apothecaries) = 480 grains
 1 kg = 10^3 g = 2.20462 lb
 1 lb = 0.453592 kg = 453.592 g

Linear measures

Meter: the standard unit of length in the metric system. It was first defined by a platinum end standard, the meter of the archives, in Paris. This length, based on a measure of an arc from Dunkirk, France, to Montzuiich, Spain, was to be one ten-millionth part of the meridional quadrant of the Earth. In 1889 at the first general conference of the International Bureau of Weights and Measures, the meter was redefined in terms of the platinum-iridium bar known as the international prototype meter at the international bureau. This standard meter is now defined as 1 650 763.73 times the wavelength in a vacuum of krypton 86.

The **micron** is a unit of length equal to 10^{-6} meters. It is commonly employed in the measure of short distances such as the wavelength of light and is represented by the Greek letter $\mu\text{\AA}$. The Angstrom unit (\AA) is also used for wavelengths; one $\text{\AA} = 10^{-10}$ m.

Mile: the mile most commonly used in English-speaking countries is the English or statute mile of 5280 feet. This distance was supposedly designated by 1000 paces of the Roman Legions stationed in Britain. Navigators use the nautical mile, which was originally defined as the length of one minute of arc on a great circle drawn on the surface of a sphere with the same area as the Earth. This length is 6080.27 feet. However, since the Earth is an oblate spheroid flattened at the poles, the length

of one minute of arc measured along a meridian varies in different latitudes. It is shortest near the poles and longest near the equator with an average length of 6077.015 feet. To resolve this confusion, an international agreement was made defining the nautical mile as 1852 meters, the present value of the international nautical mile. The United States nautical mile, equal to 1.00067387 international nautical miles, and the British nautical mile, equal to 1.00063931 international nautical miles, are occasionally used.

Foot: a unit of length used in the British system of units and employed in English-speaking countries. It was originally standardized in England in 1870 as one-third the length of a yard. In 1959 the foot was defined as 0.3048 meter in accordance with an agreement among the directors of the standards laboratories of English-speaking countries. As a linear measure the foot is of great antiquity, originally identified as the length of a man's foot.

Yard: the fundamental distance in the English measuring system is taken as the distance at 62°F between two fine lines on gold plugs in a bronze bar at Westminster, England, known as the Troughton scale. In 1893 the yard was redefined as 3600/3937 meter.

1 cm = 0.39370 in = 0.032808 ft
 1 km = 10^5 cm = 0.62137 mile
 1 fathom = 6 ft = 1.8288 m
 1 nautical mile = 1.85325 km
 1 in = 2.54001 cm
 1 ft = 30.480 cm
 1 statute mile = 1.60935 km = 5280 ft
 1 astronomical unit = 1.496×10^8 km = 92 957 000 miles
 1 light year = 9460×10^{12} km = 5.878×10^{12} miles
 1 parsec = 3.085×10^{13} km = 1.917×10^{13} miles

Metric to English units – equivalents of length
 1 micron (μ) = 0.001 millimeter (mm) = 0.00004 inch (in)
 1 mm = 0.1 centimeter (cm) = 0.03937 in
 1000 mm = 100 cm = 1 meter (m) = 39.27 in = 3.2808 feet (ft)
 1 m = 0.001 kilometer (km) = 1.0936 yards (yd)
 1000 m = 1 km = 0.62137 mile
 1 in = 2.54 cm
 12 in = 1 ft = 0.3048 m

Square measures

1 square ft = 0.00002295684 acre
 1 acre = $43 560 \text{ ft}^2$ = 0.0015625 mile 2
 1 square yard = 0.836127 m 2
 1 hectare = 2.471054 acres
 1 square mile (statute) = 640 acres
 1 square cm = 0.1550 square in = 0.0010764 square ft
 1 square km = 10^{10} square cm = 0.3861 square mile
 1 square in = 6452 square cm
 1 square ft = 929.0 square cm
 1 square mile = 2.5900 square km
 1 mm 2 = 0.00155 in 2 1 in 2 = 6.452 cm 2
 1 m 2 = 10.764 ft 2 1 ft 2 = 0.09290 m 2
 1 km 2 = 0.3861 mile 2 1 mile 2 = 2.5900 km 2

Cubic measures

1 gal (UK) = 4.5461 liters = 1.200956 gal (US)
 1 liter = 0.219969 gal (UK) = 0.264173 gal (US)

1 gal (US) = 3.7854 liters	= 0.832670 gal (UK)
1 cc = 0.0610 cu in	= 0.000035314 cu ft
1 cu in = 16.387 cc	
1 cu ft = 28.317 cc	
1 mm ³ = 0.000061 in ³	1 in ³ = 16.387 cm ³ (cc)
1 cm ³ (cc) = 0.0610 in ³	1 ft ³ = 0.028317 m ³
1 m ³ = 35.315 ft ³	1 mile ³ = 4.1681 km ³
1 km ³ = 0.239911 mile ³	

Velocity

1 knot = 51.4 cm/s
1 ft/s = 30.480 cm/s = 1.0973 km/h
1 mi/h = 1.6093 km/h = 44.704 cm/s
1 cm/s = 3.728×10^{-4} mile/min = 0.02237 mile/h
1 km/h = 27.7778 cm/s
1° ψ per day = 1.2863 m/s = 2.8774 mile/h = 2.4987 knots

Force

As units of force, frequency gram weight, kilogram weight, pound weight, etc., are used. We denote them here by g*, kg*, and lb*.

1 dyne = 0.0010197 g* = 2.2481×10^{-6} lb* = 1 g/s ²
1 megadyne = 10^6 dynes
1 g* = 980.665 dynes
1 kg* = 980.665×10^3 dynes
1 lb* = 4.4482×10^5 dynes

Pressure

The SI unit of pressure is the pascal, symbol Pa, the special name given to a pressure of one newton per square metre (N/m²). The relationships between the pascal and some other pressure units are shown in Table U1, but note that not all are, or can be, expressed exactly.

Following the Eighth Congress of the World Meteorological Organization in 1986, the term hectopascal (hPa) is preferred to the numerically identical millibar (mb) for meteorological purposes. This choice was made, despite the fact that hecto ($\times 100$) is not a preferred multiple in the SI system.

The so-called “manometric” pressure unit definitions such as millimeters of mercury and inches of mercury depend on an assumed liquid density and acceleration due to gravity, assumptions which inherently limit knowledge of their relationship with the pascal. In order to encourage the demise of non-SI units, whose definitions are becoming inadequate for the most precise measurement of pressure, there is international effort to exclude them from conversion tables or, in the meantime, restrict the precision of newly published conversion factors.

Table U1 Units of pressure

Unit	Symbol	No. of pascals
bar	bar	1×10^5
millibar	mb	100
hectopascal	hPa	100
conventional millimeter of mercury	mmHg	133.322...
conventional inch of mercury	inHg	3 386.39...
torr	torr	10 1325/760
pound-force per square inch	lbf/in ²	6 894.76...

The torr is defined as exactly 101325/760 Pa – the “760” coming from the original and arbitrary definition of standard atmosphere. Its value differs from the conventional millimeter of mercury by about 1 part in 7 million.

Other pressure units and conversions include the following.

1 barye = 1 dyne/cm ² = 9.8692×10^{-7} atmosphere = 10^{-6} bar = 1.4504×10^{-5} lb/sq in
1 bar = 10^6 baryes = 10^6 dynes/cm ² = 0.98692 atmosphere = 14.504 lb/sq in = pressure of 750.06 mm of Hg
1 millibar = 10^{-3} = 10^3 dynes/cm ² = pressure of 0.75006 mmHg
1 megabar = 10^6 bars
1 kg/cm ² = 0.980665×10^6 dynes/cm ² = 14.233 lb/sq in
1 lb/sq ft = 4.7254×10^{-4} atmosphere = 478.80 dynes/cm ² = 47.880 newtons/m ²
1 lb/sq in = 0.068046 atmosphere = 0.068947 bar = 6.8947 × 10^4 dynes/cm ² = 6894.8 newtons/m ²
1 atmosphere = 1.0332 kg/cm^2 = 1.01325 bars = 14.7 lb/sq in = pressure of 760 mmHg at 0°C and g = 980.665 cm/s ²

Energy–work

Foot candle: the unit of illumination in general use in the United States. This is defined as the illumination on an area, one foot square, on which there is a luminous flux of one lumen uniformly distributed. It may also be defined as the illumination on a surface of which all points are at a distance of one foot from a uniform point source of one candle.

Foot-lambert: a unit of luminance defined as the uniform luminance of a perfectly diffusing surface either emitting or reflecting light at the rate of one lumen per square foot. It may also be defined as 1/n candle per square foot and is sometimes referred to as the apparent foot-candle.

Foot-pound: a unit in the English gravitational system; it may be defined in two ways: (1) a unit of energy equal to the work done when one pound of force displaces a point to which the force is applied one foot in the direction of the applied force; (2) a unit of torque equal to the time-rate of change of angular momentum produced by a pound of force acting at a perpendicular distance of one foot from the axis of rotation.

Foot-poundal: a unit in the English absolute system; it may be defined either as a unit of energy, equal to the work done by a force of magnitude one poundal when the point at which the force is applied is displaced one foot in the direction of the force, or as a unit of torque equal to the time rate of change of angular momentum produced by a force of magnitude one poundal acting at a perpendicular distance of one foot from the axis of rotation.

Calorie: used in the cgs system, this unit represents the quantity of heat required to raise 1 gram of water through 1°C (at 15°C).

Kilocalorie: equal to 10^3 calories, this is often cited as a calorie in metabolic studies. This use has led to considerable confusion.

Langley: proposed in 1942 as a solar radiation unit. Initially given as calories per sq cm per minute, the time dimension was dropped in 1947. Thus 1 Langley = 1 cal/cm² = 697.8 W m⁻². The unit was named for S.P. Langley (1834–1906) of the Smithsonian Institution.

British thermal unit (BTU): the energy required to raise the temperature of one pound of water through 1°F (39° to 40°F).

1 erg = 1 dyne centimeter = 1 g cm²/s²

1 joule = 10^7 ergs = 0.102 m kg* = 0.737 ft-lb

1 gram calorie corresponds to 4.19×10^7 ergs
 1 watt = 10^7 ergs per second = 1 joule per second
 1 horsepower = 746 watts
 British thermal unit (39°F) (Btu) = 1060.4 joules (absolute)
 British thermal unit (60°F) (Btu) = 1054.6 joules (absolute)
 Gram-calorie (mean) = 1.5593×10^{-6} horsepower

Energy flow representation

In attempting to standardize the representation of energy flow, the World Meteorological Organization (1971) suggests the following symbols:

$Q\downarrow$ ($Q\downarrow = K\downarrow + L\downarrow$)	Downward radiation
$K\downarrow$ ($K\downarrow = S + D$)	Global solar radiation
S	Vertical component of direct solar radiation
D	Diffuse solar radiation
$L\downarrow$ ($A\downarrow$) ($L\downarrow = A\downarrow$)	Downward atmospheric radiation
$Q\uparrow$ ($Q\uparrow = K\uparrow + L\uparrow$)	Upward radiation
$K\uparrow$	Reflected solar radiation
R	Upward solar radiation reflected by Earth's surface alone
$L\uparrow$	Upward terrestrial radiation
Lq	Upward terrestrial radiation – surface
r	Reflected atmospheric radiation
$A\uparrow$	Upward atmospheric radiation
Q	Net radiation
K^*	Net solar radiation
L^*	Net terrestrial radiation

Given these symbols, components of the Earth's budget can be represented by equations. Of particular importance is net radiation.

$$\text{Net radiation} = \text{Incoming} - \text{Outgoing}$$

$$Q = Q\downarrow - Q\uparrow$$

$$\text{or } Q^* = K^* + L$$

$$\text{Since } K^* = K\downarrow - K\uparrow \text{ and } L^* = L\downarrow - L\uparrow$$

$$Q^* = (K\downarrow - K\uparrow) + (L\downarrow - L\uparrow)$$

alternatively

$$\text{Since } Q\downarrow = K\downarrow + L\downarrow \text{ and } Q\uparrow = K\uparrow + L\uparrow$$

$$\text{then } Q^* = (K\downarrow + L\downarrow) - (K\uparrow + L\uparrow)$$

URBAN CLIMATOLOGY

Urbanization and climate

The process of urbanization significantly alters natural surface and atmospheric conditions. Oke, in Thompson and Perry (1997), suggests that urban atmospheres demonstrate the strongest evidence we have of the potential for human activities to change climate. In the twentieth century rapid urbanization has occurred on a worldwide scale and the majority of the world's population lives in cities. Rapid expansion of cities has produced concurrent alterations in the urban climatic environment (Landsberg, 1981).

In general there are many apparent anthropogenic impacts on our atmospheric environment (Changnon, 1983). These range from microscale (e.g. replacing trees with a parking lot) to macroscale (e.g. carbon dioxide effects on global climate by fossil fuel combustion and emissions). This discussion focuses on the causes of alterations in climate in urban areas. Processes are reviewed that are keys to the formation of an urban climate and the underlying energy, moisture, and air movement patterns that distinguish urban climates from their surroundings.

An extensive literature addresses the specific problem of air pollution on regional and global scales as it relates to general processes of urbanization. The field of urban climatology has developed to the level of theory and detailed investigations that we see today in part due to early interests in air quality in cities. This discussion, however, does not focus on air pollution effects *per se*. Urban climate can be understood, to a large degree, by the study of modifications which develop primarily through the effects of land-use changes and feedbacks into the energy, moisture, and local air motion systems. Air quality certainly plays a role. The following discussion is limited to micro-, local, and meso-scales. It is also restricted to processes taking place in what are called the urban canopy

layer (UCL – beneath roof level) and the urban boundary layer (UBL – extending from roof level to the height at which urban influences are absent; Oke, 1998, see Figure U1).

The first real growth of urban climatology dates from the 1920s, followed by rapid increases in interest in urban climates between the 1930s and 1960s (especially in Germany, Austria, France, and North America). After World War II, and into the environmental era of the 1960s and 1970s and beyond, there was an exponential increase in urban climatic investigations. Investigations have simultaneously become less descriptive,

more oriented to quantitative and theoretical modeling, and more integrative and interdisciplinary (e.g. World Meteorological Organization, 1970; de Dear et al., 2000). There are many scholarly reviews of the subject and accompanying bibliographies that illustrate the overall problem of how cities alter their climatic environment (e.g. Brazel, 1987; Chandler, 1976; Beryland and Kondratyev, 1972; Landsberg, 1981; Lee, 1984; Oke, 1974, 1979, 1979, 1980; and in Bonan, 2002). Today, urban climatology has achieved its own recognition as a subdiscipline in climatology and among allied disciplines such

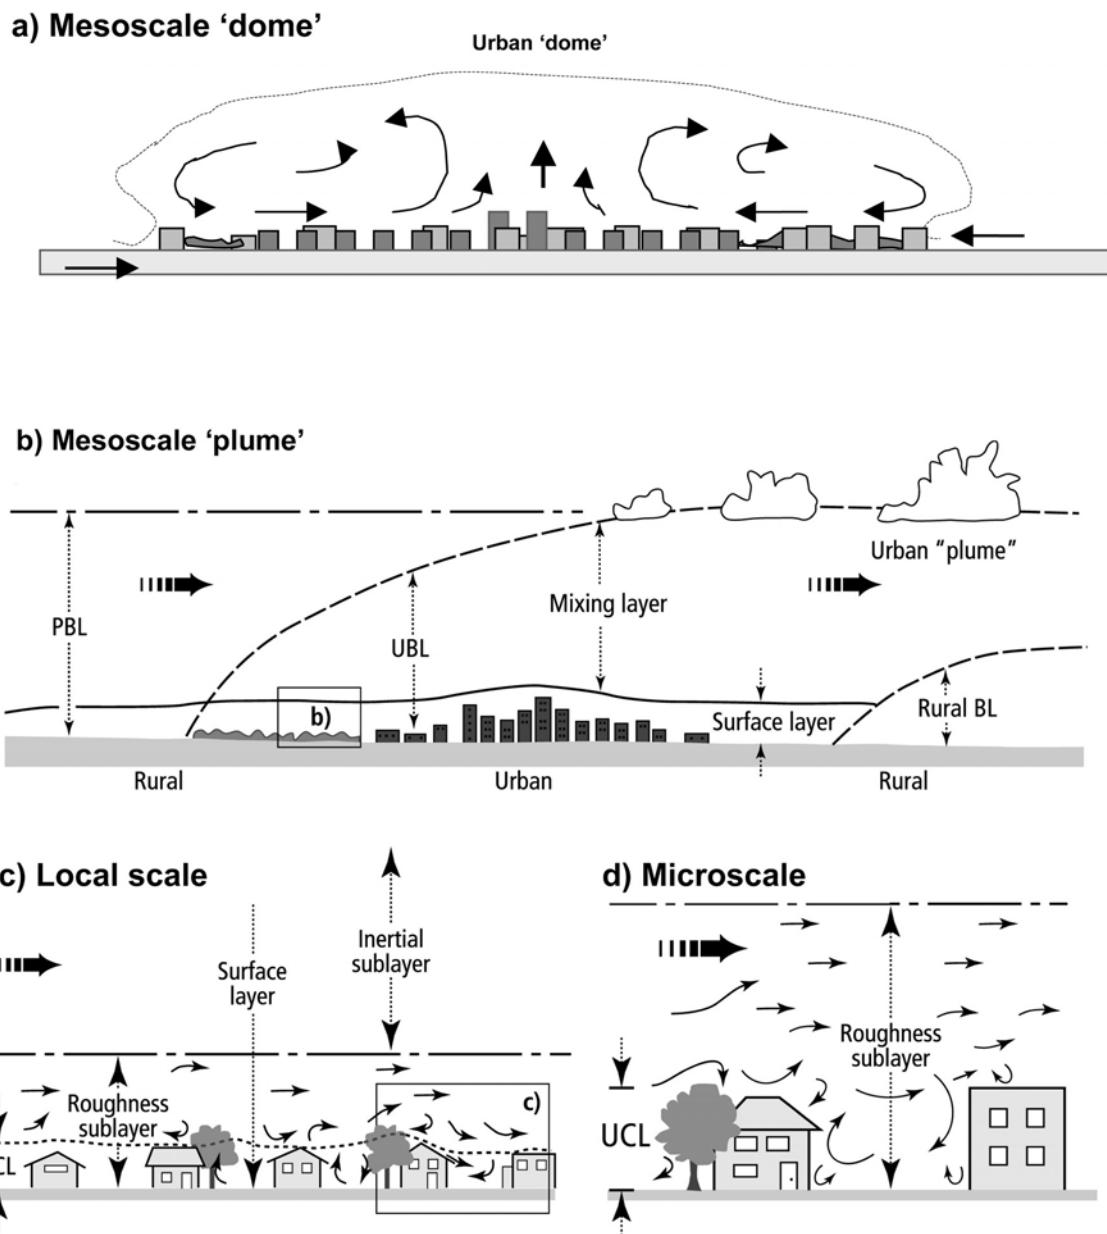

Figure U1 The idealized vertical structure of urban-modified air. (a) The whole city (mesoscale) in near-calm conditions with its “dome”, and (b) in a steady regional air flow with its urban “plume”. (c) A single urban terrain zone (local scale) showing the internal layering of the urban canopy (UCL) and lower portion of the urban boundary (UBL) layers. (d) A single street canyon (microscale) and building elements (after Oke, 1998).

as planning, ecology, environmental science, and meteorology (e.g. as evidenced in de Dear et al., 2000).

Factors controlling urban climates

Many aspects of urbanization change the physical environment and lead to alterations in energy exchanges, thermal conditions, moisture fluxes (evaporation, precipitation, and runoff) and wind circulation systems. These include: (1) air pollution, (2) anthropogenic heat, (3) surface waterproofing, (4) thermal properties of the surface materials, and (5) surface geometry (Oke, 1981). Other factors that must be considered relate to the setting of the city, such as relief, proximity to water bodies, size of the city, population density, and land-use distributions. Oke (1997) provides a summary of the typical resulting alterations of climatic elements in cities compared to rural environs (see Table U2).

The magnitude–frequency concept is important but less studied in urban climatology. How large are climatic alterations in a city and how often are they that large? The latter part of the question demands analysis of the linkages of microscale–mesoscale alteration magnitudes with more macroscale conditions, such as the role of synoptic climatology on urban climate variations (e.g. Unwin, 1980). Typically, cloudy and/or windy days reduce heat island magnitudes for a city.

Urbanization causes changes in the energy, moisture, and momentum systems, but few studies demonstrate pre–post urban climate conditions (Lowry, 1977). One excellent example is the experiment conducted to specifically illustrate how a city, as it developed from a rural environment, affected the local and regional climate (Landsberg, 1981). Most urban climate studies rely on geographic comparisons between the city and its surroundings in order to produce an estimate of the urban effect

Table U2 Urban climate effects for a mid-latitude city with about 1 million inhabitants (values for summer unless otherwise noted)

Variable	Change	Magnitude/comments
Turbulence intensity	Greater	10–50%
Wind speed	Decreased	5–30% at 10 m in strong flow
	Increased	In weak flow with heat island
Wind direction	Altered	1–10 degrees
UV radiation	Much less	25–90%
Solar radiation	Less	1–25%
Infrared input	Greater	5–40%
Visibility	Reduced	
Evaporation	Less	About 50%
Convective heat flux	Greater	About 50%
Heat storage	Greater	About 200%
Air temperature	Warmer	1–3°C per 100 years; 1–3°C annual mean up to 12°C hourly mean
Humidity	Drier	Summer daytime
	More moist	Summer night, all day winter
Cloud	More haze	In and downwind of city
	More cloud	Especially in lee of city
Fog	More or less	Depends on aerosol and surroundings
Precipitation		
Snow	Less	Some turns to rain
Total	More?	To the lee of rather than in city
Thunderstorms	More	
Tornadoes	Less	

Source: Adapted after Oke (1997), p. 275.

on local climate. Considerable attention has been given to the study of historical weather records in cities to evaluate temperature trends that are more urban in origin versus trends more attributable to global signals of change (e.g. global warming). A large number of stations with long records are needed for trend analyses, and many of the world's weather stations are in or near urban-affected locales. Thus, it is often difficult to decipher global change from such sites (e.g. Hansen, et al., 1999, 2001). Furthermore, placing typical weather stations in urban areas to study how cities alter climate is a most challenging endeavor in and of itself (Oke, 1999). This arises because of the complex structure of the urban atmosphere, processes operating at differing scales, and the resultant climate patterns in the city (see Figure U1, after Oke, 1998).

Methods of evaluating urban climate

Many methods are used to determine how a city affects climate. Early methodologies included sampling the differences between urban–rural environments, upwind–downwind portions of the urban area, urban–regional ratios of various climatic variables, time trends of differences and ratios, time segment differences such as weekday versus weekend, and point sampling in mobile surveys throughout the urban environment (Lowry, 1977). Much of this sampling led to the discovery of the famous heat-island phenomenon.

Methodological inadequacies of many of the early studies have been pointed out in recent decades, and accurate time-series data remain a problem of analysis (Lowry, 1977; myriad studies on filtering out urban effects to reveal global trends). These inadequacies led to increased studies of processes involved, particularly fluxes of energy, moisture, and momentum in urban environments. Process studies help to provide a better characterization of how urbanization alters the surface–atmospheric system (Oke, 1979). Much attention has been given to internal variability of climate conditions within the urban environment and to the importance of the UCL (Arnfield, 1982; Grimmond, 1992; Grimmond and Oke, 1995, 1999; Johnson and Watson, 1984; Oke, 1981).

The urban heat island

Cities, no matter what their size, tend to be warmer than their surroundings. One can observe this biking through the urban landscape (Melhuish and Pedder, 1998). This fact was discovered by scientists well over a century ago (e.g. Howard, 1833), and is well known as evidenced by its mention in virtually every book on modern climatology and ecology (e.g. Thompson and Perry, 1997; Bonan, 2002). Since cities are regional agglomerations of people, buildings, and urban activities, they are spots on the broader, more rural surrounding land. These spots produce a heat-island effect on the spatial temperature distribution in an area (see Figures U7a and b in the later section on remote sensing).

The reasons for heat-island formation are many-fold (Table U3 after Oke, 1979). City size, morphology, land-use configuration, and geographic setting (e.g. relief, elevation, regional climate) dictate the intensity of the heat island, its geographic extent, orientation, and its persistence through time. Oke (1981) illustrates the effect of city size (as indicated by population size) on the maximum urban heat-island intensity (see Figure U2). Although population is only a surrogate measure for many of the causes of a heat island, there is a significant correlation

indicated, and population serves as a useful reference for expected heat-island formation.

In evaluating the heat-island intensity of cities, several cautionary notes must be emphasized. The method of sampling and/or the accuracy of historical weather records from available rural and urban locales must be carefully considered (Oke, 1999). Much of the earlier work in heat-island detection is of somewhat limited value due to non-specification of probable pre-urban conditions in an area, and biases in spatial sampling of the extent of the heat island (Lowry, 1977; Landsberg, 1981).

Table U3 Mechanisms hypothesized to cause the urban heat island effect

- Urban Boundary Layer
 - Anthropogenic heat from roofs and stacks
 - Entrainment of air scoured from warmer canopy layer
 - Entrainment of heat from overlying stable air by the process of penetrative convection
 - Shortwave radiative flux convergence within polluted air
- Urban Canopy Layer
 - Anthropogenic heat from building sides
 - Greater shortwave absorption due to canyon geometry
 - Decreased net longwave loss due to reduction of sky view factor by canyon geometry
 - Greater daytime heat storage (and nocturnal release) due to thermal properties of building materials
 - Greater sensible heat flux due to decreased evaporation resulting from removal of vegetation and surface waterproofing
 - Convergence of sensible heat due to reduction of wind speed in the canopy

Source: After Oke (1979).

Numerical adjustments of historical temperature records must be considered by the urban researcher, since available data may be biased (e.g. observation time of various stations may be different) and influences of local changes in station locations on temperature and precipitation statistics may go undetected (e.g. Winkler and Skaggs, 1981). The more process-oriented urban climatic studies in the last two decades are not only providing measures of explanation of the heat-island phenomenon, but also are allowing for a better understanding of the efficacy of the earlier, more descriptive studies of the urban heat island.

Radiation and energy balance of the city

Shortwave radiation

An urban area affects the exchanges of shortwave and longwave radiation by air pollution and complex changes of surface radiative characteristics. Figure U3 illustrates radiative fluxes and processes in a city atmospheric system and the profiles of shortwave radiative heating and longwave radiative cooling due to the existence of an urban aerosol layer. The attenuation of incoming shortwave radiation (fluxes 2 and 4 divided by 1; see Figure U3) has been analyzed in numerous urban climatic environments. It is thought that the attenuation in the city is 2–10% more than in the country. Generally, the ultraviolet portion of the electromagnetic spectrum (< 0.4 μm), the so-called UV, is depleted by as much as 50% (e.g. Petersen et al., 1978). However, total depletion across all solar wavelengths (0.15–4.0 μm) is much smaller, less than 10% (Petersen and Flowers, 1977; Petersen and Stoffel, 1980). The processes of scattering and absorption, which account for the attenuation, require further study to predict their relative contribution to total shortwave radiation depletion.

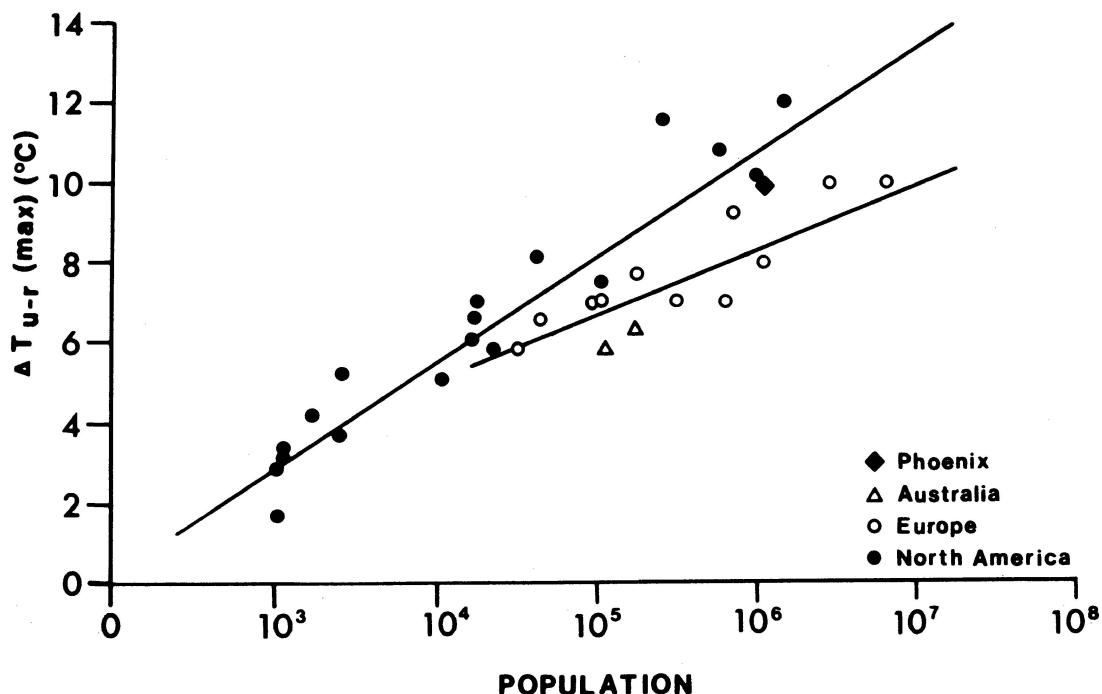

Figure U2 The maximum urban heat island intensity (ΔT_{u-r} [max]) versus population for 32 cities in Europe, North America, and Australia (data from Oke, 1981).

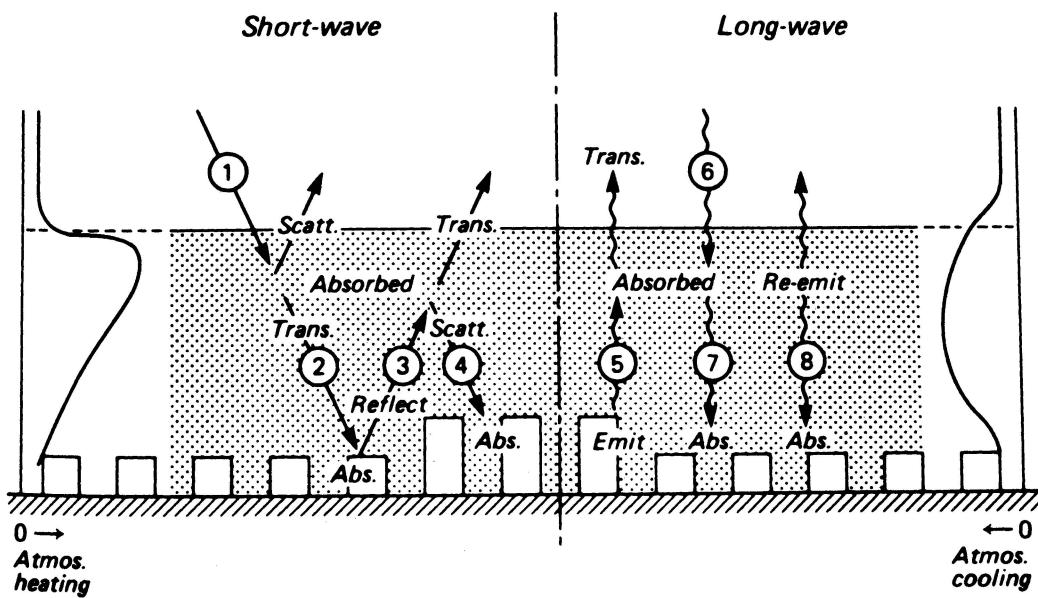

Figure U3 Radiative exchanges in a polluted urban boundary layer, including generalized profiles of shortwave radiative heating (left) and longwave cooling (right) due to the aerosol layer (shaded). Numbered fluxes are referred to in the text (after Atwater, 1971; Oke, 1982).

Albedo

The second major effect by the city is the change in the ratio of outgoing shortwave radiation (flux 3) to that of incident shortwave radiation at the complex, three-dimensional city interface (fluxes 2 and 4). This ratio, the albedo, is typically less in urban areas than in the surrounding landscape. Lower albedoes are due to darker surface materials making up the urban landscape mosaic and also due to effects of trapping of shortwave radiation by the vertical walls and the urban canyon-like morphology. There is considerable variation of albedo within the city depending on the percent vegetative cover, building material variation and roof composition, and land-use characteristics (see Table U4).

The difference in albedo between a city and its environs depends also, of course, on the surrounding terrain. A city surrounded by dark forest may experience very little albedo difference from the forest cover (both may range from 10% to 20%). In winter a midlatitude to high-latitude city with surrounding snow cover may display a much lower albedo than its surroundings. Thus, since cities receive 2–10% less shortwave radiation than their surroundings, yet have slightly lower albedoes (by less than 10%), most cities experience very small overall differences in absorbed shortwave radiation from rural locations nearby.

Longwave radiation

Longwave radiation is affected by city pollution and the fact that most urban surface areas are warmer. Warmer surfaces promote greater thermal emission of energy vertically upward from the city surface compared to rural areas, particularly at night (flux 5). Some longwave radiation is reradiated by urban aerosols back to the surface and also from the warmer urban air layer (fluxes 7 and 8). Thus, increases in incoming longwave

Table U4 Albedo values of urban surface materials

Material	Albedo (%)
Concrete	27.1
Blacktop/asphalt	10.3
Brick, red	32.0
Brick, yellow/buff	40.0
Brick, white/cream	60.0
Glass	9.0
Paint, dark	27.5
Paint, white	68.7
Roofing shingles	25.0
Snow, weathered	55.0
Stone	31.7
Tar-gravel roof	13.5
Yard (90% lawn, 10% soil)	24.0

Source: Data from Arnfield (1982), p. 104.

radiation and outgoing longwave radiation are usually experienced in urban areas (that is, fluxes 7 and 8 are greater than flux 6 would be at the urban surface).

It is thought that outgoing longwave radiation increases are slightly greater than the incoming increases in the city, again especially on clear, calm nights. During daytime there is little difference between the city and its surroundings. However, surface emissivity (amount emitted relative to black-body amounts for a given temperature) can be quite different between country and city areas, and can account for considerable longwave radiation variations (Yap, 1975). A major consideration is that in the city a three-dimensional surface temperature must be characterized to accurately estimate the flux values of radiation and the energy budget (e.g. Voogt and Oke, 1997, 1998).

Net all-wave radiation

Generally, variations in the shortwave and longwave radiation fluxes between a city and its environs are relatively small, and the net all-wave radiation (the balance between incoming and outgoing shortwave and longwave radiation) may actually be less in urban areas (e.g. in St Louis there is 4% less net radiation in the city; White et al., 1978). The exact differences depend on land use, city building density and arrangement, aerosol composition of the urban atmosphere and climate of the city surroundings, as well as other factors such as artificial heat emissions and the topography of the region. In the UCL, what is called the urban sky view factor (USVF) is decreased considerably below a totally unobstructed horizon. This latter condition is more typical of the countryside. An obstructed horizon consisting of structures that make up the UCL reduces radiative loss and can account for excess heat in the city (Oke, 1981). The emission of heat from the UCL structures has been hypothesized as explaining a city's heat-island intensity. Figure U4 shows a correlation of the UCL sky view factor with the maximum heat island intensity for 31 cities plotted in Figure U4. The USVF is specifically defined as:

$$\text{USVF} = (1 - 2\text{UWVF})$$

$$\text{UWVF} = 0.5(\sin^2 \theta + \cos \theta - 1)(\cos \theta)^{-1}$$

$$\theta = \tan^{-1}(H/0.5W)$$

where: H = height of UCL

W = width of the UCL.

Note the tightening of the correlation, indicating that for a given population, a European city has a more open geometry, whereas most US cities have deeper canyons in their core areas. The individual correlations of European–Australian and North

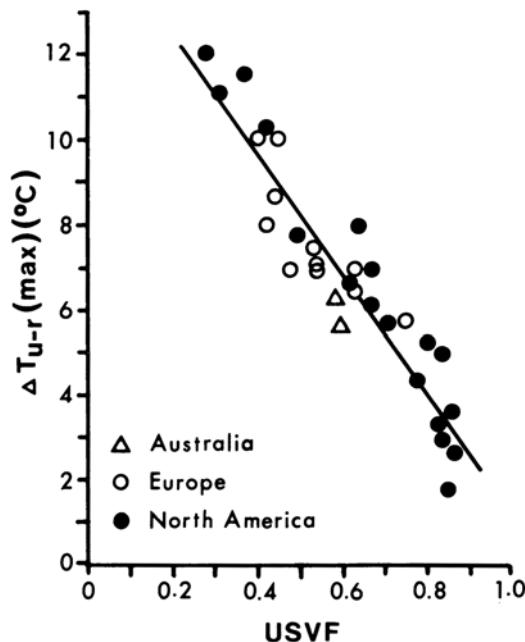

Figure U4 The maximum urban heat-island intensity (ΔT_{u-r} [max]) versus urban sky view factor (USVF) for 31 cities. The equation is ΔT_{u-r} (max) = $-13.3 \text{ USVF} + 14.86$ ($r^2 = 0.87$, standard error of the estimate = 0.96°C).

American population versus maximum heat-island intensities now merge into one generalized correlation shown in Figure U4. Urban climatologists are increasingly using photographic and GIS methods to derive USVF variability within cities. Figures U5a and b illustrate results for downtown Salt Lake City for USVF and building heights (Brown and Grimmond, 2001).

Total energy balance

Not many long-term studies of a city's entire energy balance have been made (Oke, 1979). One specific reason relates to important paradigms in climatology, shifting only in the last five decades to considering physical principles of the energy, moisture and mass exchanges at the Earth–atmosphere interface (Miller, 1965). However, over the last decade, many cities worldwide have been studied through the use of tall towers with energy flux sensors, GIS, remote sensing and modeling procedures (e.g. Grimmond, 1992; Grimmond and Oke, 1995, 1999).

The city energy budget or balance can be simplified in Figure U6a to:

$$Q^* + Qf = Qe + Qh + \Delta Qs + \Delta Qa$$

where: Q^* = net all-wave radiation

= $K^* + L^*$ (net shortwave and longwave radiation)

Qf = anthropogenic heat emission ($Qfv + Qfh + Qfm$)

Qe = latent heat flux

Qh = sensible heat flux

ΔQs = net heat storage in the city

ΔQa = net advection into or out of the city.

Since Q^* is not that different between a city and its surroundings, the observed heating in cities is likely accounted for by Qf , (Qe, Qh) , and ΔQs . Usually, ΔQa is negligible. The contribution of Qf to the total energy balance is highly city-dependent and seasonally variable. Qf ranges from nil to 300% of Q^* , depending on the degree of industrialization (Qf is high in more industrialized cities), latitude (Qf is high in higher-latitude cities), and season (Qf is higher in winter). Qf is composed of heat produced by combustion of vehicle fuels (Qfv), stationary source releases such as within buildings (Qfh), and heat released by metabolism (Qfm). Qfv is a function of type and amount of gasoline used, number of vehicles, distance traveled, and fuel efficiency. Qfh requires an analysis of consumer usage of fuel such as gas and electricity. Qfm can be evaluated by active and sleep rates. For people metabolic rates have been given (Oke, 1979). Bach (1970) suggests rates for animals.

Sensible, latent, and storage heat

The repartitioning of energy in urban areas among sensible, latent, and storage heat processes primarily depends on the mosaic of land uses in the city as compared to rural areas. Generally, the drier urban building and road materials induce higher Qh , less Qe , and higher ΔQs in urban areas. A term labeled Qg is specified in the energy budget equation often as part of ΔQs and is the soil heat flux. Significant Qe does occur in cities. This is theorized to be due to urban irrigation effects and vegetation in the city (Kalanda et al., 1980). Marotz and Coiner (1973) indicate that vegetation in urban areas is not as limited as supposed, and Oke (1978) shows that $\Delta Qs/Q^*$ ratios for rural areas vary by only about 0.10 from those for suburban and urban areas.

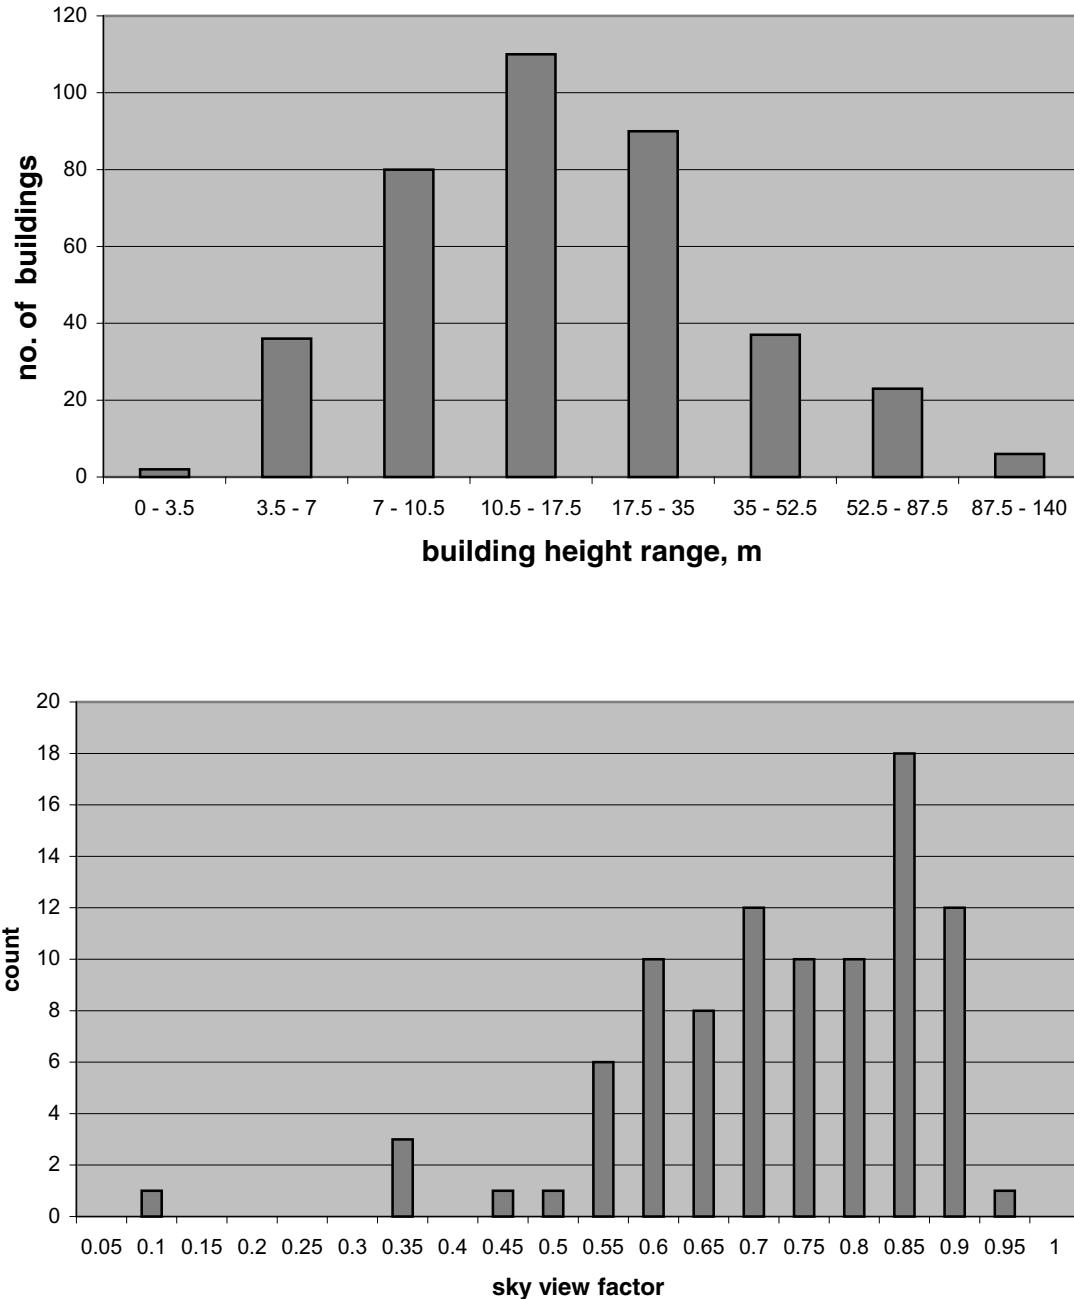

Figure U5 *Upper:* histogram of the computed sky view factor for street-level positions in downtown Salt Lake City. *Lower:* histogram of the building heights for downtown Salt Lake City (after Brown and Grimmond, 2001).

Table U5 shows some recent results for selected US cities after Grimmond and Oke (1995). Note the substantive fluxes of Q_h and ΔQ_s , also significant Q_e , especially for the more moist city of Chicago. In a detailed evapotranspiration study of nine places, Grimmond and Oke (1999) show that the ratio of Q_e/Q^* ranges from 0.09 (Mexico City with very little external water use) to Chicago's ratio of 0.46 (Table U5).

Goward (1981) lists thermal properties of typical interface materials, noting that urban area materials have similar thermal

properties and that urban thermal inertias are higher than dry soils but lower than wet soils (see Table U6). Differences in UCL structure and composition are the keys to explaining heat excesses in cities, rather than just the thermal properties of city materials *per se*. Much research remains on this point, and has become a focal point in the field of urban climatology (Arnfield, 1982; Barrling et al., 1985; Goldreich, 1985; Goward, 1981; Grimmond and Oke, 1995, 1999; Johnson and Watson, 1984; Oke, 1981, 1982; Terjung and O'Rourke, 1980).

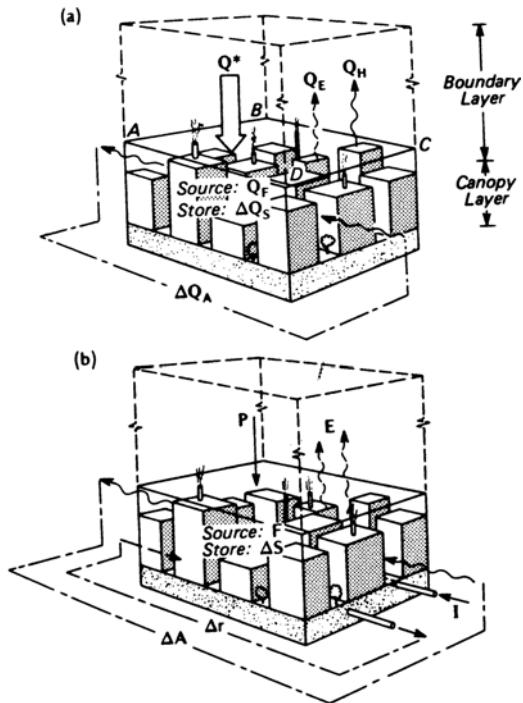

Figure U6 Schematic depiction of the fluxes involved in (a) the energy and (b) the water balance of an urban building air volume (after Oke, 1978, p. 242).

Table U5 Summary of daytime mean summer energy balance fluxes ($\text{MJ/m}^2/\text{day}$) for selected cities derived from tall tower observations (Grimmond and Oke, 1995).

Location	Q^*	Q_h	Q_e	ΔQ_s	Q_g
Tucson, AZ	16.27	7.54	4.11	4.62	Na

Los Angeles, CA	16.40	5.74	4.12	6.54	1.37

Remote sensing of urban surface temperature

The extreme land cover and spatial heterogeneity of the city landscape is problematic to the synoptic collection of *in-situ* measurements of energy balance flux parameters. Longwave radiation emitted upward from the urban surface (L^*), however, can be measured as a separate flux across the city landscape using thermal infrared (TIR) remote sensing. A number of investigators have provided evidence using TIR remote sensing data that urban areas are strong daytime longwave emitters (Rao, 1972; Pease and Nichols, 1976; Auer, 1978; Carlson and Boland, 1978; White et al., 1978; Roth et al., 1989). Other researchers have used remote sensing data to observe nighttime longwave radiation characteristics of cities (Dabberdt and Davis, 1974; Roth et al., 1989). As indicated by Table U6, however, the thermal properties of surfaces typical of the urban landscape are highly variable, and this variability is compounded even further by other factors, such as inconsistencies and deterioration caused by weathering or residue formation from automobiles. Flynn (1980), therefore, suggests that the problem related to the effects of surface material types and patterns on urban climatological phenomena, including the urban heat island effect, is a spatial one. A solution is to measure the attributes of space at a scale commensurate with that where the process becomes evident. The object of study then becomes the urban space that describes the energy budget or climatic processes within an areal unit. Flynn (1980) notes that approaching the problem in this way focuses on the pattern analysis and measurement of a basic urban surface (i.e. surface material type) and may explain some of the variability in urban temperatures across the city landscape. Thus, although TIR remote sensing data obtained from satellites are useful for discerning the general temperature characteristics of urban surfaces, these data must be obtained at spatial scales at which energy budgets for discrete surfaces material types can be identified (e.g. concrete, trees, rooftops, asphalt) to adequately quantify how thermal energy emanating from the composite urban landscape forces development of the urban heat island effect.

In this respect, high spatial resolution (i.e. $< 20\text{ m}$) TIR remote sensing data have been shown to be extremely useful for measuring urban thermal energy balance characteristics (Quattrochi and Ridd, 1994, 1998; Lo et al., 1997; Quattrochi et al., 2000). For example, Figure U7a is a mosaic of individual

Table U6 Thermal properties of typical interface materials

Material	Thermal conductivity $\text{W m}^{-1} \text{°C}^{-1}$	Specific heat $\text{J kg}^{-1} \text{°C}^{-1} \times 10^3$	Density $\text{kg m}^{-3} \times 10^3$	Thermal admittance $\text{J m}^{-2} \text{°C}^{-1} \text{sec}^{-1/2} \times 10^3$
Asphalt	0.7454	0.92	2.114	1.204
Brick	0.6910	0.84	1.970	1.067
Concrete	0.9338	0.67	2.307	1.185
Glass	0.8794	0.67	2.600	1.213
Granite	2.7219	0.67	2.600	2.176
Limestone	0.9338	0.92	1.650	1.182
Sand (dry)	0.3308	0.80	1.515	0.633

flight lines of airborne TIR data acquired at a 10 m spatial resolution during the day in summertime over the Atlanta, Georgia, USA, central business district (CBD). Given these are TIR data, surfaces that emit high surface temperatures (i.e. exhibit a high thermal energy response) are depicted in white to very light gray tones on Figure U7a. On the other hand, surfaces that are comparatively low emitters of surface temperatures (and subsequently, exhibit lower thermal energy responses in relation to other surfaces) are represented as dark gray to black in tone in the figure. The A–A' line in Figure U7a represents a transect centered on the Atlanta CBD and extending 5 km to the northwest and southeast of the CBD. There is a mixture of land covers along the transect that, in turn, is reflected in the fluctuations of temperatures along the graph given in Figure U7b. It may be seen in reference to Figures U7a and b that, in general, the residential land covers that inherently have more vegetation

(e.g. trees, grass) are relatively cool (~20°C) as opposed to the surfaces in the CBD that have considerably less vegetation and are predominantly composed of pavements, rooftops and other impervious surfaces, exhibit considerably higher surface temperatures of approximately 35°C. Hence, these high spatial resolution TIR aircraft remote sensing data can be used to identify thermal energy responses from discrete urban surfaces to assist in more accurately measuring longwave energy upwelling from the city surface as a factor in the overall city landscape regime and, ultimately, in assessing their effects on urban climatology.

Moisture environment of cities

The processes of urbanization affect the surficial and atmospheric water budget. The water balance of an urban area is (Figure U6b):

$$p + I + F = E + \Delta r + \Delta S + \Delta A$$

where: p = precipitation

I = water supply from rivers and reservoirs

F = water released to air by combustion

E = evapotranspiration

Δr = net runoff

ΔS = moisture storage

ΔA = net moisture advection.

Precipitation

Many studies have shown that precipitation has appeared to have increased up to 30% in, and/or downwind of, large urban areas (e.g. Changnon, 1969; Dettwiller and Changnon, 1976; Atkinson, 1971). Stemming from Changnon's famous La Porte, Indiana, anomaly (1968) of increased precipitation downwind of the Chicago-Gary industrial area, much attention has been given recently to this subject. Detailed climatic investigations as part of the Metropolitan Meteorological Experiment (METROMEX) in St Louis, Missouri, have yielded estimates of urban effects on precipitation (Changnon et al., 1977; Ackerman et al., 1978; Changnon, 1981). Results indicate that summer is the time of maximum urban effect on precipitation (Figure U8) due to the dominance of convection. Analysis of rain cells, radar echo counts, detailed raingauge measurements, and temperature and wind field studies in and around St Louis have led to causal explanations of rainfall excesses that include: (1) pollution; (2) modification of the thermal structure of the UBL; and (3) deepening of the mixing layer and stronger vertical entrainment of heat and moisture in portions of the metropolitan area. A convergence zone over the city is set up by increased sensible heating. The city is aerodynamically rougher, has more pollution (condensation nuclei sources), causes more thermal and mechanical turbulence, and particularly affects convective cloud formation and precipitation. However, topographic settings of cities must be clearly understood relative to induced differences in precipitation receipt in the urban region, before causal explanations such as the above can be applied to other cities in different environments.

Sheppard et al. (2002) use the Tropical Rainfall Measuring Mission (TRMM) satellite's precipitation radar (PR) data to identify warm-season rainfall patterns in and around six selected cities in the southeast United States (Atlanta, Georgia; Montgomery, Alabama; Nashville, Tennessee; San Antonio, Waco, and Dallas, Texas). The results substantiated earlier

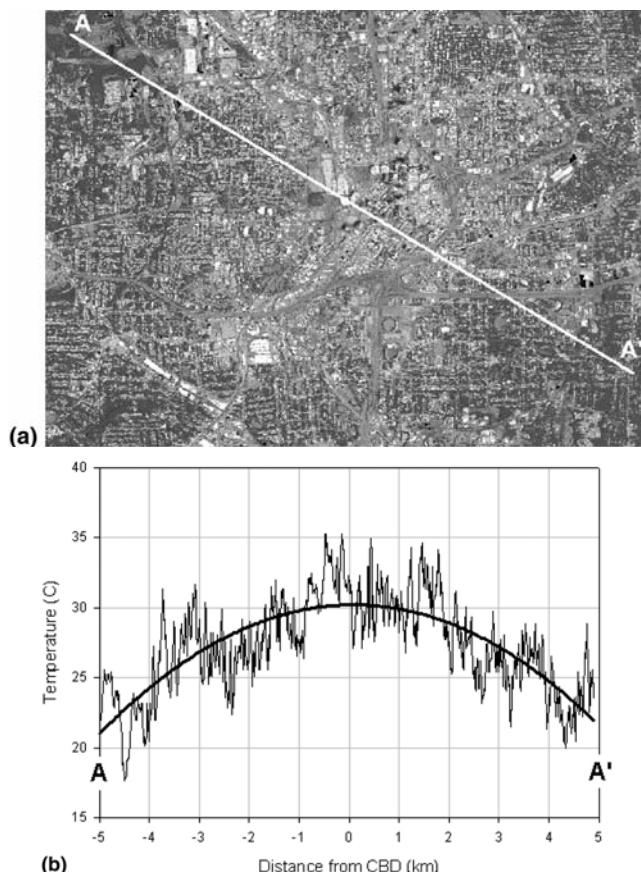

Figure U7 (a) Mosaic of individual flight lines of daytime airborne thermal infrared remote sensing data obtained over the Atlanta, Georgia, USA, central business district in summer. The A–A' line represents a transect across the area to illustrate the variability in surface temperature energy responses across the Atlanta urban landscape (refer to b). (b) Graph of the mean surface temperature (solid line) across the Atlanta, Georgia, USA, central business district area as identified from daytime high-resolution TIR aircraft remote sensing data. "A Decision Support Information System for Urban Landscape Management Using Thermal Infrared Data." *Photogrammetric Engineering and Remote Sensing (PE&RS)*. October 2000: 1195–1207.

METROMEX findings of downwind increases in the rainfall of about 28% on average some 30–60 km downwind of the cities studied, and highlight the usefulness of satellite data to determine urban effects. Precipitation increases due to human influences may show cyclic behavior due to pollution effects, even at the weekly time scale, as suggested in a study of the regional pollution and precipitation enhancement toward end of workweeks on the Atlantic seaboard of the US (Cerveny and Balling, 1999). Table U7 illustrates results from several cities focusing on the fluxes of Q_e relative to Q^* and the expression of water loss in millimeters per day, after Grimmond and Oke (1999).

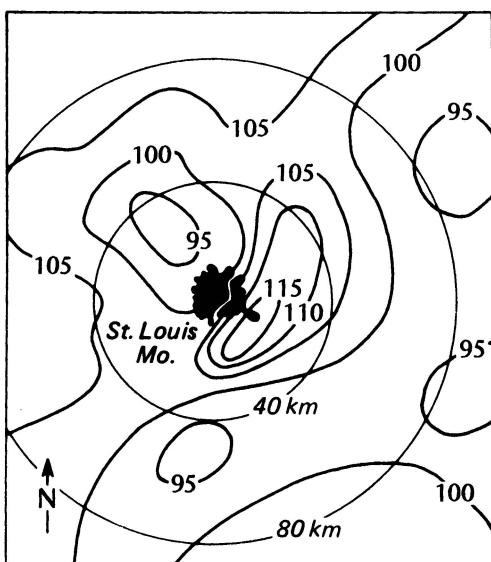

Figure U8 Average rural–urban ratios of summer rainfall in the St Louis area in the period 1949–1968. The rural–urban ratio is the ratio of the precipitation recorded at any station to that at two stations near the urban center (after Oke, 1978, p. 266).

Runoff

Since I and F are extra sources in cities, there is a net gain of moisture by urbanization. Water loss through E would be less in a city due to a waterproofing effect (Oke, 1980). The ΔS term would correspondingly be less. Assuming ΔA to be negligible, Δr would thus increase in cities. Indeed, many studies have indicated increased r in city environments, as well as changed hydrographic characteristics (e.g. Mather, 1978). There are four effects of land-use changes on the hydrology of the urban area: (1) peak flow is increased; (2) total runoff is increased; (3) water quality is lowered; and (4) hydrologic amenities – appearance of river channel and aesthetic impressions – are lowered (Mather, 1978).

Figure U9 illustrates two factors that control discharge characteristics before and after urbanization, shown here as a ratio related to percent impervious area and percent area served by storm sewers. These two factors are controls on the discharge of an area. Note that urban–preurban ratios of runoff increase as percent impervious surface area and percent storm sewers increase. Geographic information system processing of data is now used in hydrological studies, merged with simulation programs for stream flow analysis in urban areas (e.g. Brun and Band, 2000). In their work, relationships among runoff, base flow, impervious cover, and percent soil saturation for upper Gwynns Falls watershed, Baltimore, Maryland, were studied. It was possible to determine through modeling procedures the threshold percent impervious cover that would significantly alter runoff in the urbanizing watershed. In this case, current percent impervious surface cover is approximately 18%, whereas modeling suggests 20% is a threshold beyond which runoff alterations by land cover would significantly occur.

Humidity

Since E and ΔS are less, dewpoint is usually less in daytime in cities (e.g. Sisterson and Dirks, 1978; Brazel and Balling, 1986). At night a humidity island may result (e.g. Chandler, 1967; Kopec, 1973), due to extra E at night and contributions of F . Since recent studies have not shown Q_e and E to be that

Table U7 Daily mean fluxes of Q_e and water loss (E) for selected cities and conditions (after Grimmond and Oke, 1999)

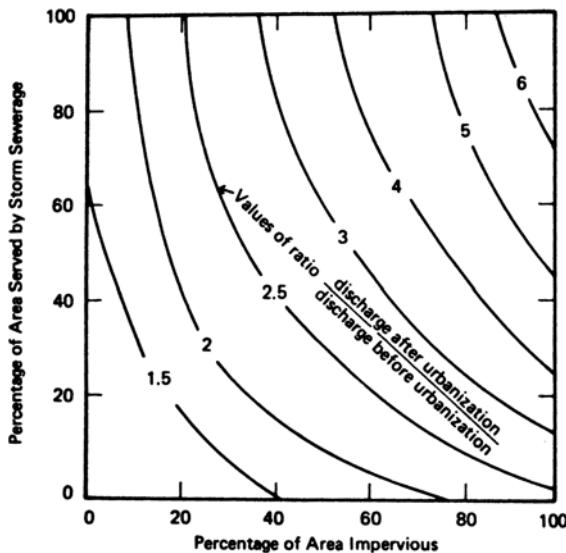

Figure U9 Two factors that cause increased discharge in the urban area as related to the ratio of discharge *after* urbanization to that *before* urbanization (after Mather, 1978).

different between city and surroundings, evaluations of F are important in the understanding of the humidity contrasts. Its absence may mean a negative humidity island in the city (drier); its presence a positive humidity island (wetter). Fog differences are not great between cities and rural areas although, due to pollution, cities have more haze, smog, and perhaps more slight fog. More cloud condensation nuclei and ice nuclei have been observed in cities, but knowledge is very unsatisfactory at this point about the effects on urban precipitation (Landsberg, 1981). Holmer and Eliasson (1999) report vapor pressure results between urban and rural areas for nine locations from previous studies plus their own study in Goteborg, Sweden. They identified an urban moisture excess, particularly at night, that also was related to the urban heat island and long-wave radiative fluxes.

Air movement in cities

Urban areas affect air flow, both speed and direction, on micro- and meso-scales. The aerodynamic roughness of urban areas (level above the ground where wind speed becomes greater than zero on average) is larger by some 0.5–4.0 m than in rural areas, and the city therefore produces more frictional drag. A heat-island effect in cities influences the pressure field and also vertical stability of the air. This will affect local airflow. These effects also depend on overall gradient wind strength across the urban region. Many studies have shown that, as wind increases, the magnitude of the urban heat island diminishes.

Wind speeds

When regional air flow is strong, the aerodynamic roughness of the city is dominant and is important in inducing increases in mechanical turbulence on the order of 30–50% (Oke, 1980). Under light winds, air pressure differences and atmospheric stability effects, in addition to roughness, are critical in determining city wind speeds from place to place. The built

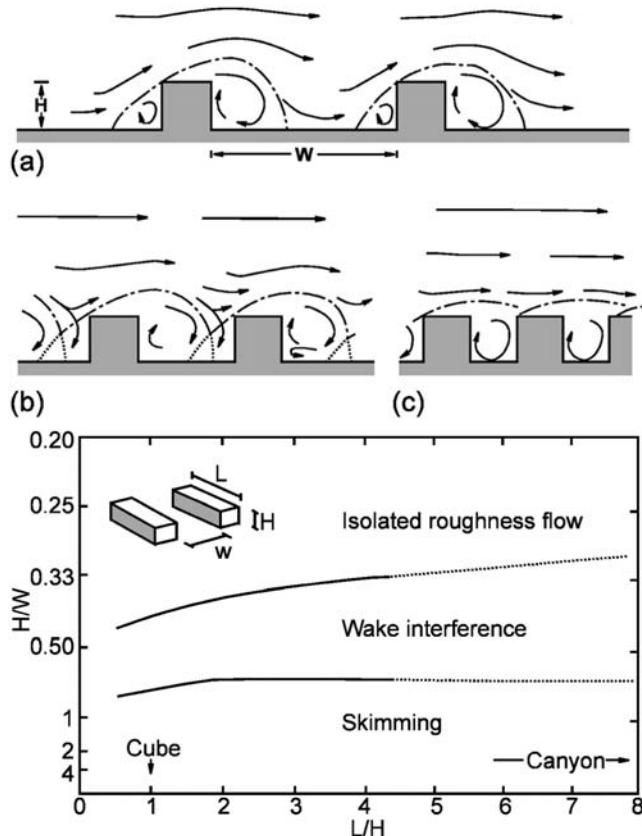

Figure U10 Threshold H/W ratios for the transition flow between flow regimes (a) skimming → wake interference; (b) wake interference → isolated roughness (from Hunter et al., 1992, used by permission of Pergamon Press Ltd).

environment affects the flow regimes of air through and over the city (Hunter et al., 1990). Generally, the length/height ratio and height/width ratio of buildings control the flow regime among isolated roughness flow, wake interference flow, and skimming flow (viewed in Figures U10a and b). Generally, under light regional flow, winds tend to accelerate in cities compared to rural areas because of strong rural atmospheric stability and the increased turbulence over the warmer, rougher city surface. Under strong flow, winds generally decelerate in the urban area due to greater frictional effects of the city on airflow. Studies have shown that there appears to be a critical regional flow speed separating the accelerating from decelerating wind response in the city (Chandler, 1965; Bornstein and Johnson, 1977; Lee, 1979). This speed, however, is quite variable and ranges from 0.8 to 5.6 m/s.

Wind direction

Wind direction differences in cities and in rural areas relate to frictional retardation effects. Decelerating winds will promote cyclonic turning toward lower pressure; accelerating winds produce anticyclonic turning (Ackerman, 1974; Angell and Bernstein, 1975; Lee, 1973). Wind direction changes induced by a city also vary diurnally in relation to the depth of the mixing layer. During the day the turning effect lessens, whereas at night it reaches a maximum.

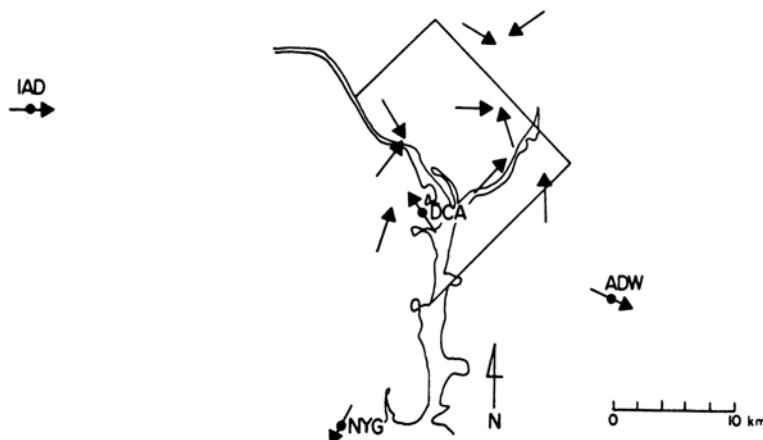

Figure U11 Wind convergence on a hot summer afternoon toward the city of Washington, DC. IAD = Dulles International Airport; DCA = Washington National Airport; ADW = Andrews Air Force Base; and NYG = Quantico Marine Base (after Landsberg, 1981, p. 135).

Urban circulations, much like the classic sea breeze, have been documented in addition to being theorized from laws of thermodynamics (Bach, 1970; Hjelmfelt, 1982; Shreffler, 1978; Vukovich and King, 1980). Landsberg (1981) illustrates the summer air circulation for Washington, DC (Figure U11). Note the convergence locally in the city boundary. Other air flow systems, such as synoptic fronts and sea breezes, also can be affected by cities. Manhattan, New York, for example, slows cold frontal passages upwind of the city and speeds them up downwind, especially when a strong heat island prevails (Loose and Bornstein, 1977). Wind conditions at street level and in the UCL are very complex and relate to physical barriers, building sizes, orientations, building densities, and general land-use patterns. As a generalization, winds are slowed in the UCL. However, effects of wind channeling and funneling can occur, depending on prevailing winds and the overall orientation and morphology of the city landscape.

Conclusions

The climate of cities will continue to be of importance to the ever-expanding urban population of the world. The application of research findings of urban climatology in building designs and urban environmental planning is beginning to emerge but is not yet widespread (Bonan, 2002). Due to the complexity of the urban landscape and the variability of dimensions, land use, morphology, and other characteristics, much research still remains on just how a city affects the surface and atmospheric climatic environment, and the city's overall urban ecology. Equally, if not more important, are the interactions of the city climate system with other elements of the entire urban ecosystem (Douglas, 1981; Bonan, 2002). The discovery of these interrelationships will eventually aid in planning solutions related to pollution, health, comfort, water supplies, and general quality of life among urban dwellers.

V

VEGETATION AND CLIMATE

Descriptions of the processes that shape the world around us emphasize the roles that energy and water budgets play. Much recent work in physical geography has been concerned with understanding the interactions of the various systems and subsystems that make up our environment. Utilizing factors derived from moisture and energy budgets, we have been able to achieve a more rational understanding of the distribution of the great vegetation biomes as well as the general relation of climatic factors to vegetation.

Scales of interactions

Monteith (1981) has suggested the scales shown in Figure V1 involving the coupling of the surface vegetation to the atmosphere. On the continental scale the location and extent of the major plant biomes may be determined by the general circulation of the atmosphere as well as by the space and time variations of the principal energy and moisture factors of climate. Local climates (mesoclimates) are more influential in the development of plant communities and plant associations and their ultimate survival. It is, of course, the interactions of the mesoclimate with the plant communities that result in the microclimates (or climates near the ground) to which the

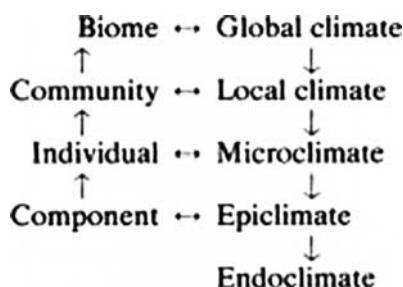

Figure V1 Monteith scales.

individual members of the plant community must react. On an even smaller scale, the interaction of the individual plant with its microclimate results in the epiclimate (called teleoclimate by Gates, 1968), which involves what occurs in the individual air layer in direct contact with the leaves, branches, and stems of plants. This climate, in the immediate vicinity of the plant, influences the temperature, gas concentration, and moisture condition within the plant tissue. The endoclimate determines the rate of growth and development of the individual plant organs and, in this way, provides a feedback from the individual plant through the community to the biome (Monteith, 1981).

History

Long before instrumental observations were available, climates were often named after their characteristic vegetation. For example, forest, desert, savanna, and tundra have long been used as names of climate types as well as of vegetation types. With the development of meteorological instruments and the collection of systematic climatic observations, the possibility of expressing explicitly the relation between climate and the growth and development of plants or of vegetation covers seemed about to be realized.

The eighteenth-century French scientist Réaumur was possibly the first to make an exact determination of the quantity of heat required to bring a plant from one stage of maturity to another. He felt that the mean daily air temperatures, summed between one stage of development and another for a plant, should be approximately constant for that particular period of development from year to year. Each plant species should have its own *thermal constant* to progress from germination to maturity. Réaumur's work stimulated others to undertake more detailed observations on plant development. There was a rapid expansion of observations of the relation between climatic factors and the dates of budding, leafing, flowering, and fruiting of annuals. Such phenological studies suggested a general relation between climate and the geographical distribution of vegetation.

The early work of Wahlenberg (1813) and von Humboldt (1817) showed the relation between temperature and vegetation distribution on mountain slopes, whereas Dove (1846) and

Linsser (1869; see references in Thornthwaite and Mather, 1954) pointed out that, in many regions of the world, rainfall would exercise a greater control than temperature over the distribution of vegetation. Linsser actually developed a moisture factor that allowed him to subdivide the vegetation zones of the Earth into five major categories. The important vegetation classification of de Candolle (1855) established five basic types of plants – four temperature types including megatherms (plants needing continuously high temperatures and moisture), mesotherms (plants needing only moderate amounts of heat and moisture), microtherms (plants able to survive short summers and colder winters), hekistotherms (plants of the polar zones – beyond the tree limit), and xerophytes (plants tolerant of dryness) – in terms of their physiologic response to climate.

Schimper's world map of vegetation formations (1898) separated, for the first time, the vegetation of the tropics and temperate zones into rainforest, forest, woodland, grassland, and desert. Tundra was used to represent the one vegetation class of the polar zone. He also introduced two transitional zones, without definite boundaries – the parklike landscape and the semidesert.

Köppen (1900) was among the first to express the idea that plants could serve as meteorological instruments capable of integrating the various climatic elements and that climatic regions could be defined in terms of plant regions as long as the climatic and edaphic influences on vegetation were carefully separated. His well-known climatic classifications were based on climatic records, but the climatic boundaries were identified by study of vegetation, soil, and hydrologic features.

Köppen's first map of climate classification appeared in 1900. In it he attempted to combine certain of the details of Grisebach's early map (1866) of vegetation regions (24 regions were identified on floral content) and de Candolle's 1855 classification described earlier. Köppen accepted temperature divisions of tropical, warm temperate, sub-Arctic, and polar to accord with the four temperature classes of de Candolle, along with four moisture divisions (forest – not xerophytes; tree savannas – xerophytic trees and shrubs; steppe; and desert). Through a combination of temperature and moisture types, he identified 14 types of climate.

By the mid-1900s the standard vegetation map generally included an assemblage of specific vegetation types having spatial qualities and a strong relationship to one of the earlier climatic maps of Köppen. However, even Köppen recognized that not all his climates could be readily identified by distinct vegetation classes even though most users attempted such a direct correlation. Often, schematic diagrams were constructed suggesting the close similarities between idealized patterns of vegetation and climate (see Figure V3). Such diagrams are misleading in their simplification and generalization and their failure to identify vegetation on the basis of form, taxonomic, and cover factors.

Vegetation specialists today would question whether plant formations are entities that are only produced and delimited by climate (de Laubenfels, 1975). Many vegetation maps in current use depict ecosystems rather than vegetation formations. Correlation of such maps with the distribution of other environmental components may not truly indicate the role of the environment in the distribution and growth of vegetation formations.

De Laubenfels (1975) suggests that only four distinct undisturbed vegetation formations can be identified (rainforest,

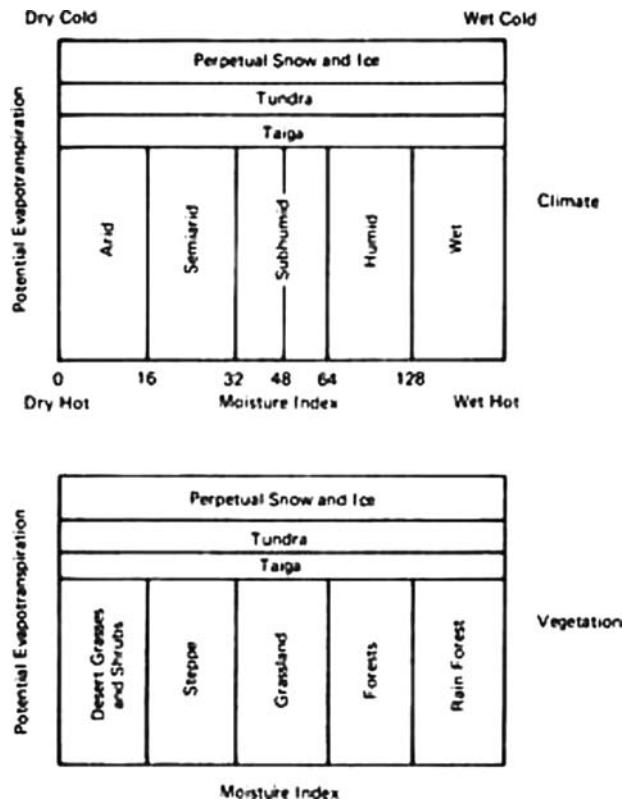

Figure V2 Schematic distribution of climate and vegetation on the basis of varying temperature (energy) and moisture indices.

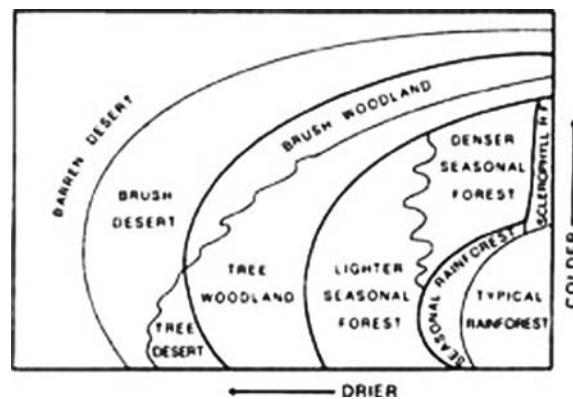

Figure V3 Schematic representation of various primary and secondary vegetation types with respect to moisture and temperature gradients. Grasslands and savanna may often replace many of them over large areas (from de Laubenfels, 1975).

seasonal forest, woodland, and desert; see Figure V3). These are distinct groupings rather than points or regions along a continuum. In addition to the four major vegetation formations, there are three others – grassland, savanna, and brush – that might be considered as disturbed cover types. The disturbance – often fire – if repeated frequently may result in fairly permanent vegetation types.

Limitations of climatic observations

The standardized climatological stations used to record the climate of a country or region are neither situated nor equipped to measure temperature or humidity at the places and at the times that are critical for plants.

The climate at 5 feet above the ground in a standard weather shelter is very different from that within a few inches of the ground in the open. Nocturnal temperatures are lower and daytime temperatures are higher close to the ground, where many plants grow, than they are a few feet above it.

Climatic influences on crop scheduling and irrigation

Food producers recognize that yield and quality are higher if plants receive the proper amount of moisture throughout the growing season and are harvested at the peak of their maturity. To help in the scheduling of crops, Thornthwaite and his associates (Thornthwaite and Mather, 1954) undertook studies of the relations between climate and crops. They attempted to link the water used by plants in transpiration with the rate of plant development. This approach involved a study of the old field of phenology (the study of the timing of periodic biologic events with respect to climate and other conditions of the natural environment).

Thornthwaite was one of the first scientists to provide quantitative evaluation of the moisture factor in climate by relating precipitation to potential evapotranspiration (defined as the amount of water that will be lost from a surface completely covered with vegetation all growing to the same height that never suffers from a lack of water). Potential and actual evapotranspiration are the same only under ideal conditions of soil moisture and vegetation. Unlike actual evapotranspiration, potential is defined to be independent of soil type, kind of crop, or mode of cultivation, and is thus a function of the climate alone.

Soil tanks, covered with the same kind of vegetation that surrounds them and having a water supply fully adequate to the needs of the vegetation, have been used to measure potential evapotranspiration water losses. Various investigators have also developed physical and empirical methods to compute this quantity (for example Rosenberg, Hart, and Brown; Penman; Baier and Robertson; Blaney and Criddle; Jensen and Haise, see references in Mather, 1978).

Daily observations of plant development by Thornthwaite and his associates at the Laboratory of Climatology (Higgins, 1952) made it possible to associate definite climatic conditions with definite amounts of plant development as well as with definite amounts of plant water need (potential evapotranspiration). The daily observations showed that, as incoming energy from the sun increased, both plant development and plant water use increased. This led to the formulation of a development unit as the amount of development that will occur in a plant as a unit amount of water is being transpired. The units, given in the metric system, show that as 100 development units are accumulated in a plant's life, 10 mm depth of water is transpired by the plant. This is an unfamiliar idea but it is useful because it provides a single solution for the important agricultural problems of scheduling supplementary irrigation and crop planting and harvesting.

Active climatic factors and vegetation distribution

The influence of climate on vegetation under different environmental conditions may be quite variable. Eyre (1963) indicated

that, in certain cases, chemical composition and physical characteristics of the soil and parent material could be as important as climatic factors. Thornthwaite (1952), writing as a climatologist, took a somewhat more deterministic view of the influence of climate. He felt that climatic factors almost by themselves could be used to distinguish vegetation associations. For example, he stated that the evidence for a "grassland climate" was unmistakable. Such a climate is marked by a specific balance between moisture deficit and surplus so that few periods of either very dry or moist soil conditions would exist during the year. This led Thornthwaite to conclude that grasslands are a natural phenomenon, in equilibrium with their climatic environment. Whereas Eyre considered the climatic factors of temperature and precipitation (P), Thornthwaite considered soil moisture distribution, plant water need, and the seasonal course of moisture surplus and deficit. He felt that these were climatic factors that might truly influence vegetation distribution. Soil moisture content, for example, can combine both climatic and edaphic factors. Since soil moisture storage is a climatic factor according to Thornthwaite, his reference to a definite grassland climate becomes more understandable.

Hare (1954) and later Thornthwaite and Hare (1955) attempted to correlate the factor of potential evapotranspiration (PE) and the moisture index ($I_m = 100 \times [(P/PE) - 1]$) with the distribution of vegetation. They found in a temperate, humid climate, I_m can roughly distinguish different forest types, whereas the sub-Arctic, boreal forest subdivisions are better correlated with PE. Major (1963), in an alternative approach, has considered a third factor, actual evapotranspiration (AE), and has suggested that vascular plant activity and growth might be related to the actual water loss of the vegetation since this factor expresses the real water activity of the plant rather than some unrealized potential value.

Relation of vegetation to global and local climates

North America

Mather and Yoshioka (1966, 1968) have studied the relation among natural vegetation, the climatic moisture index, I_m , and potential evapotranspiration, PE, at stations in all major vegetation regions across North America (see Figure V4). Information concerning the characteristic natural vegetation at each station, as identified from the Shantz and Zon (1924) vegetation map, supplemented with data from the Kühler (1964) map, has been indicated by means of a letter symbol. (All references in this section will be found in Mather and Yoshioka, 1966). Climatic stations were located in the different vegetation regions and the data of I_m and PE obtained for each station.

By using annual potential evapotranspiration and the climatic moisture index, it has been possible to locate discrete and, in many cases, nonoverlapping areas that are related to regions of natural vegetation. If truly active factors of climate can be selected, it appears possible to obtain a relation between climatic and botanic distributions in midlatitudes. From the distributions shown in Figure V4 one might conclude that it is possible to speak not only of a forest climate as opposed to a grassland or a desert climate, but that it also may be possible to identify a birch-maple as opposed to a spruce or oak-chestnut forest climate in a region such as the United States. It does not, of course, eliminate the possibility of edaphically influenced vegetation associations within large, homogeneous climatic

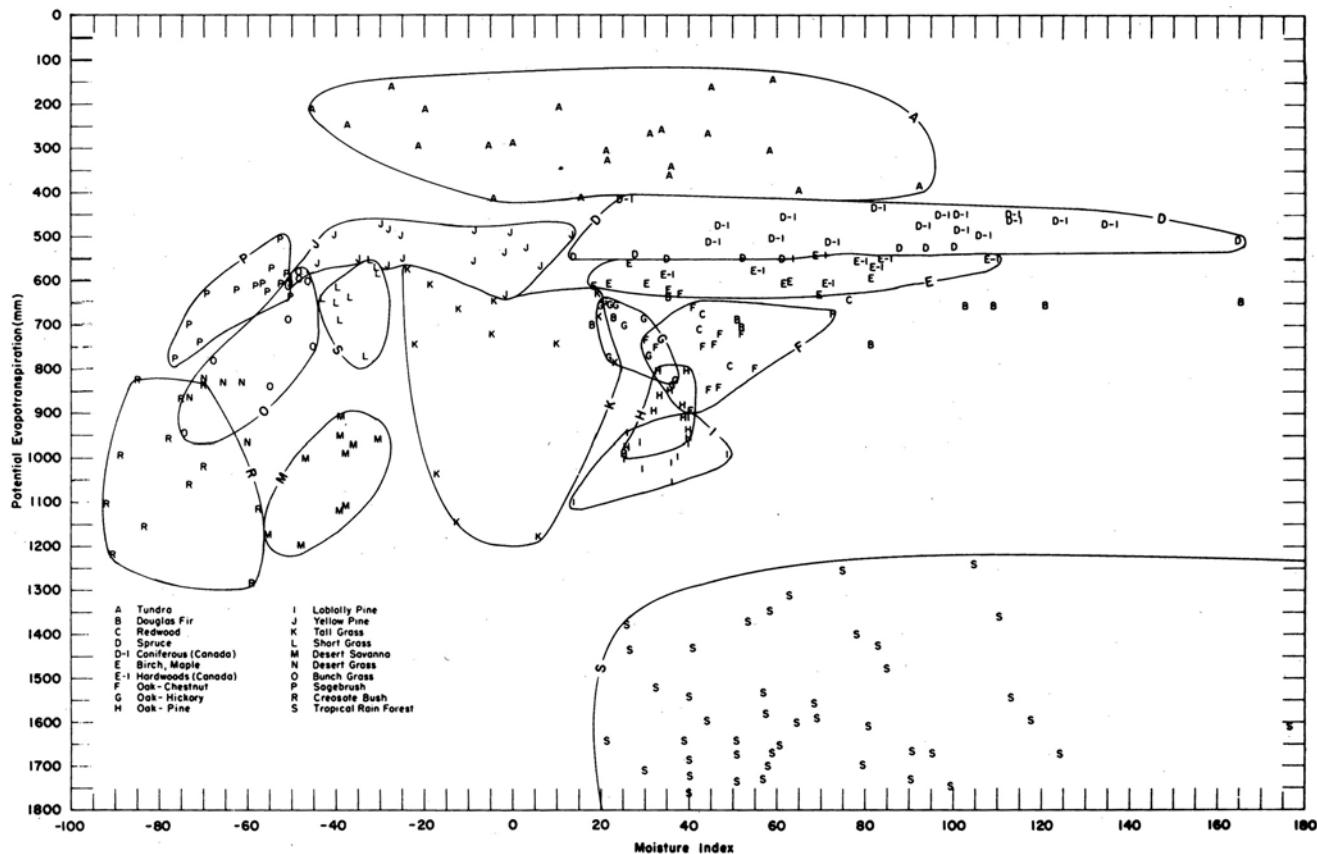

Figure V4 Relation between the climatic moisture index, potential evapotranspiration, and natural vegetation at representative locations in North America (from Mather and Yoshioka, 1968).

regions, or the possibility of more than one vegetation association being able to survive and compete successfully within a given climatic range. Edaphic and other environmental factors must also contribute to these areas of overlap, but the general lack of overlap bears witness to the responsiveness of the botanic environment to significant climatic stimuli.

South Africa

It is possible to locate 22 stations within one degree of 30°S across Africa at which climatic moisture balances can be evaluated. The moisture indices at these stations range from the very dry ($I_m = -92$) Port Nolloth on the west coast to the moist Mid Illovo ($I_m = 26$), Umbogintwini, or Durban (both $I_m = 12$) on the east coast. There is a progressive change in the moisture index at stations along 30°S as one traverses the continent. The stations used and their moisture indices are shown in Figure V5.

Vegetation varies across South Africa in a manner entirely consistent with the climatic indices. On the west coast there is a definitely arid-type vegetation consisting of succulent bush, as Adamson (1938) calls it, or a desert shrub, desert grassland type of vegetation. Adamson separates the succulent bush ($I_m = 80$ to -90) from the arid bush ($I_m = 50$ to -75) and indicates that slightly more moisture is found in the arid bush country. At Bethulie the vegetation is in transition from arid bush to grassland and the moisture index has dropped to -45 .

Grassland prevails in the region from 26°E to 29°E as the moisture index varies from -45 to -6 . Another change in the vegetation occurs as the moisture index shifts from negative to positive between Kokstad (29°25'E) and Nottingham Road (30°01'E). According to Adamson, east of 30°E at this latitude the vegetation shifts to a temperate savanna and then farther east to a subtropical forest. Small but definitely positive moisture indices are found here. There, thus, appears to be a clear relationship between climatic indices and the broadscale pattern of vegetation in South Africa.

Pine-savanna vegetation association of Nicaragua

Within the tropics, and especially when tropical savanna vegetation associations are considered, the role of climate seems of less importance. Parsons (1955) has described in some detail the Miskito pine savanna of the Nicaraguan and Honduran coast. Not only is this pine savanna significant in that it marks the most tropical penetration of pines in the western hemisphere but it is one of the雨iest areas in the western hemisphere with a savanna-type vegetation. Parsons feels that it clearly contradicts the concept that there is such a thing as a "savanna climate". He feels that the limits of the pine savanna are well marked by the termination of the gravel shelf on which this vegetation association is found. Parsons also considers fire, hurricanes, and impeded subsurface drainage as possible

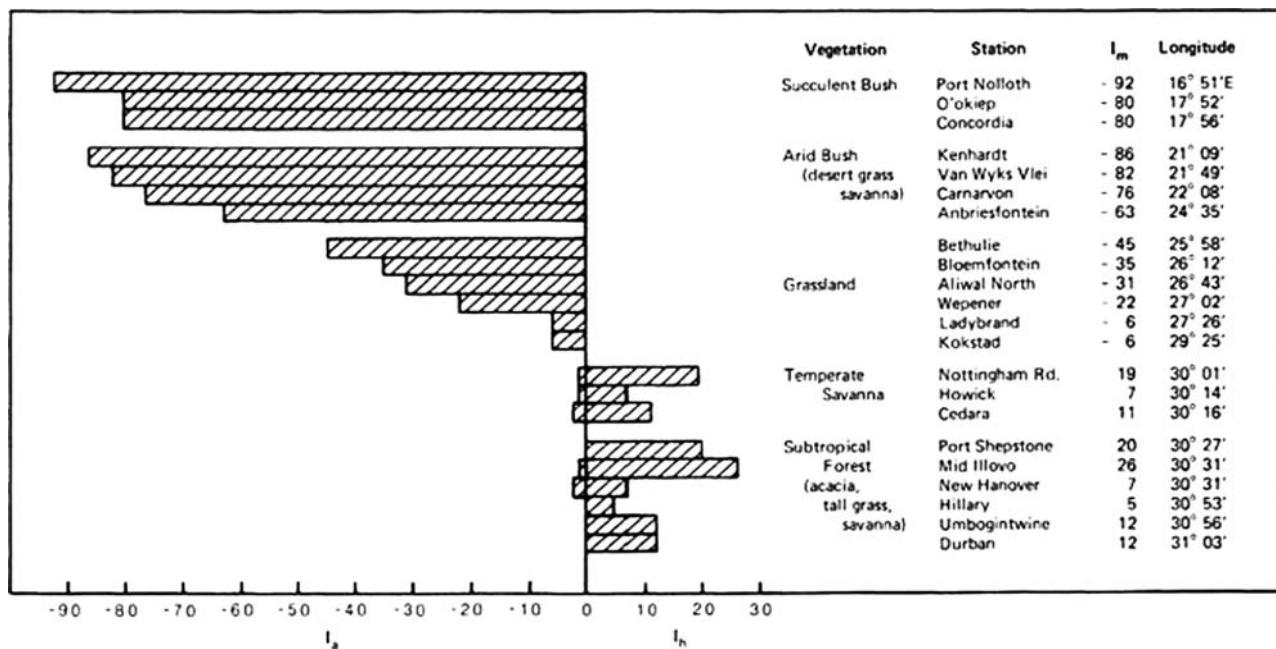

Figure V5 Relation of natural vegetation and climatic moisture indices at selected locations near latitude 30°S across South Africa (from Mather and Yoshioka, 1966).

contributing factors. There is a suggestion that hardwoods might be able to take over the area if fire and other cultural destructive agents were eliminated.

Puerto Cabezas is located on the coast of Nicaragua near the middle of the area of pine savanna. It experiences 3293 mm of precipitation on the average through the year, ranging from 458 mm in June to 50 mm in March. The moisture index for Puerto Cabezas is +106. With a potential evapotranspiration of 1545 mm, this area, by all rights, should experience a tropical rainforest type of vegetation. Climate, in this case, may be a "permissive" factor, but it certainly is not a determinant one since savanna rather than rainforest exists there.

Denevan (1961), in a study of the upland pine vegetation of Nicaragua, emphasizes the role of fire in the development of the pine savanna. He considers the frequency of burning as the determining factor. The existence of a pine savanna in this region poses two separate problems; first, there is the problem of conifers in tropical and subtropical climatic regions; second, there is the problem of the savanna vegetation and its relation, if any, to climate. Denevan feels that pines are not able to compete successfully against broadleaf vegetation in tropical and subtropical areas without the aid of fires and humans. Other pine associations in tropical areas should be restudied with this possibility in mind.

Global natural vegetation

Extending Mather and Yoshioka's climate and vegetation analyses to the entire Earth, Brewer (2001) achieved similar success. Using global long-term averages of seasonal values of PE and Thornthwaite's I_m from the spring, summer, and fall, he was able to estimate global natural vegetation from an independent dataset. Vegetation data were obtained from the Matthews' (1983) natural vegetation database, composed by merging numerous

descriptions and maps of vegetation, augmented with satellite data, into a single vegetation database. Vegetation categories were defined according to United Nations Educational, Scientific and Cultural Organization (UNESCO) guidelines including lifeform, density, and seasonality (UNESCO, 1973).

Using multivariate statistical analysis, Brewer accurately determined the locations of natural vegetation cores, including the elusive "grassland climate". Discriminant analysis effectively grouped vegetation based on common responses to seasonal active climate factors. Transition zones and certain transition-stage vegetation categories, however, proved difficult to determine precisely.

Seasonal climatic values used in Brewer's analysis yielded higher correlation to natural vegetation distributions than did annual climatic values. Adding wintertime PE and I_m values provided negligible improvement in determining vegetation categories. Indeed, it appears that the winter contribution to vegetation development is masked by the other seasons. In mid- and high-latitudes there is very little or no vegetation growth during the winter while in tropical regions the winter season is potentially redundant as it merely represents one-quarter of the total growing season. Additionally, moisture index modifications such as that proposed by Willmott and Feddema (1992) and the use of monthly active climatic factors show promise in further improving global vegetation-climate relationships. Also, neighborhood classification techniques readily available in geographic information systems may lead to better understanding of vegetation in transition zones.

Relation of vegetation to microclimates and epiclimates

One has to be impressed with the great variety of responses of individual vegetation species and vegetation components

(leaves, branches, trunks, and stems) to the different factors of the microclimates and epiclimes. It is difficult to make generalizations since plant reactions are so influenced by individual exposures of the plants and their leaves. These change both from plant to plant and from level to level within the same plant. Exposure of a number of different plants next to each other within a single environment will result in the measurement of quite different leaf temperatures as well as transpiration, photosynthetic respiration, and growth rates. Gates (1980) reported on three trees in Sydney, Australia, at noon on a warm summer day (air temperature 32°C) with a thin overcast of high cirrus clouds. The leaves of *Erythrina indica* were all standing in a vertical position, whereas those of a nearby cottonwood were horizontal. Leaf sizes and temperatures were essentially the same, but the *Erythrina* was regulating its temperature by the vertical exposure of its leaves (less surface exposed to radiation), whereas the cottonwood was controlling its leaf temperature by increased evapotranspiration loss. A nearby jacaranda tree maintained nearly the same leaf temperature as a result of the small size of its leaves in relation to the other two trees and a larger convection coefficient.

Under conditions of heat stress, taller-growing plants have some advantage over lower-growing plants because the higher leaves are exposed to greater convective cooling as a result of increased air movement at those levels. Temperatures of desert plants with very small leaves are closely coupled to air temperature by convection. Such plants may even drop their leaves under extremely dry conditions, whereas desert succulents have thick waxy cuticles to prevent undue water loss. Many desert plants have dense crowns of thorns to reflect sunlight, to shade the upper part of the plant, or to slow the movement of solar heat inward to the plant surface itself. Alpine or tundra plants tend to be low or dwarfed to protect them from convectional heat loss and, possibly, to protect them from the extreme cold of winter under a blanket of insulating snow. Gates has measured needle temperatures 9°C warmer on the leeward side of alpine fir trees than on the exposed windward side, which were at air temperature. He feels such a temperature gradient is partly the reason for the increased leeward growth of such trees. The physical effect of the wind itself will also help shape the tree with the prevailing wind direction.

Raunkiaer (1934), Taylor (1975) and others (see references in Gates, 1980) all concluded that leaf size and form were strong indicators of climatic or environmental conditions. To illustrate this, they pointed to the small leaves of desert, Arctic, or alpine plants, the small-lobed sun leaves on trees, the large understory leaves on tropical forest plants, and the systematic manner in which leaves graded in cross-sections from wet to dry or warm to cool.

Grace (1981) suggests that the shape and size of trees and the physiognomy of the vegetation are partially controlled by wind. Structural features of the vegetation influence the rate of transport of heat, gases, and momentum across the boundary layer between the plant and the atmosphere, with higher transport rates existing when vegetation is tall rather than short, or possessing small leaves, stems, and branches rather than large. Thus, with other factors being equal, tall plants or those with small leaves will be at a competitive disadvantage to short plants with large leaves in areas where temperatures are low and wind speeds high. The very low-growing, large-leaved plants of the Arctic and alpine environments (so-called cushion plants) illustrate this point since their low stature decreases convective heat loss and their large leaves increase solar

heating, permitting them to maximize productivity under generally cold environmental conditions.

Gates (1980) has noted rapid changes in leaf temperatures as wind or solar radiation conditions change. A leaf that was 5–7°C above air temperature in clear, still air might cool by 2–3°C when clouds move across the sun or by as much as 10°C when the leaves are rapidly exposed to windy conditions. The temperature changes are almost instantaneous. Although he feels that these large changes in temperature may produce some physiological consequences, they are uncertain at present.

Climatic effects of vegetation change

Flohn (1973) has estimated that, over the last 8000 years, 11% of the land area of the globe has been changed into arable land, while more than 30% of the existing forest land is no longer in its undisturbed state. Extrapolating the present rate of removal of tropical rainforests, Peters et al. (1989) estimate that none will exist by 2030. Sixty percent of Central Europe has been converted from forest to farmland since AD 1000 (Darby, 1956).

Vegetation influences the hydrologic cycle through the receipt and disposition of precipitation. Forest vegetation will intercept and reevaporate large amounts of precipitation, whereas the deep root systems of trees will remove water from greater depths of soil and for a longer time than will grassland. Thus, the effect of changing land use or crop type within a basin is to alter interception loss, transpiration, moisture loss from the soil, and, through feedback processes, the soil moisture content and the runoff from the basin. Muller (1966) has shown that the regrowth of forests in the central New York state area has reduced runoff to the Delaware River by about one inch over the past 30 years (resulting in further upstream movement of the salt line during dry periods). Sellers and Lockwood (1981) developed a complex multilayer model to simulate the action of the hydrologic cycle in four distinct vegetation regions in Britain (pine forest, oak forest, wheatland, and grassland). The model was used with hourly climatic data for the year 1977 and showed the smallest runoff from the pine forest and the greatest runoff from the wheat field. Oak forest and grassland gave nearly the same runoff, the latter being slightly larger. Sellers and Lockwood found these differences largely to be a result of differences in the interception and evaporation properties of the different canopies (Table V1).

Thus, changing a forest to a nonforest vegetation will lead to a marked increase in runoff, as will a change from a grassland to cultivated crops. As a result, a change in vegetation cover may have significant consequences for soil hydrology, soil development, and erosion potential.

Vegetation and general circulation models (GCMs')

Encouraging large-scale links between vegetation and climate has led to the development of vegetation models that can

Table V1 Annual totals of simulated runoff, intercepted loss, and transpiration (in mm depth) for four vegetation types

Vegetation	Runoff	Interception loss	Transpiration
Wheat	417	158	134
Grass	318	62	335
Oak forest	279	172	263
Pine forest	152	253	309

Source: After Sellers and Lockwood (1981).

translate the output from a GCM into maps of past, present, or potential future vegetation. These future vegetation estimates also feed back into the GCMs' to provide more accurate estimates of possible future climate. Most vegetation models used in conjunction with GCMs' simulate an existing ecosystem rather than natural or potentially dominant vegetation.

Brewer (2001) estimated potential vegetation under a $2 \times \text{CO}_2$ climate change scenario using GCM model output for temperature and precipitation similar to that used by the IPCC. Likely areas of core natural vegetation change are shown in Figure V6. Most changes appear in the southern hemisphere, specifically South America and Africa, with minor changes throughout North America, Europe, and Asia. Most startling in his analysis is the global loss of deserts under possible future climate conditions, similar to conditions thought to exist nearly 8000 years ago (Bradley, 1994).

Recent Intergovernmental Panel on Climate Change (IPCC) reports are the result of a combination of biogeography and biochemistry process-based model outputs frequently linked to GCMs'. While each of these types of models has inherent limitations, efforts are under way to blend the two types of process-based models into realistic assessment tools for climate change (IPCC, 1997). Many of the models examined by the IPCC, including the biogeography-based MAPSS (Neilson, 1995) and BIOME3 (Haxeltine and Prentice, 1996) and the biochemistry-based CENTURY (Parton et al., 1987) and BIOME-BGC (Hunt and Running, 1992) (see IPCC, 1997 for a complete list of models tested) exhibited similar skill in simulating current ecosystems from climate data. The models showed, however, broad divergence in attempting to explain vegetation under alternative climates (IPCC, 1997). Similar to Brewer's (2001) multivariate method, these models also showed difficulty with transitional zones both spatially and temporally.

A continuing analysis of the aforementioned vegetation models is under way through the Vegetation/Ecosystem Modeling

and Analysis Project (VEMAP members, 1995). This project addresses the response of vegetation to environmental variability and climate both temporally and spatially (Kittel et al., 1995). Future refinements in GCMs' should lead to more reliable estimates of the position and extent of vegetation change.

Conclusions

It is clear that vegetation develops in response to many different stimuli, among which we might list climatic, edaphic, and cultural conditions as possibly the most important. The response of vegetation to climate is both direct and indirect: direct through the role that the factors of temperature, radiation, moisture, and wind play on the growth and development of the vegetation, and indirect through the influence that the climatic factors have on soil conditions, disease organisms, competing botanic associations, and cultural practices. In addition, the reciprocal influence of vegetation on the microclimate of the particular area and on the other factors of the microenvironment creates another level of influence that must be considered in evaluating the factors that contribute to the distribution of vegetation.

The degree to which the distribution of vegetation can be explained on the basis of climatic conditions depends *in part* on the proper selection of climatic factors. Temperature and precipitation by themselves are poor descriptors of climate. The active factors of climate from a vegetation viewpoint are water surplus or water deficit (water supply in relation to water need), potential evapotranspiration (available energy expressed in terms of water need), actual evapotranspiration (actual plant water use), and soil moisture storage. Knowledge of these factors is available from computations of the climatic water balance, and combinations of these factors are expressed in shorthand form in the moisture index of the Thornthwaite climatic water balance.

Figure V6 Potential areas of vegetation change (shaded) under $2 \times \text{CO}_2$ climate change scenarios. (from Brewer, 2001).

Use of more expressive climatic parameters, or finally the use of the frequencies of some of these elements to describe distributions in environmental biology, should yield increased appreciation of the role of climate. The ability to identify some individual formation classes within the biochores provides a new and powerful tool for analysis and classification of the vast body of existing environmental data from many parts of the world. It introduces another aspect of rationality and simplification into the complex world of environmental influences and distributions.

The foregoing should not deprecate the role of edaphic, cultural, and other factors in influencing vegetation distribution. There are many examples of nonclimatic controls on vegetation such as the savanna and the low-latitude pine associations. It is, of course, only through a complete interpretation of all contributing influences that the most understandable picture of the geographic distribution of vegetation can be obtained. As more basic studies of climatic influences on vegetation growth and development are completed, we should be able to develop even more powerful tools for evaluating the botanic potential of newly developing areas and for increasing productivity. Additionally, the increased knowledge of the interaction between climate and vegetation will yield more realistic approximations of future climate in our changing world.

VOLCANIC ERUPTIONS AND THEIR IMPACT ON THE EARTH'S CLIMATE

"The bright Sun was extinguish'd, and the stars did wander darkling in the eternal space...." So begins Byron's lament *Darkness*, inspired apparently by the gloom of 1816, "the year without a summer". The missing summer is linked to effects of the most explosive eruption in modern history and perhaps the last 10 000 years, that of Tambora on the Indonesian island of Sumbawa. Widespread famine in Europe and China, southward and westward migration of New England farmers are commonly quoted anthropological effects, while proposed cultural impacts range from Byron's poetry to influences on J.M.W. Turner's paintings, and even Mary Shelley's "Frankenstein".

That volcanic eruptions can affect the Earth's climate has been appreciated for some time. On a heuristic and phenomenological level this is easy to understand – powerful volcanic eruptions eject ash and gases into the atmosphere, and the resulting cloud or plume intercepts sunlight and causes changes in weather. Cooling is most often associated with volcanic eruptions. However, in detail, the response of the climate system to volcanic eruptions is quite complex.

Sulfur-rich aerosols are the primary culprit in the effect of volcanism on climate, and these set up complex radiative responses in the climate system that involve stratospheric heating, surface cooling, and loss of ozone. This review examines the origin and evolution of our ideas on volcanic effects on climate, discusses these effects in the context of eruption variables such as size of eruption and composition of the magma, and then traces the impact of volcanic input into the atmosphere with an emphasis on mechanisms. Table V2 gives some definitions of terminology.

Proposing the connection

The earliest known appreciation of the volcanic effect on weather is generally accepted to be Plutarch's writings from about AD 100. The descriptions relay events in 44 BC, the year of Julius Caesar's brutal assassination, and notes a dim sun that was "pale and without radiance" that resulted in a cold summer "owing to the feebleness of the warmth" that was responsible for shriveled crops and famine from Rome to Egypt. While the association is oblique, most workers believe that Plutarch was describing the effect of an eruption from Mount Etna in Sicily that year. A celebrated early account of the volcanic eruption–climate association is that of the great American intellectual and diplomat Benjamin Franklin, who opined that the "dry fog" and unusually cold summer of 1783 and cold winter of 1783–1784 may have been the result of "great burning balls

or globes" (meteorites) or "the vast quantity of smoke, long continuing to issue" from volcanoes in Iceland. It is now known that these effects were associated with the 1783 Lakagigar or Laki fissure eruption emanating from the Grimsvötn volcano. Severe impacts of volcanic eruptions on global climate are recognized from two major eruptions in Indonesia in the 1800s. The cold summer of 1816 is part of an average global temperature drop of 0.4–0.7°C generally attributed to the Tambora eruption. On the back of the rapid spread of global communications in the late 1800s, remarkably insightful and prescient Dutch Government and Royal Society of London studies of the effects of the 1883 eruption of Krakatau produced the first widespread reports of strange atmospheric effects linked to volcanoes. This prompted others such as W.J. Humphreys in 1913 to suggest a cause and effect between volcanoes and climate. The examples above are but a few of the eruptions recorded in human history that have lent valuable insight into our understanding of the volcanic impact on climate. Current research is revealing other past eruptions that are associated with major global climatic perturbation. One such eruption, the 1600 eruption of Huaynaputina, in southern Peru, is now recognized as one of the most important in recent history.

Teasing out the volcanic signal

While it may be known that an eruption occurred at a certain time and place, the impact of that eruption on climate is quite hard to pin down against the background of meteorological variability, an issue of signal to noise. The utility of historic weather data with spotty global coverage for synoptic analysis notwithstanding, even well-known eruptions have confusing accounts. For instance, while many records suggest that the summer of 1783 was abnormally cold, some records indicate that it was exceptionally hot, leading to an early harvest. The awful 1816 summer attributed to the eruption of Tambora happened within the framework of the Little Maunder Minimum – a global temperature decline that appears to have started before the eruption. These examples illustrate that the context of volcanic eruptions within natural variability needs to be better understood.

The importance of written records in helping identify the volcanic signal and assessing the impact of eruptions in historic times is clearly demonstrated above. However, a complete picture requires a multidisciplinary approach involving the detective work of gleaning the volcanic signal contained in the deposits of the eruption and a variety of other proxy records such as ice cores and tree rings. Some of the more common proxies are described in Table V3. To help produce a coherent database of volcanic effects these data are compiled into various indices such as Volcanic Explosivity Index (VEI), the Dust Veil Index (DVI), and the Ice Core Volcanic Index (IVI). Alan Robock and co-workers have assessed the veracity and utility of these indices. They note that none of them is perfect. Any perfect index would have to include the radiative forcing associated with each eruption and this is most directly a function of the sulfur content of the stratospheric aerosol. This is difficult to measure even for recent large eruptions, and is therefore a major drawback for historic eruptions; the problems increase the further back one looks.

Despite these difficulties it is generally accepted that a statistically significant average temperature decrease of 0.2–0.5°C for 1–3 years after an eruption can be expected (Figure V7). It is generally agreed now that the key to the severity of the climate

Table V2 Glossary

Aerosol – A suspension of fine liquid or solid particles in a gas (air).
Albedo – A measure of surface or atmospheric reflectivity. The fraction of incident radiation reflected back.
Caldera volcanoes – Depression marking the sites of volcanic eruption that have collapsed due to the removal of magma, a decrease in magma pressure, or due to weakness of the rocks. Smallest are typically a few kilometers, while the largest can be ~100 km in size.
Dust Veil Index (DVI) – A quantitative measure of the amount of fine ash in the atmosphere after a volcanic eruption. Developed by H.H. Lamb it is based on historic reports, estimates of volume of ejecta, temperature data, optical phenomena and, after 1883, radiation measurements.
Effusive eruption – Passive, largely non-explosive, eruptions of lava, fire fountains, and small explosions resulting from gas release from relatively fluid magma with low silica content such as basalt (~50% SiO ₂).
El Niño–Southern Oscillation (ENSO) – A climatic cycle consisting of quasi-periodic warming and cooling phases, El Niño and La Niña respectively, driven by interactions between the atmosphere and ocean in the tropical Pacific.
Eruption intensity – A measure of the mass eruption rate which controls column height, and therefore potential stratospheric injection of an eruption. High-intensity eruptions are more likely to penetrate well into the stratosphere.
Eruption magnitude – A measure of the mass (kg) of material ejected during an eruption.
Explosive eruption – Violent eruptions that involve explosive disruption of magma driven by the escape of gas at high pressure. These typically involve relatively viscous magma with high silica content such as andesite (~58–63% SiO ₂) to rhyolite (>70% SiO ₂). They commonly produce eruption columns of ash, gas, and pulverized rock (pyroclasts) that penetrate into stratosphere.
Flood basalt – Effusive eruptions resulting in sheet-like regionally extensive basalt lava. Often form thick plateaux such as the Columbia River (Washington/Oregon, USA) or Deccan Traps (India). Commonly associated with the break-up of continents or tectonic plates, these are the largest volcanic phenomena and can result in over a million cubic kilometers of lava being erupted.
Heterogeneous chemical reactions – Reactions that occur between reactants of different phases, i.e. species in gas with those in liquid or solid phases in an aerosol.
Ice Core Volcanic Index (IVI) – Index of volcanic aerosol loading developed by Robock and Free based on ice-core records of acidity or sulfate.
Magma – Molten silicate from the interior of the Earth discharged during a volcanic eruption. Consists of liquid silicate, crystals, and gas.
Microphysics – Processes affecting the size, number, and distribution of aerosol particles. Microphysical processes include nucleation, condensation, evaporation, coagulation, and sedimentation.
Nucleation – Process by which gas or liquid phase species form new liquid or solid particles. Heterogeneous nucleation involves the presence of a pre-existing nucleus onto which molecules can aggregate. Homogeneous nucleation occurs spontaneously. Stratospheric sulfate aerosols are thought to form from binary homogeneous nucleation of water vapor and sulfuric acid vapor.
Optical depth – Measure of the cumulative extinction of electromagnetic radiation in transit through the atmosphere.
Plinian eruption – Most explosive, widely distributed, and highest eruption column type of pyroclastic eruption.
Proxy record of volcanic activity – Written record, natural phenomenon or feature that provides some indication of a volcanic event.
Pyroclastic eruptions – Eruptions dominated by explosive production of ash, gas, and rock fragments resulting from violent fragmentation of magma. See explosive eruption, above.
Radiative effects – Pertaining to the net effect of absorption, reflection, and transmission on atmospheric dynamics.
Residence time – Longevity of particles in the atmosphere before they are removed through sedimentation or physicochemical reactions.
Sedimentation – Process of removal of particles (ash, aerosol) due to gravity.
Sulfate – The SO ₄ ²⁻ molecule (oxidized sulfur) found in solution with liquid water; dissolved form of sulfuric acid.
Teleconnection – Broadly (globally) correlated pattern that is not necessarily continuous.
Volcanic Explosivity Index (VEI) – Classification scheme describing the size (deposit mass or volume) of a volcanic eruption.
Volcanic plumes – Eruptive mixtures of volcanic particles, gases, and air that form vertically rising clouds associated with volcanic eruptions. Plumes may spread laterally as gravity currents at neutral buoyancy levels.

Table V3 Common proxy records for volcanic eruptions

Ice cores	Volcanic aerosols deposited on permanent ice become part of the seasonal record of ice layers. Drill cores through key ice accumulations reveal acidity profiles that record volcanic deposition with accuracies of 1–3 years going back at least 10 000 years. Identifying the source volcano for a given acidity peak is a complex process requiring an understanding of eruption style, magnitude, location, and magma composition.
Dust layers	Allied to acidity profiles, some permanent ice caps can record periods of volcanic “dust” deposition as well. This typically indicates close proximity to the volcano and with knowledge of the ash compositions from various volcanoes a match can be made. An example is the Quelcaya Ice Cap in Peru, where ash from the 1600 Huaynaputina eruption is recorded.
Tree rings	Annual growth rings in trees in temperate regions provide a highly accurate record of time. Coupled to variations in the density of rings or evidence of frost damage within rings, this record provides a faithful record of eruptions large enough to perturb climate so that growing conditions are altered.
Written records	Although somewhat subjective, scholarly, historical, and religious records, as well as works of art and literature, can provide valuable insight into poorly documented eruptions in the recent past or broader impacts of “known” eruptions. Examples include Etna, Italy in 44 BC, Huaynaputina, Peru in 1600, and the “mystery cloud” of 536 AD.
Atmospheric phenomena <i>Coloured and dim suns and moons</i> Large sunspots, coronal appearances Hazy and pale sky (no clouds) Vivid sunsets, twilight effects	Resulting from the scattering, transmission, and absorption of the sun’s radiation by volcanic dust palls and aerosols, these phenomena, often seen after major eruptions, led to the development of the Dust Veil Index (DVI) by Lamb, 1970.

effect caused by an eruption is the magnitude of the eruption, the sulfur content of the magma, and the amount of sulfur released into the stratosphere as an aerosol. A classification of eruptions based on the magnitude of an eruption, the Volcanic Explosivity Index (VEI) is presented in Table V4, while key climate-impacting parameters of important volcanic eruptions are given in Table V5.

The scale of volcanic eruptions and their effects

The foregoing should impress on the reader that the climatic effects of volcanic eruptions can be quite perturbing and severe. However, the eruptions highlighted above are puny compared to those recorded in Earth history. Some of the largest eruptions in the geological record form large caldera volcanoes such as

Toba in Sumatra, and Flood Basalt plateaux such as those of the Columbia River, in Oregon and Washington, and the Deccan Traps, in Mahabaleshwar in India. These have a VEI of 8 – the highest. The 74 ka eruption of Toba, erupted almost 40–50 times as much magma as Tambora in 1815, and individual eruptions such as the Roza flow in the Columbia River plateau are at least a couple of orders of magnitude greater than the Laki eruption of 1783. It should be no surprise then that authors such as Rampino, Self, and Stothers have drawn an analogy with the “nuclear winter” scenario and offer the theory that “volcanic winters” might be a likely consequence of the largest eruptions. This concept is rooted in the effect of volcanic aerosols on the opacity of the atmosphere and reduction of sunlight. The effect appears to increase with eruption magnitude as shown in Figure V8. Based on this, the coincidence of the Toba eruption with the end of the Brørup interstadial and the Wisconsinan glacial advance has been suggested as a cause-and-effect relationship by Rampino and his colleagues. Presciently, Humphreys had already speculated in his 1913 paper the possibility that sustained volcanic activity might trigger Ice Ages. Developing this further, Stanley Ambrose has proposed that the Toba volcanic winter brought widespread famine and death to human populations around the world. This abrupt “bottleneck” in population is thought to have favored evolutionary changes, which occur much faster in small populations, to produce rapid population differentiation of modern human races only 70 000 years ago.

In the early 1980s several studies posited a primary cause-and-effect relation between the eruption of the Deccan Trap flood basalts and the mass extinctions at the Cretaceous–Tertiary (K–T) boundary 65 million years ago. While this is now eschewed by the mainstream community in favor of the more supportable impact hypothesis, the temporal coincidence and the significant effect suggested by the results of scaling calculations of eruptions such as the 1783 Laki eruption to those of the Deccan scale beg the question of what the exact relationship is.

The effect of eruption size is not straightforward, however, and, as explained below, the size of the eruption, or its magnitude, may be less important than the sulfate aerosol production and intensity of the eruption.

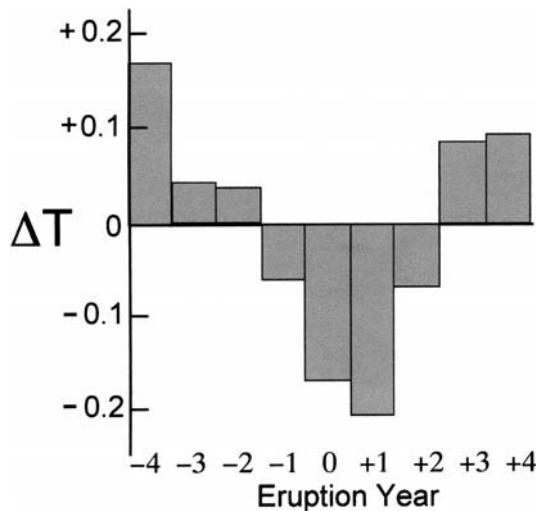

Figure V7 Northern hemisphere temperature variation averaged over several major eruptions. Eruption years are: 1815, 1875, 1883, 1902, 1947, 1956, 1963. Data suggest a 0.2°C drop in the year following the eruption (after Self et al., 1981).

Table V4 Classification of volcanic eruptions in the Volcanic Explosivity Index (VEI) – a measure of the magnitude of eruptions. Modified after Newhall and Self, 1982

VEI	Description	Plume height	Volume range	Classification	Period	Example
0	Non-explosive	< 100 m	1000 m ³	Hawaiian	Days	Kilauea, Hawaii
1	Gentle	100–1000 m	10 000 m ³	Hawaiian/Strombolian	Days	Stromboli, Italy
2	Explosive	1–5 km	1 000 000 m ³	Strombolian/Vulcanian	Weeks	Galeras, Colombia, 1992
3	Severe	3–15 km	10 000 000 m ³	Vulcanian	Years	Ruiz, Colombia, 1985
4	Cataclysmic	10–25 km	0.1 km ³	Sub-Plinian	Decades	Galunggung, 1982 Lascar, Chile, 1993
5	Paroxysmal	> 25 km	1 km ³	Sub Plinian/Plinian	Centuries	Mt St Helens, USA, 1980
6	Colossal	> 25 km	10 km ³	Plinian	Centuries	Krakatau, Indonesia, 1883 Huaynaputina, Peru, 1600
7	Super-colossal	> 25 km	100 km ³		Millenia	Pinatubo, Philippines, 1991
8	Mega-colossal	> 25 km	1000 km ³	Ultra-Plinian	Millenia	Tambora, Indonesia, 1815
					Megallenia	Toba, Indonesia, 74 ka
						Yellowstone, USA, 2 Ma

Note: Effusive eruptions are poorly represented in this scheme. For instance, flood basalt eruptions would be VEI 0–1 in terms of description, but a VEI 8 in terms of volume.

Table V5 Magnitudes, plume heights, stratospheric aerosol loadings, and climate impact of some key eruptions

Eruption latitude, year	VEI	Magma volume (km^3)	Plume height (km)	H_2SO_4 aerosol (kg)	Northern hemisphere temperature decrease ($^{\circ}\text{C}$)
<i>Explosive eruptions</i>					
Toba ^a 2°S, 73.5 ka	8	>1000	~40?	10^{12-13}	3–5
Tambora 8°S 1815	7	>50	>40	2×10^{11}	0.4–0.7
Krakatau 6°S 1883	6	>10	>40	5×10^{10}	0.3
Huaynaputina ^b 16°S 1600	6	>9	33–42	7×10^{10}	0.8
St Helens 46°N 1980	5	0.35	22	3×10^8	0–0.1
<i>Effusive eruptions</i>					
Rosa Flow ^c Columbia River Plateau 46°N, 14.7 Ma	8?	1400	13	10^{13}	5–15
Laki 64°N 1783	4	14	13	10^{11}	~1.0

^c Thordarson and Self, 1996.

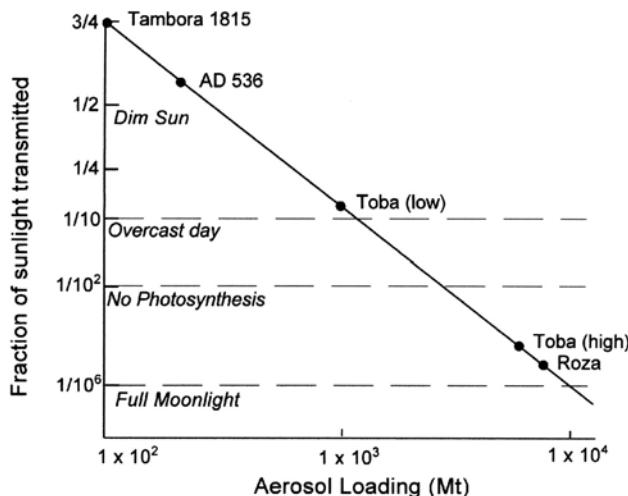

Figure V8 Volcanic aerosols commonly increase the opacity of the atmosphere and this can be quantified by the reduction in sunlight transmitted. Show here are estimates from major historic and pre-historic eruptions. All these eruptions are mentioned in the text (from Rampino et al., 1988).

Cause, effect, and mechanisms

The complex set of interactions summarized in Figure V9 constitute the volcanic impact on the Earth's climate. Volcanic eruptions inject finely comminuted magma as ash and gases into the atmosphere. Ash consists of frozen magma shards and fragments, pulverized rock fragments from the conduit of the volcano, and crystals. Volcanic gases are dominated by water

vapor (~80%), and carbon dioxide (~10%), and the rest is made up of N_2 , SO_2 , H_2S , CO , H_2 , HCl , and HBr . It is volcanic aerosols, formed by sulfur species injected into the stratosphere, rather than the ash, that are the main agent of climate effects. These stratospheric aerosols affect the global radiation by absorbing and back-scattering incoming solar radiation; the former leads to stratospheric heating, and the latter to surface cooling. Stratospheric heating results in a perturbation of the atmospheric dynamics by affecting both vertical and meridional circulation. The volcanic aerosols may also catalyze a reduction of stratospheric ozone through heterogeneous chemical reactions. This may be exacerbated by the aforementioned dynamic processes, and so lead to reduced radiative heating of the lower stratosphere.

As ash, water vapor, sulfur dioxide (SO_2), HCl and other gaseous species are injected into the atmosphere, the ash falls out of the atmosphere very rapidly – in a matter of minutes to weeks. Ash therefore has little global climate impact beyond local cooling that is often manifested in reduced amplitude of the diurnal cycle of surface temperature variations. Moreover, water vapor, and soluble gaseous components such as HCl , condense as temperatures drop in the upper troposphere and these components often rain out before they enter the stratosphere. Thus tropospheric particles are removed from the atmosphere in several weeks by frequent precipitation. The intensity of an eruption is therefore another important factor in the impact on the global climate. Since most volcanic eruptions are effusive, they have little chance to impact the global atmosphere as their eruption plumes do not penetrate the tropopause.

Predominantly effusive eruptions involving relatively low-viscosity basalt magma such as the 1783 Laki eruption, and those that occur on the islands of Hawaii, do not in general have global impacts, even though these magmas typically have a higher concentration of sulfur. Therefore it is the very

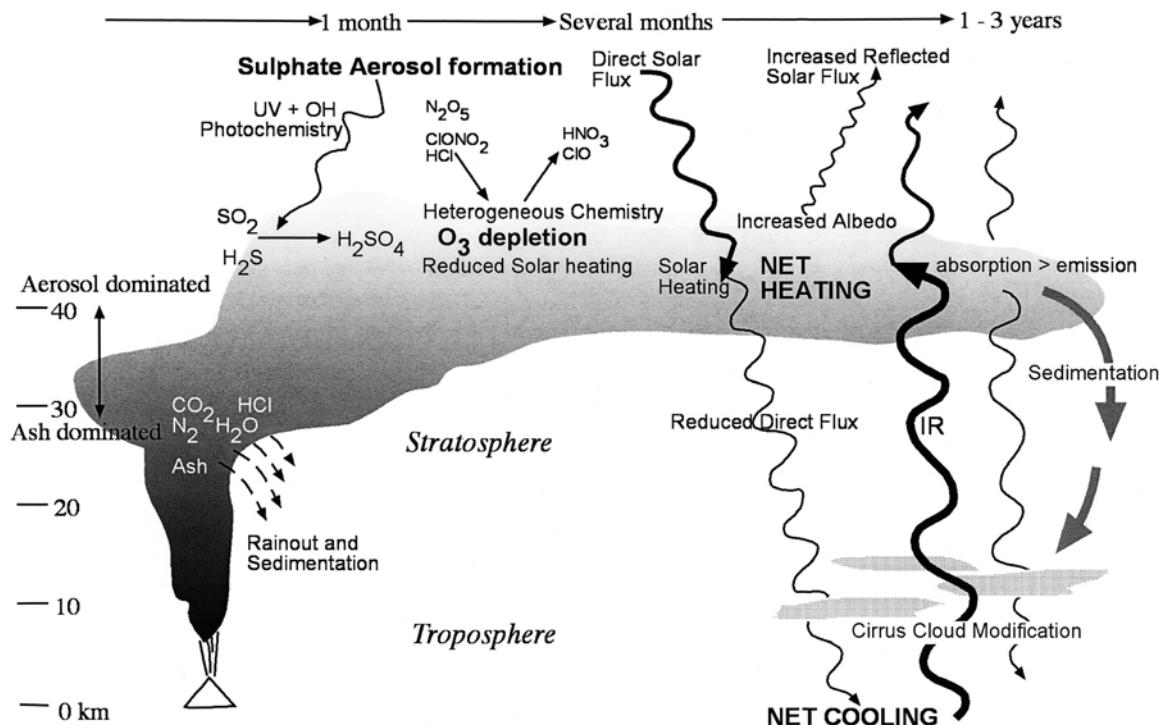

Figure V9 Evolution of the atmospheric input from a major plinian eruption (VEI 6) and the key processes that lead to climatic impact. Ash and gases are injected directly into the stratosphere but most solid and gaseous species are washed out rapidly (days to weeks). Sulfur gases have a much longer life in the atmosphere and may form an aerosol within a month or so. Over several months scattering of solar radiation may lead to cooling of the surface. In the stratosphere, absorption of the direct solar flux and infrared radiation escaping from the surface and troposphere results in stratospheric heating despite the reduction in solar heating resulting from ozone. These effects may persist for 1–3 years, after which growth and coagulation lead to sedimentation and recirculation of the aerosol into the troposphere. Here it may seed cloud formation and increase planetary albedo. Further details are in the text (adapted and modified from similar drawings by Richard Turco, Alan Robock, and others).

explosive, plinian-style pyroclastic eruptions, e.g. those at Mount St Helens, Washington, USA, in 1980; El Chichón, Mexico, in 1982; and Mount Pinatubo, Philippines, in 1991, that penetrate the tropopause and inject sulfur-rich aerosols into the stratosphere. These eruptions involve more silica-rich magmas such as andesite or rhyolite that are more viscous and volatile-rich, and hence more explosive. However, they are relatively sulfur-poor compared to basalts. This demonstrates the importance of stratospheric input, and thus magnitude of the eruption, for climate effects. Since the stratosphere is drier than the troposphere, particles are not rained out, so ash that enters the stratosphere may remain in the stratosphere for several months before sedimenting out, while aerosols, depending on latitude and altitude of the initial injection, are known to have atmospheric residence times of 1–2 years. During this time the aerosols are picked up by meridional circulation in the tropics, transported poleward in the midlatitudes, and then brought back to the troposphere at higher latitudes. Volcanic aerosols are rapidly advected around the globe in a matter of weeks, and thus circle the globe many times during their lifetime. They become more dispersed with time.

Once injected into the stratosphere the sulfur species, mainly SO_2 , oxidizes within about a month to produce H_2SO_4 . This combines with water vapor to give stratospheric aerosols. The aerosols act to cool the surface by reflection and/or warm the stratosphere by absorbing the direct solar flux or infrared being

emitted from the surface and escaping through the troposphere. Whether cooling or warming dominates depends on particle size of the aerosol; for warming to dominate, particles must be greater than $2 \mu\text{m}$. However, these particles would sediment out in a matter of months, and it seems unlikely that significant periods of surface warming can result from volcanic aerosols.

Particle size also affects the optical depth of aerosols, and this in turn affects the radiative response to volcanic input. Smaller particles provide greater aerosol optical depth per unit mass and thus a greater relative effect than larger particles. These size-related properties moderate the radiative and climate influences of volcanic eruptions, and this leads to the counterintuitive assertion that the influence of a volcanic eruption on global climate may be limited as the size of a volcanic eruption increases. It turns out that larger eruptions may not necessarily produce proportionally larger temperature anomalies; the greater input of volcanic SO_2 from a larger eruption leads to larger particles, rather than greater numbers, and these not only sediment out faster, but have smaller optical depth per unit mass than smaller particles.

Impact of a tropical eruption

The latitude of eruption is another important factor. Tropical eruptions have a more pronounced impact on global climate because of atmospheric circulation and the likely spread of

aerosol across hemisphere. Alan Robock and his colleagues have modeled the effects of a tropical eruption and show that the stratospheric heating is larger in the tropics than in the higher latitudes. This leads to an enhanced pole-to-equator temperature gradient that is naturally more pronounced in the winter. In the northern hemisphere winter, horizontal advection may result in winter warming as the jet stream (polar vortex) is made stronger and amplifies the North Atlantic Oscillation circulation pattern.

Two years after the 1991 Pinatubo eruption, stratospheric temperatures were found to have changed from higher than average to new lows. These observations are correlated with an observed decrease in stratospheric ozone following the eruption. It is probable that the loss of ozone resulted in less ultraviolet absorption and thus reduced the heating of the lower stratosphere. As far as we know, volcanic eruptions catalyze the loss of ozone in two ways: through chemical reactions and through changes in atmospheric dynamics. Ozone-destroying Cl and Br in volcanic aerosols are rained out before reaching the stratosphere. So it is not the introduction of these species that causes ozone depletion. Instead volcanic aerosols alter stratospheric chemistry in a way that activates stratospheric Cl and Br, from anthropogenic sources. These reactions, known as heterogeneous reactions, are recognized by workers such as Susan Solomon and others as a crucial part of the aerosol–ozone connection. The reactions involve atmospheric gases and liquid and solid aerosols. They are inversely temperature-dependent, and thus lead to enhanced stratospheric ozone depletion at mid-latitudes and polar regions. Ozone depletion can also result from dynamic uplifting from convection produced by the heating effect of volcanic aerosols. In the tropics this enhanced circulation can lead to ozone “depletion” by simply pushing ozone out to higher latitudes. Michael Mills notes that the 6–8% decrease of the total equatorial ozone column after the Mount Pinatubo eruption was substantially greater than tropical ozone depletion caused by anthropogenic sources, although this effect lasted only about a year. These competing effects notwithstanding, the net effect of aerosols in the stratosphere is stratospheric heating.

Aerosols are eventually transported to the troposphere through sedimentation and atmospheric circulation and are taken up by clouds or rain. This may lead to increased planetary albedo as the incorporation of aerosols results in a decrease in the average size of droplets in cirrus clouds, which may contribute to tropospheric and surface cooling. Significant tropospheric cooling on a global scale has been identified after recent eruptions of Agung in 1964, El Chichon in 1982, and Pinatubo in 1991 after removal of natural variations in temperature in the troposphere caused by phenomena such as the ENSO and the recent global warming trend. In the case of Agung and Pinatubo, cooling of the troposphere was of the order of 0.4°C. Mills notes that “Pinatubo more than offset the climate forcing of greenhouse gases added to the atmosphere since preindustrial times, at least for a short while.” For El Chichon the effect was swamped by the 1982–1983 El Niño. Krakatau, 1883, and Tambora, 1815, may have cooled the atmosphere by about 0.3°C and 0.4–0.7°C respectively.

Teleconnections and broader Earth system impacts

More abstract volcano–climate connections have been posited over the years. One intriguing connection is that the El Niño–Southern Oscillation cycle (ENSO) may be enhanced

by stratospheric aerosols. ENSOs are known to be a response to changing sea-surface temperatures. Since stratospheric volcanic aerosols can influence sea-surface temperatures through surface cooling, an impact of a tropical explosive eruption may be a change in tropospheric circulation and sea-surface temperatures that leads to an ENSO event. Paul Handler originally suggested this but was challenged on the basis of weakness in his statistical analysis showing coincidence of volcanic eruptions and ENSOs, relative timing of the two phenomena, and the weakness in the physical model. A viable physical model was developed by M. Hirono through an analysis of the impact of aerosols from the 1982 eruption of El Chichon. However, Alan Robock effectively dismissed the notion that volcanic eruptions can produce El Niños, and argued that the contemporaneity of volcanic eruptions such as El Chichon 1982 and powerful El Niños is a coincidence. The debate has come full circle as, recently, Adams and colleagues have presented a much stronger statistical case that over the past 400 years the ENSO phenomenon has been influenced by the after-effects of explosive volcanic eruptions. Volcano–climate interactions are clearly an important part of the systemic view of the Earth, and understanding their impact will lead to increased awareness of the teleconnections that abound across the various “spheres” of the Earth system.

We end the discussion of volcanic effect on climate with a broader perspective. Earth-system impacts of superexplosive eruptions or prolonged episodes of volcanism have been suggested as perturbations or forcings throughout Earth history. Numerous periods of anomalous climate from the geological record, e.g. “greenhouse” periods such as the Mesozoic Warm Period, and even the K-T Strangelove ocean, have been associated with anomalous volcanism. While these are contentious issues and are actively debated they nevertheless are part of the volcanism and climate story. In ending this review it is important to remind the reader that volcanism is a primary source of planetary atmospheres, supplying the gases that accumulated as the atmosphere or condensed into a hydrosphere after the primordial atmosphere was lost to space. Addressing these any further is beyond the scope of this article, and for more detailed treatments of these issues the reader is referred to the *Origin and Evolution of Planetary and Satellite Atmospheres* edited by Atreya et al. (University of Arizona Press, 1989) and the works of Kastings, Schubert, and others therein.

Acknowledgments

The author is grateful to Mike Rampino for his review and to John Oliver for editorial input. This article has been improved in both style and substance as a result. Any errors remain the responsibility of the author.

VORTICITY

Large-scale fluid circulations are of great significance in Earth systems as they redistribute energy, moisture and momentum over the planetary surface. Of the various motions observed in the atmosphere and hydrosphere, three-dimensional rotation, or vorticity, is commonly calculated to diagnose the behavior of weather systems and ocean circulation. Simply, vorticity is a vector description of the local rotation in fluids. Expressed as the total magnitude of change in wind components u , v , w along orthogonal Cartesian axes x , y , z , vorticity describes the complete spin experienced by a fluid parcel:

$$\nabla_2 \times V_3 = \mathbf{i} \left(\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} \right) + \mathbf{j} \left(\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} \right) + \mathbf{k} \left(\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} \right)$$

where \mathbf{i} , \mathbf{j} , \mathbf{k} are unit vectors in x , y , z coordinates, u , v , w are wind speed components in x , y , z coordinates.

Vorticity is used in numerous meteorological models to describe the rotational dynamics of atmospheric phenomena (Holton, 1972; Carlson, 1991; Cushman-Roisin, 1994). For example, the generation of updraft rotation in severe thunderstorms appears to be greatly influenced by the orientation of the horizontal vorticity vector in relation to the horizontal velocity vector, i.e. streamwise and crosswise vorticity (Davies-Jones, 1984). Most regional or synoptic-scale studies of atmospheric circulation focus on the so-called vertical component of vorticity (spin about the z -axis) owing to the relationship between horizontal vorticity, divergence and vertical motion in the atmosphere.

Absolute and relative vorticity

The vertical component of vorticity is typically expressed as:

$$\zeta = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}$$

Absolute vorticity is a measure of the total vertical vorticity experienced by a fluid parcel in the Earth-reference frame. Mathematically, absolute vorticity simplifies to:

$$\zeta_A = \zeta_R + f$$

the sum of ζ_R , the relative vorticity produced by wind shear and airflow through a curved path, and f , the Coriolis parameter, which quantifies the background rotation of the Earth. Earth

vorticity, f , is a function of latitude and positive (negative) in the northern (southern) hemisphere. Thus, positive/counterclockwise (negative/clockwise) rotation is cyclonic in the northern (southern) hemisphere. Earth vorticity values range from 0 at the equator to $\pm 2\Omega$ at the poles, where Ω equals the angular rotation rate of the Earth.

Relative vorticity, ζ_R , is the sum of shear and curvature vorticity components and ranges from positive (cyclonic) to negative (anticyclonic) values; at 0, relative spin = 0. Relative vorticity is measured in relation to the ground, in contrast to absolute vorticity, where the “background” motion of the Earth’s rotation is an additional portion of the total spin. The shear component of relative vorticity arises from horizontal variations in wind velocity. In the vicinity of an isotach maximum (jet streak), winds increase toward the center across transects along and normal to the current within which the jet is embedded. Air parcels on the poleward side of a jet streak experience cyclonic vorticity; conversely, parcels on the equatorward side of a jet streak occur in a zone of anticyclonic vorticity. Thus, even in straight-line airflow, vorticity is generated by lateral shear.

The remaining source of relative vorticity derives from rotation incurred as air flows through a curved path. In the northern hemisphere, cyclonic (anticyclonic) flow trajectories exert positive (negative) torque on air parcels. In geostrophic flow patterns, therefore, curvature vorticity maxima (minima) are associated with geopotential height minima (maxima).

The sum of Earth vorticity and relative vorticity, absolute vorticity, ranges from near-zero values in regions where ζ_R and f are opposed, to large positive or negative values in regions where ζ_R and f are aligned. Absolute vorticity is usually expressed as a unitless quantity, 10^{-5} s^{-1} (length measurements cancel).

Rossby (1940) observed that air parcels flowing at a level of non-divergence (divergence terms = 0), typically near 500 mb in the troposphere, conserve their absolute vorticity through time. Earth vorticity increases (decreases) occur as air flows across parallels of latitude toward the hemispheric pole (equator). Air parcel trajectories adjust for changing values of f by curving to raise or lower relative vorticity. As continued adjustments produce oscillations of Earth and relative vorticity after an initial perturbation, conservation of absolute vorticity produces a train of standing waves, or Rossby waves.

Airflow at 500 mb gains Earth vorticity as it translates toward the hemispheric pole. In the northern hemisphere, conservation of absolute vorticity is realized through anticyclonic curvature of this airflow, which is associated with a ridge in geopotential height contours. Air flowing through the ridge returns equatorward, and begins to lose Earth vorticity. As Earth vorticity declines toward the equator, relative vorticity increases in association with cyclonic curvature in the parcel trajectory, culminating in the formation of geopotential trough. The features of this wave train are related to one another via absolute vorticity conservation in a process known as teleconnection.

Vorticity advection and vertical motion

As air flows through a pattern of vorticity (the pattern is determined by curvature and shear), vorticity is advected downstream. Because the magnitude of relative or absolute

vorticity and its advecting current are large above the friction layer (in relation to near-surface values), deformations of the three-dimensional wind field caused by differential vorticity advection are most significant in the upper troposphere.

Because the rotation of a fluid and its horizontal radius are related by the conservation of angular momentum, positive vorticity advection (transfer of large vorticity toward regions of smaller vorticity), or PVA, is associated with horizontal divergence. Upper troposphere divergence attends rising motion by continuity and overlies surface convergence (a configuration known as “Dines compensation”). Similarly, upper tropospheric negative vorticity advection, or NVA, corresponds to regions of horizontal convergence, subsidence and surface divergence. Because of the co-location of geopotential minima (maxima) with vorticity maxima (minima), the region downstream of a northern hemisphere geopotential trough (ridge) is a zone of PVA (NVA). Within an isotach maximum, quadrants of PVA (NVA) are located in the right (left) entrance and left (right) exit of the jet streak.

The relationships between spin, divergence and vertical motion provide large-scale, dynamic mechanisms that drive relative humidity and static stability adjustments and deep convection. Vorticity advection patterns can provide a preliminary diagnostic assessment for the prediction of cloudcover, precipitation and severe weather.

Potential vorticity

Potential vorticity (PV) represents the balance between horizontal rotation and atmospheric thickness (or static stability). PV is defined mathematically as:

$$PV = \zeta_\theta \left(\frac{d\theta}{dp} \right)$$

where ζ_θ is the isentropic absolute vorticity, and θ is the potential temperature and p is pressure. On isentropic surfaces (surfaces of constant potential temperature), PV is conserved (Hoskins et al., 1985). Thus, following isentropic motion, static stability decreases (increases) are accompanied by absolute vorticity increases (decreases). As a result, the stratosphere, a reservoir of highly stable air, is a significant source of vorticity. A key mechanism of midlatitude cyclogenesis is the downslope flow along isentropic surfaces of stratospheric air into the upper and middle troposphere. As the stratospheric air becomes destabilized, absolute vorticity leads to positive vorticity advection, ascending motions and surface cyclone development.

The vorticity–thickness relationship defined by potential vorticity conservation also plays a role in the generation of anchor waves, perturbations of the midlatitude westerlies that generate the Rossby wave trains described above. Anchor waves are “anchored” to geographical features that induce thickness variations in the westerlies. Topographic anchor waves, such as the mountain ridge and lee trough of the Rocky Mountains of western North America, are year-round perturbations. Anchoring associated with baroclinic gradients, such as the troughs in the lee of east coast margins of Asia and North America, are strongest in winter, when cold continental surfaces are juxtaposed against warm ocean currents. The vorticity forcing of topographic and thermal anchors, in coordination with the strength of the zonal current of the westerlies, determines the number of waves and their position within the circulation. Thus, in addition to

driving large-scale vertical motions, vorticity is closely related to seasonal climatology.

WALKER CIRCULATION

In a series of articles extending from 1923 to 1937, Sir Gilbert Walker statistically defined the concept of the Southern Oscillation. As part of the research a distinctive circulation pattern located in the equatorial Pacific Ocean was described. This subsequently has been called the Walker Circulation (Bjerknes, 1969).

The Walker Circulation is a convective cycle that owes its origin to the gradient of sea surface temperatures along the equator in the Pacific Ocean. When the cold water belt off the coast of equatorial South America is well established, the air above will be cool and will not become part of the ascending air of the Hadley Circulation. Instead, the air flows westward between the Hadley cells of the two hemispheres. Upon reaching the eastern part of the oceans, in the vicinity of 170°E , it is in contact with warmer water and becomes heated and supplied with moisture. A thermal circulation, embedded in the normal equatorial flow, results. Figure W1 provides a schematic

representation of the extent and location of the Walker Circulation during a non-ENSO period.

The flow of air in the Walker Circulation is contingent on ocean temperatures and must be considered part of a larger atmospheric system. Whereas the Walker Circulation maintains an east–west exchange of air in the equatorial belt from South America to the west Pacific, the Southern Oscillation results in an exchange of mass along the complete circumference of the globe in tropical latitudes. As Bjerknes (1969) notes, the Walker Circulation is distinguished from other tropical east–west exchanges in that it taps potential energy by combining the large-scale rise of warm–moist and descent of colder dry air. Fluctuations in the Walker Circulation are therefore likely to initiate some of the major pulses of the Southern Oscillation.

WATER BUDGET ANALYSIS

Water budget analyses represent an environmental systems approach to the hydrologic cycle, with emphasis on the transport, storage and utilization of water at the Earth's surface. The geographical scales of analyses range from global water budgets down to studies of the income, outgo, and storage of water from small tanks set in the soil, known as lysimeters or evapotranspirometers. Time scales range from average water budgets derived from climatic data averaged over a number of years (typically 30 or more) to continuous daily water budgets within a real-time framework. This overview of water budget methodology begins with a description of the climatic water budget, with applications organized within a time scale beginning with long-term averages and closing with daily water budgets.

Mather (1974, 1978) has published comprehensive compilations of water budget procedures, analyses, and applications; Muller (1982) has published an overview of his water budget approaches to runoff and river regimen; and Miller (1977) has published a detailed survey of interactions of water with ecosystems at the surface of the Earth.

Climatic water budget

The climatic water budget is usually developed for a place, with the data inputs based on mean monthly temperature and precipitation derived from a climatic station or array of stations. The climatic water budget was introduced into the literature by Thornthwaite and his colleagues (Thornthwaite, 1948; Thornthwaite and Mather, 1955), initially for analyses of global and regional climatic classification in terms of the interactions of energy and moisture in the various regions. Focus was directed toward the determination of humid and dry climatic realms, identification of sub-humid climatic regions neither humid nor dry, and establishment of an orderly or regular structure of climatic types based solely on climatic parameters rather than vegetation characteristics (Carter and Mather, 1966). Numerous applications for environmental monitoring and analyses were developed at about the same time, and professional interests in applications quickly surpassed the initial studies of climatic classification (Thornthwaite and Mather, 1955).

Another key feature of the climatic water budget is that it serves as an excellent instructional tool for environmental managers and decision-makers, while providing a working foundation of many climatological principles for students interested in water resources. The various components of the water budget are easy to understand, and the bookkeeping methodology provides a straightforward assessment of the distribution of moisture in the environment.

The climatic water budget for Seabrook, New Jersey (Figure W2), is used to illustrate components of the budget. Thornthwaite developed and refined many of his water budget concepts at the Laboratory of Climatology at Seabrook Farms, and this average water budget for Seabrook appeared in the initial monograph about the water budget and its applications (Thornthwaite and Mather, 1955).

Potential evapotranspiration

Potential evapotranspiration (PE), the basic building block of the water budget, was developed as a concept by Thornthwaite in the mid-1940s. Potential evapotranspiration is defined as the amount of water that would evaporate and transpire from a landscape fully covered by a homogeneous stand of vegetation without any shortage of soil moisture within the rooting zone. Another specification is that estimates of PE be determined for a large area with similar vegetation and soil moisture conditions so that advection effects are eliminated.

Thornthwaite used measurements of water use in irrigation districts (primarily from the United States) and evapotranspiration data to derive a complex set of empirical equations for estimation of monthly PE based solely on temperature data and a latitude factor to adjust for daylength. The calculation procedures were set out in an instruction manual (Thornthwaite and Mather, 1957), so that climatologists rather quickly calculated PE and average climatic water budgets for most climatic regions.

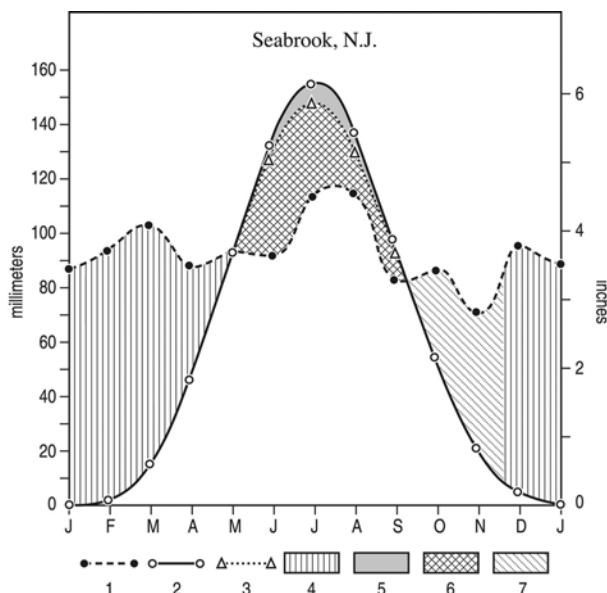

Figure W2 Traditional climatic water-budget graph. (1) P; (2) PE; (3) AE; (4) S; (5) D; (6) soil-moisture utilization; (7) soil-moisture recharge (Thornthwaite and Mather, 1955).

PE can be measured on a daily basis by means of moist evapotranspirometers or weighing lysimeters. These devices are large tanks filled with soil set into the ground with the top flush with the soil surface. Plants are grown in the evapotranspirometers, with a large buffer zone of similar plants around the tanks, to reflect natural field conditions.

The evapotranspirometer can be treated as a water budget system in terms of transport and storage of water. Precipitation or irrigation represents income, and measured percolation to subsurface drainage tanks represents one component of outflow. If the soil moisture in the tank is maintained close to capacity, the difference between total income (precipitation and irrigation water) and percolation represents an estimate of PE.

Weighing lysimeters are much more elaborate and expensive, but these instruments provide much more information. Decreases in weight represent evapotranspiration losses, after the other incomes and outflows of water are taken into account. Hence, weighing lysimeters have the capability even of estimating the diurnal regimes of PE rates, but it is difficult to maintain representativeness to the surrounding landscape. In the United States weighing lysimeters have been limited mostly to drier western states where the economy depends on availability of inexpensive water from well-watered uplands.

PE can be thought of as an energy supply term and, at the same time, as the climatic demand for water from the landscape. PE became the keystone of the water budget analysis; it represented an approximate estimate of potential or optimum water demand in the landscape that could be met by current precipitation and soil moisture utilization. It provided the basis for the budgeting procedure.

At the same time the PE concept became controversial. For some investigators PE estimates were great improvements over pan evaporation data; pans behave much like wet wicks in dry landscapes, and pan evaporation data needed to be adjusted downward by geographical coefficients to represent water loss from ponds and small lakes (Farnsworth et al., 1982). At the same time, the PE concept for a dry region is not entirely satisfying. This dilemma revolves around dimensions of irrigated buffer zones necessary to eliminate advection effects for measurement of PE in dry landscapes.

Thornthwaite also recognized that PE estimates based on temperature and daylength were necessary surrogates for measurements of surface energy budgets needed for rigorous estimates of PE, and he justified use of the empirical equations because of the unavailability of routine energy budget data. Over the ensuing decades more rigorous estimates of PE based on solar and longwave radiation, humidity, and wind have been developed, with the most frequently used estimates based on modifications of formulations originally developed by Penman (1948) in England and Jensen and Haise (1963) in the United States. Nevertheless, unavailability of energy budget data on a routine basis has restricted use of the more rigorous PE estimates mostly to scientific investigations, with the standard Thornthwaite PE estimates used for regional analyses. In general, error rates for regional PE estimates are considered to be rather minimal, particularly in most midlatitude environments; Brutsaert (1982) has published a comprehensive analysis of evaporation, including the PE concept.

Precipitation

Precipitation (P) represents the atmospheric delivery of moisture for the fundamental interactions of energy and moisture at

the surface. Unfortunately, most national and regional networks of precipitation gages represent minuscule samples of precipitation. Some networks are reasonably adequate for water budget analyses, especially on an average annual basis. However, standard precipitation data are clearly inadequate in areas marked by large spatial and temporal variability in rainfall, over many sparsely settled areas and especially in mountainous regions with complex patterns of orographic precipitation and rainshadow valleys. Furthermore, there are few long-term observational series over the world's oceans, which occupy more than two-thirds of the surface areas of the Earth, and remote-sensing techniques have not as yet been refined to fill in data gaps between standard gages satisfactorily. Of particular significance is the generally agreed upon undercatch of standard rain gages, especially during windy storms, as opposed to the true precipitation delivered to global landscapes (Mather, 1974); indeed, in river-basin analyses, precipitation may be more in error than PE.

Soil moisture storage

Soil moisture storage (ST) represents water available within rooting zones of the plants for transpiration and evaporation. In classical terms it represents the differences between field capacity and the wilting point. In the water budget framework, soil moisture is generally expressed in units equivalent to precipitation. On an average worldwide basis, Thornthwaite originally estimated the available soil-moisture storage capacity to approximate 100 mm, but 300 mm later was used for global comparisons (Carter and Mather, 1966). In the United States the modern county soil surveys published by the Natural Resources Conservation Service include useful information for estimating available soil moisture capacities for combinations of geological substrate, soil types, slopes, land use, and vegetation covers.

Within the water budget model it is assumed that soil moisture will be utilized by plants to meet the demands of PE when precipitation is less than PE. For the calculation of soil-moisture depletion, Thornthwaite originally suggested that plants could draw on soil moisture equally as needed until the available soil moisture within the rooting zone was exhausted; this approach became known as the equal-availability model (Figure W3, curve A). A few years later Thornthwaite and his

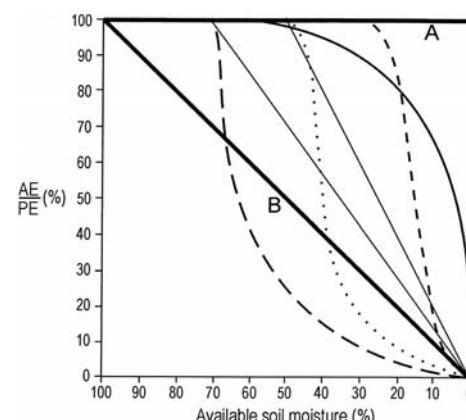

Figure W3 Selected soil-moisture depletion curves. Curve A represents equal availability, and B decreasing availability (after Mather, 1974).

colleagues introduced the decreasing-availability model (Figure W3, curve B), which stated that the plants would withdraw soil moisture to meet the PE demand in proportions relative to the availability of soil moisture within the rooting zone. For example, if available soil moisture within the rooting zone amounted to only 60% of capacity, the plants would withdraw 60% of the PE demand, but if available soil moisture were only 20% of capacity, plants would be able to withdraw only 20% of the demand (Mather, 1974). Figure W3 also illustrates various other soil-moisture depletion models either proposed or in use.

Most investigators prefer some form of the decreasing-availability model over the equal-availability model. A later innovation has been the introduction of a two-layer or even multiple-layer accounting system for soil moisture storage and depletion. The most commonly used approach is to set up a two-layer accounting system, with an upper shallow layer in which moisture is treated as equally available and given the first priorities for soil moisture depletion and recharge. Soil moisture in the thicker lower layer is treated as decreasingly available and second in the priority system of depletion and recharge. Multiple-layer systems are most commonly used with daily or weekly water budgets, and are particularly well adapted to computer modeling.

Actual evapotranspiration

Actual evapotranspiration (AE) in Thornthwaite's average water budget models represents precipitation and soil moisture withdrawals actually used by the plants to try to meet the energy demand represented by PE. Actual evapotranspiration, then, can be equal to but never greater than PE; there are, of course, places and times when AE is less than PE. Thornthwaite's adoption of the term actual evapotranspiration was unfortunate, however, because it implies empirical measurements of evapotranspiration, rather than calculations within the model framework. Most researchers in the agricultural sciences have substituted evapotranspiration, or simply ET, for actual evapotranspiration (AE), regardless of whether ET is measured or calculated.

No distinction is made between transpiration by plants and evaporation from soil surfaces in the Thornthwaite water budget models. Thornthwaite pointed out that most water loss from fully vegetated surfaces was transpiration by plants rather than small amounts of evaporation from shaded soil surfaces; linking of the two pathways of water vapor to the atmosphere as evapotranspiration, either potential or actual, was the cornerstone of water budget analyses as applied to landscapes, river basins, and regions.

In most situations ET represents water passing through plant systems. Indeed a number of measures of biological activity, plant development and growth, crop yields, and even physical and chemical processes in the soils are tied to climatic processes and are indexed effectively from a climatic perspective by AE or ET.

Moisture deficit and surplus

The moisture deficit (D), often simply termed the deficit, is defined as the difference between PE and ET. The deficit represents the additional water that would have been used by plants if it were available, and can serve as a measure of irrigation potential of places and regions; thus, D is also a measure of potential increases in plant growth and crop yields.

The moisture surplus (S), represents precipitation not used for evapotranspiration or soil moisture recharge, and, therefore, water available for surface runoff to lakes and streams or for percolation to groundwater tables. The term surplus betrays an agricultural bias; surplus becomes the input to the surface and groundwater systems studied by hydrologists and engineers. In water budget climatology, surplus water is just as much a part of regional climates as clouds and precipitation are for meteorologists and atmospheric scientists. The surplus is useful for estimating runoff, streamflow, groundwater recharge, and physical or chemical processes in the soil related to downward migration of water.

Figure W2 shows the standard graphical format of the average climatic water budget components of a place. Seabrook, New Jersey, is used here to represent typical annual regimes for a humid climate region in middle latitudes. This average monthly budget is based on an available soil moisture storage capacity of 300 mm and the decreasing-availability model of soil moisture depletion (Figure W3, curve B). Figure W2 emphasizes the seasonality of water budget components, soil moisture withdrawals and deficits during summer, soil moisture recharge during fall, and production of surplus water during winter and early spring.

The average climatic water budget model can be expressed in two interrelated fundamental equations expressing water movement and storage (1) $P = ET + S$; and energy demands (2) $PE = ET + D$, with the terms as defined in the text.

Average water budgets

In recent decades there has been considerable interest in global water budgets, in which both storage and exchanges of water in the atmosphere, on the continents in terms of surface waters, soil moisture, groundwater, snow, and glacial ice, and ocean water are evaluated. These analyses indicate, in part, the very small storage of water vapor in the atmosphere at any one time, estimated to average only about 25 mm of equivalent precipitation on a global basis, the large magnitude of evapotranspiration on the continents relative to runoff to the oceans, the importance of evaporation from the oceans, and the dominance of maritime sources of atmospheric moisture for precipitation over most regions of the continents (Baumgartner and Reichel, 1975; Mather, 1974). Figure W4 is a schematic representation of

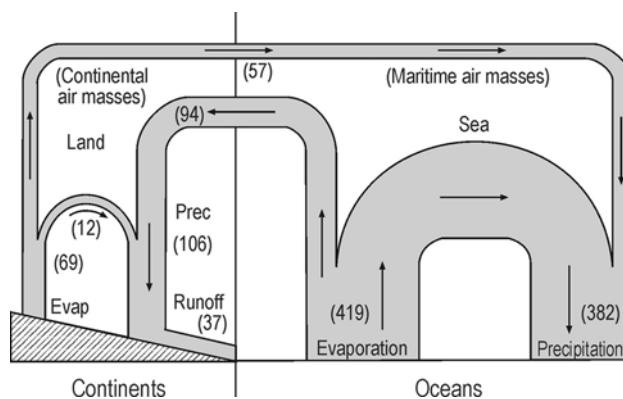

Figure W4 Schematic representation of the global hydrologic cycle. Widths are proportional to volumes of water; values are mean annual water volumes in thousands of cubic kilometers (after Mather, 1974).

the hydrologic cycle in terms of the average annual water budget of the Earth.

The water budget graph for Seabrook, New Jersey (Figure W2) is a representation of the average water budget of a place. Thornthwaite and his associates have calculated average climatic water budgets for thousands of places using a soil moisture storage capacity of 300 mm and the decreasing-availability model of soil moisture depletion; these average budgets have been published by continents in *Publications in Climatology* (Mather, 1962–1965). A moisture index (Im) was also derived from the average water budget calculations; it represents a comparative index of the degree to which mean annual precipitation meets the climatic demands for water (PE) at each place. The index was used as part of an overall climatic classification having five basic types from wettest to driest: perhumid, humid, subhumid, semiarid, and arid (Carter and Mather, 1966). Detailed maps of each of the continents are available, but there has been less interest in classification than applications.

Components of the average water budget, especially PE, AE, and Im, have been used to illustrate regional and global patterns of natural vegetation (Mather and Yoshioka, 1968) and the basic types of the United States comprehensive soil classification (Mather, 1978). Actual evapotranspiration (ET) also has been used to describe global patterns of a host of biological interactions with climate including primary productivity of land plants (Leith and Box, 1972), the decomposition of organic debris and forest-fire hazards (Meentemeyer, 1978), and plant-litter production (Meentemeyer et al., 1982). Carter et al. (1972) prepared a summary statement setting out environmental relationships and responses to components of the average budget, extending relationships to weathering and geomorphology.

Monthly water budgets

For study and management of environmental resources in most climatic regions, average water budget components suggest an unrealistic seasonal stability of moisture conditions. Although variability of energy availability from one year to another on a given month (expressed by PE) is relatively small, the variability of precipitation for a given month over a series of years can be very large. In addition, use of average monthly precipitation in average water budget calculations masks the effects of precipitation variability on evaporation, deficits, and surpluses through time.

As an example, Table W1 shows mean annual water budget components for Baton Rouge, Louisiana (based on the period 1961–1990) calculated first by means of the average water budget, and secondly by means of a continuous monthly water budget procedure. In the continuous monthly water budget

procedure, components for each month are calculated before proceeding on to the following month through the period of interest. Monthly precipitation variability is taken into account, and a deficit, for example, will be calculated for a very dry month that, on the average, is very wet. When monthly means of continuous water budgets are calculated and summed on an average annual basis, Table W1 shows that average annual ET (AE) decreased at Baton Rouge from 1045 mm to 946 mm, or a decrease of nearly 100 mm. At the same time, deficits and surpluses increased to 105 mm and 601 mm, respectively. Mean annual totals based on continuous monthly water budget analyses are more representative of the inter-annual variability of environmental conditions than components of the average water budget.

Figure W5 illustrates the monthly water budget components at Baton Rouge during a recent period of years. This graphical style does not show monthly precipitation, but emphasizes the seasonality of generation of surplus water for runoff in humid subtropical and midlatitude climatic regimes. Effects of climatic variability also are illustrated in Figure W6, which shows seasonal and annual values of the AE/PE ratio plotted against PE for four places on the United States beginning with New Brunswick, New Jersey, in the humid continental climatic region. Despite the designation as a humid climate, dry years at New Brunswick are much drier in terms of the AE/PE ratio than wetter years in the subhumid climate at Dodge City, Kansas, where the variability is very great. Bradford, in the mountains of Pennsylvania, is just about always wet in these terms, and Alamosa, located on a rain-shadow valley of Colorado, is always dry.

The Palmer drought index series (Palmer, 1965) and the crop-moisture index are developed from continuous monthly and weekly water budgets using a two-layer soil moisture system. These two indices represent unique adaptations of water budget components for the identification of periods of significant departures-from-normal of seasonal moisture characteristics for each place or region. The Palmer indices and the crop moisture index are both prepared on a near real-time basis by the Climate Prediction Center of the National Weather Service (NWS) for climatic monitoring across the United States; these products are available in the *Weekly Weather and Crop Bulletin*, published by Joint Agricultural Weather Facility, operated by the NWS and the US Department of Agriculture.

Table W1 Comparison of average annual and continuous monthly water budgets, Baton Rouge, Louisiana, 1961–1990 (in millimeters)

Water budget component	Average annual budget	Means of continuous monthly budgets
PE	1064	1051
P	1546	1546
AE	1045	946
D	20	105
S	502	601

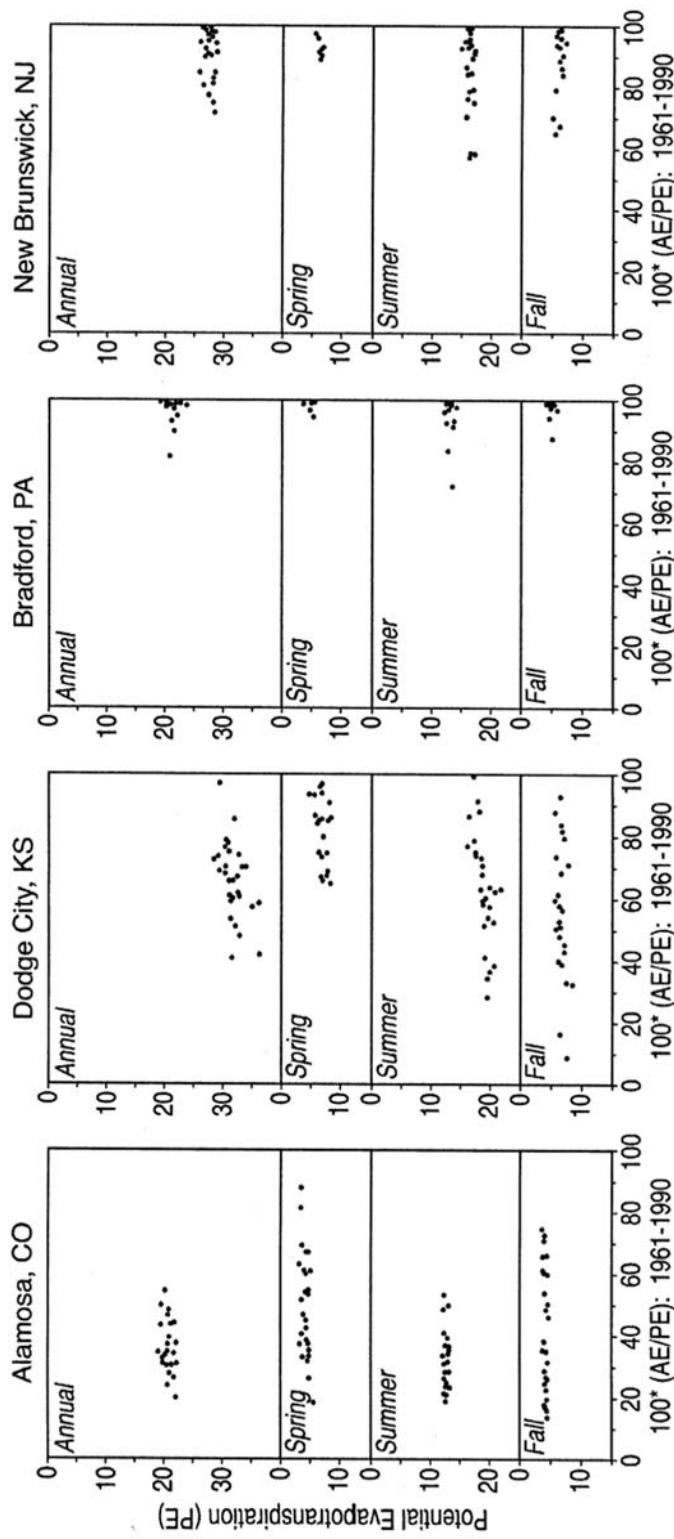

Figure W6 Seasonal and annual ratios of AE/PE plotted against PE for the humid East (New Brunswick, New Jersey, and Bradford, Pennsylvania), the subhumid Great Plains (Dodge City, Kansas), and a high rainshadow desert (Alamosa, Colorado).

An especially interesting application of continuous monthly water budget procedures has been the study of relationships of land use and land cover to runoff and streamflow. For a given climatic regime, does a parcel of land or an entire drainage basin yield more or less water now than, say, 50 years ago because of changes in the use of the land and because of engineering modifications of the drainage systems? These relationships are difficult to evaluate because the investigator is usually searching for relatively small differences among quantities that are difficult to estimate well for entire drainage basins, with climatic variation adding to the complexity of the problem.

The first water budget analysis of this problem was an investigation of the effects of reforestation on water yield from small drainage basins on the Allegheny Plateau in New York (Muller, 1966). Monthly water budget calculations were used to estimate runoff and streamflow due directly to month-by-month variations of PE and precipitation. Monthly estimates of streamflow were then compared to measured streamflow, which is the consequence of climatic variability and changes in land cover. In these drainage basins the land-use changes were mostly replacement of pastures with conifer reforestation

blocks. The differences between calculated and measured runoff (Figure W7) were assumed to represent the effects of reforestation, and this study indicated that reforestation significantly reduced annual runoff for a number of years.

Water budget analyses have also been used to show some of the effects of urbanization on runoff. Figure W8 shows the results of a simulation of the monthly surplus or runoff for undeveloped land in Middlesex County, New Jersey, and for the same land and years as if this land had been developed for typical middle-class subdivisions (Muller, 1969). The figure shows extra water coming off the subdivisions; most of the supplementary runoff is generated during summer and fall when undeveloped land normally produces little to no runoff. Examples of other hydrologic applications of continuous monthly water budget procedures include, for example, effects of land-use changes on river-basin regimen for water resources optimization (Shelton, 1981), comparisons of drainage basin modeled and measured runoff (Rohli and Grymes, 1995), and long-term trends of precipitation and modeled runoff (Keim et al., 1995).

In another study of the Mississippi River drainage basin using monthly temperature and precipitation data from 147 climate divisions for 1932–1988, the standard continuous monthly water budget accounted for 96% of the variation in annual discharge for the entire basin above Tarbert Landing, Louisiana (Hoff and Muller, 1998). Comparisons between modeled and observed runoff suggested that land use and river management had not changed precipitation and runoff relationships from the entire basin through the years, but that significant runoff changes had occurred within the Ohio–Tennessee basins.

Most recently, the water budget methodology was utilized to evaluate the sensitivity of runoff from the Cannonsville watershed in the Catskill Mountains (one of the primary sources for potable water for the City of New York) during historical periods of extreme high and low precipitation since the mid-1950s (Frei et al., 2002). A modified daily Thornthwaite water budget with snowpack and groundwater storage was developed for the study. Using four GCM model estimates of global warming by 2080, estimated average annual runoff is shown to range from between +10% and -30% of average annual water yield in recent decades, about equal to extreme wet and dry years in the 1960s and 1970s, respectively.

Other applications include monitoring salinity regimes in estuaries (Mather et al., 1972), analyses of water budget components of a large lake system (Sanderson, 1966), relationships

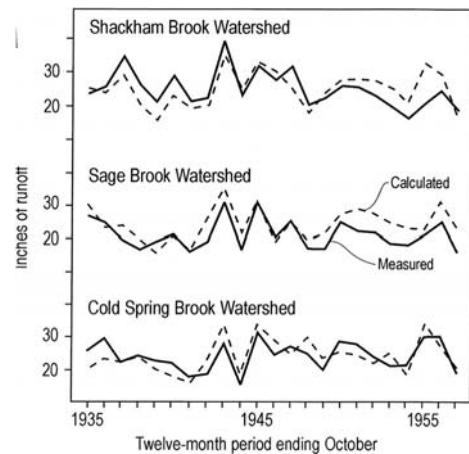

Figure W7 Modeled and measured water yield from partially reforested watersheds on the Allegheny Plateau, New York (after Muller, 1966).

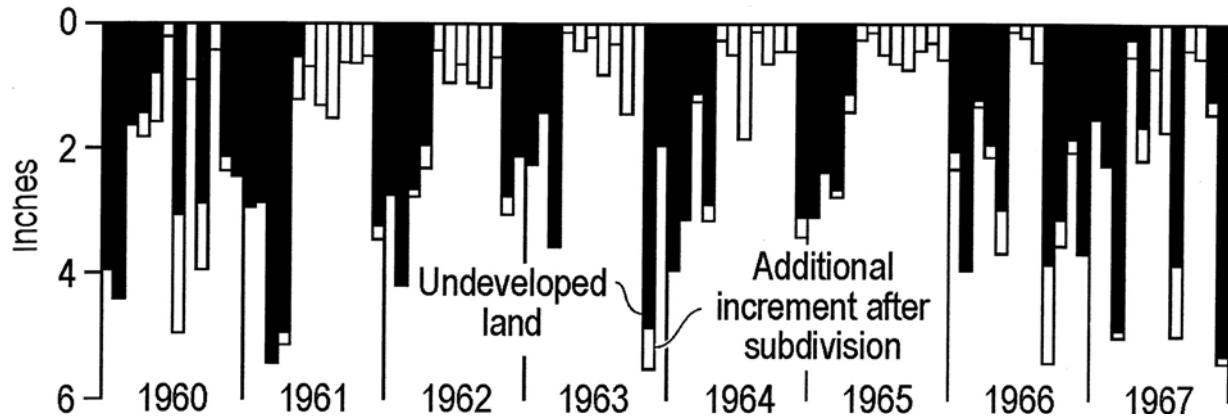

Figure W8 Water-budget simulation of surplus water generated from undeveloped land and residential subdivisions in Middlesex County, New Jersey (after Muller, 1982).

among water budget components and crop yields (Chang, 1968), and evaluations of the relationships of pine bark beetle outbreaks to deficits and surpluses (Kalkstein, 1981).

Weekly and daily water budget analyses

The annual sums of estimated evapotranspiration, deficits, and surpluses are changed if weekly or daily water budget calculations are used to replace continuous monthly calculations. In humid and subhumid climatic regions, daily and weekly variability of precipitation results in smaller seasonal or annual sums of ET and correspondingly larger sums for D and S. Weekly or daily water budget data are even more representative of real-world climate and environmental interactions than continuous monthly water budgets. As a result of the increased demand for daily and weekly water budgets, there are now a number of computer programs available for long-term analysis.

Daily water budgets, in which daily values of PE are compared to available soil moisture, are being developed extensively in the agricultural sciences. Basically, daily budgets are being used to model crop development and growth, and to study the water economies of commercial crops. Examples include quantification of relationships between ET and productivity (Hank, 1974), development of specialized water budget models for agriculture (Ritchie, 1972), and simulation models for growth of corn and sorghum (Stapper and Arkin, 1980). Daily water budget models also have been used to analyze differential stress in terms of deficits on crop production at various physiological growth stages in corn and soybeans (Sudar et al., 1981). Daily water budget models also have been incorporated by the National Weather Service in their River Forecast Centers for real-time prediction of river stages and floods on selected drainage basins (Peck, 1976).

WEATHER

A major component of the atmospheric sciences, weather is defined as a state or condition of the atmosphere at any particular place and time. A broad, integrated weather picture is known as a weather system. Weather is specifically distinguished from climate, which represents a regional or global synthesis of weather extended through time on the scale of years, rather than minutes or hours. Weather involves measurement of multiple parameters, so-called weather elements: temperature, pressure, wind, cloud condition, visibility, humidity, precipitation, and other hydrometeors (dew, rain, hail, snow). In relation to humans, weather often conditions personal comfort or economy and goes further to embrace related factors such as sea state, tidal hazards, avalanche liability, and river flooding. Additionally, weather study also includes optical phenomena, such as lightning, aurora, and solar phenomena.

In aviation, the word weather is used in relation to the synoptic weather observations of the immediate past and present. Weather also has a special geological meaning. *Weathering* is the process of rock disintegration (both mechanical and chemical, abrasion and corrosion) under the influences of the atmosphere.

The scientific study of weather is meteorology. This is defined by the American Meteorological Society (Geer, 1996) as the study dealing with phenomena of the atmosphere. This not only includes the physics, chemistry and dynamics of the atmosphere, but is extended to include many of the direct effects of the atmosphere upon the Earth's surface, the oceans, and life in general. The goals often ascribed to meteorology are the complete understanding, accurate prediction, and artificial control of atmospheric phenomena.

The term “wind chill” was coined by the Antarctic explorer Paul A. Siple in his dissertation, “Adaptation of the explorer to the climate of Antarctica”, submitted in 1939. During their stay in Antarctica, Siple and his colleague, Charles F. Passel, conducted experiments on the time required to freeze 250 grams of water in a plastic cylinder placed outside in the wind, including a formula relating the rate of energy loss of the cylinder to the air temperature and wind speed. The formula was later used to compute the *wind chill equivalent temperature*. This parameter was supposed to take into account the exaggerated sensation of cold that one experiences when the wind is blowing at low temperatures. For example, according to the formula, an appropriately clothed person exposed to a temperature of -15°C and a wind of 12 meters per second (m s^{-1}) would feel as cold as when walking in still air at a temperature of -39°C . The US National Weather Service adopted the wind chill formula in 1973 and used it until 1 November 2001, when it was replaced.

Flaws in the formula for wind chill equivalent temperature were recognized from the start. Water has no internal heat source like the human body. A plastic bottle does not resemble human skin: the formula ignores the thermal resistance of skin, and the assumed skin temperature is unrealistically high. Wind speed, customarily measured on a 10-meter tall mast, is greater than that experienced at face level. Finally, people accustomed to cold winter weather complained that the wind chill equivalent temperature overstated the effect of wind.

In the fall of 2000, responding to the apparent inadequacies in the formula for wind chill equivalent temperature, the US Office of the Federal Coordinator for Meteorology formed the Joint Action Group for Temperature Indices (JAG/TI), whose first job was to evaluate the shortcomings of existing wind chill formulas and, if necessary, propose a new formula. The JAG/TI included government and university representatives from the US and Canada. The JAG/TI enlisted Dr Maurice Bluestein (Indiana University–Purdue University in Indianapolis) and Mr Randall Osczevski (Defense and Civil Institute of Environmental Medicine – DCIEM, Toronto, Ontario, Canada) to devise a new formula, based in part upon their recent research on wind chill and in part upon new tests with human subjects (Table W2).

DCIEM conducted clinical trials in a wind tunnel under controlled conditions of temperature and airflow. Subjects had

FROSTBITE GUIDE

Low risk of frostbite for most people

Increasing risk of frostbite for most people in 10 to 30 minutes of exposure

High risk for most people in 5 to 10 minutes of exposure

High risk for most people in 2 to 5 minutes of exposure

High risk for most people in 2 minutes of exposure or less

sensors for measuring temperature and energy transfer attached to various parts of the face. Bluestein and Osczevski calibrated their new formula for wind chill temperature against the tests with human subjects. Following JAG/TI adoption of the formula, the Meteorological Service of Canada began using it operationally on 1 October 2001; the US National Weather Service followed suit on 1 November 2001.

The new wind chill temperature (WCT) has the following features:

1. It corrects the observed wind speed, normally measured at a height of 10 meters, to the average height of the human face, about 1.5 meters.
2. It is based on a model of the human face that incorporates modern heat transfer theory.
3. The formula builds in a margin of safety in that it applies to persons whose skin has unusually high thermal resistance. For

these people, interior body heat does not pass as readily to the surface of the skin as in the great majority of the population.

4. It uses a low-wind threshold of 4.8 km/h rather than the 6.4 km/h used in the Siple–Passel formula. Pedestrians on busy streets are more likely to walk at 4.8 km/h than 6.4 km/h.
5. The formula assumes nighttime conditions with clear skies (no incoming solar radiation and minimal infrared radiation received from the sky).
6. It gives values higher than those generated by the old Siple–Passel formula.

In metric units the equation for wind chill temperature (°C) is

$$WCT = 13.12 + 0.6215T - 11.37V^{0.16} + 0.3965TV^{0.16}$$

where T is the air temperature in °C, and V is the wind speed in kilometers per hour measured at a height of 10 meters (standard practice).

In English units the equation for wind chill temperature (°F) is

$$WCT = 35.74 + 0.6215T - 35.75V^{0.16} + 0.4275TV^{0.16}$$

where T is the air temperature in °F and V is the wind speed in miles per hour measured at a height of 33 feet.

The JAG/TI agreed to delay incorporating the effects of solar radiation on the formula until researchers determine the correct adjustments for solar zenith angle and cloudiness. In addition, the JAG/TI wants to refine estimates relating exposure time at a given WCT to the onset of frostbite. Finally, they may devise a formula that takes into account the chilling effects of water on the skin.

WIND POWER CLIMATOLOGY

Humans have long used the wind to ease workloads in a wide variety of applications. Sailing ships have been in use for at least three millennia and wind-driven gristmills were invented more than two millennia ago. At the beginning of the twentieth century, wind took on a new importance in powering electrical devices that revolutionized the quality of life. In the United States and in other developed countries, wind power generation became virtually moribund after rural electrification efforts started in the 1930s. However, the relatively high costs of fuel in Europe and environmental concerns revitalized the wind power industry at the end of the twentieth century. Key to this wind revolution was improvement of the machines. As of the beginning of the twenty-first century, wind power represented less than 1% of world electrical generation, but was the fastest-growing source of alternative energy.

The successful use of wind power is largely dependent on climatic knowledge. The problem concerning productive use is that winds do not blow evenly over space and time over Earth. Witness the global circulation components known as the trade winds and the doldrums. The former was closely associated with dependable winds that made for dependable sailing schedules. The latter was associated with light and variable winds presenting a challenge to their productive use. As humans attempt to tap the kinetic energy of winds for generating electricity we are, ironically, still subject to basic limitations of an area's climatology.

Turbine technology

The wind has been used to turn turbines ever since the first small turbines were attached to windmills in Denmark in the 1890s. The fossil energy crises of the 1970s drove investors to fund wind power generation, notably in California. These machines were much smaller and less reliable than today's versions. As government tax credits declined, so did the wind power industry. Modern wind turbines used in utility-scale wind power farms represent a quantum leap in technology from that era. The late twentieth century witnessed considerable improvement in turbine technology including use of strong, lightweight carbon fiber materials in the blades, blade designs employing lift instead of drag, and computerized controls. Large turbines have the ability to continuously adjust blade pitch so as to maximize the wind power harvest or halt the revolution of the blades. However, the most noticeable change has been in their size. Modern turbines represent some of the largest machines ever built.

As turbine sizes have increased, they become more cost-effective in electrical production. In the late 1970s the cost of utility-scale wind power per kilowatt hour (kWh) was nearly 40¢. By the first decade of the twenty-first century the cost had decreased to on the order of 3–5¢ per kWh. Although there has been continued argument over the appropriateness of state and federal production tax credits in the United States, it is clear that the cost of utility-scale wind power has declined to become competitive with fossil-fuel-derived power.

A typical utility-scale turbine of today has a height of 50 meters or more at the hub connecting three blades that may be larger than 30 meters. Newer turbines produce more than a megawatt (one megawatt is enough to power in excess of 250 US households). Most installations will have many turbines strung along a ridgeline in order to take advantage of the strongest winds in the area and to make the most of the economies of scale. Figure W9 illustrates a typical utility-scale

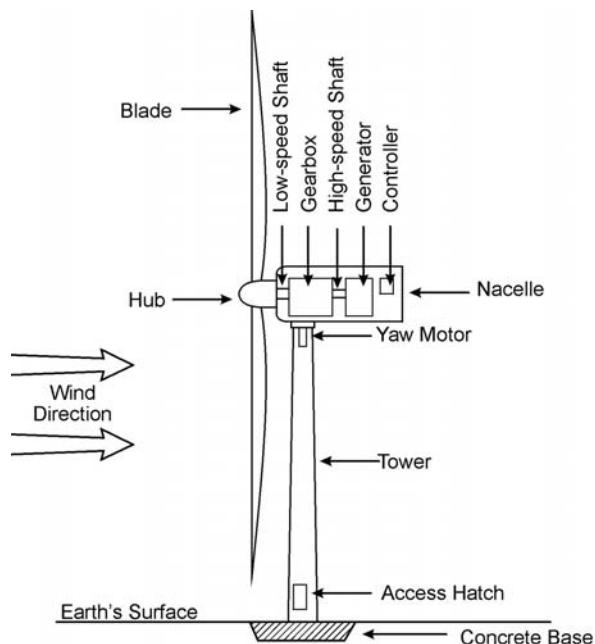

Figure W9 Utility-scale wind turbine.

turbine designed for a 20-year lifetime. An anemometer feeds wind speed and direction data to the controller. When wind speeds exceed 3 m/s the blades start to turn. An onboard yaw motor keeps the hub turned toward the wind direction and the controller adjusts blade pitch in order to maximize the power derived from the wind. Blade rotation speeds are moderate on large turbines, with 30–60 rpm being typical. At the hub the blades are connected to a shaft connected to a gearbox in the nacelle. The purpose of the gearbox is to convert rotational speeds up to 1200–1500 rpm on a high-speed shaft; these higher speeds are suitable for use in generators. The generators in the nacelles produce electricity at high voltage (e.g. 960 kV) and the electricity is fed to transformers at an electrical substation in order to be put on a power grid at 25 kV. At wind speeds of 25+ m/s the turbine's energy production will be cut out so that neither blades nor surroundings are damaged.

Small turbines are used for on-site power. A typical small turbine installation might have blades sweeping an area 10 m across while mounted on a 15 m tower. These have outputs less than 50 kW. A small turbine is shown in Figure W10. Though small turbines tend to cost more to produce each kilowatt hour than do large turbines, their relatively small up-front costs and

Figure W10 A small wind turbine (courtesy Bergey Windpower Company).

greater flexibility in siting make them attractive in some home, small industrial, and cooperative ownership settings.

Turbine technology continues to improve and has been fostered by government-led research and development. For instance the US Department of Energy's National Wind Technology Center runs a low-speed turbine program. By increasing electrical output at progressively lower wind speeds, the aim is to make lower wind areas commercially viable for wind development, thus increasing the usable area by 20 times. In Europe, Denmark's Risø National Energy Laboratory is a leading organization in wind power research.

Wind power calculation

The key to economic success in developing wind power is in understanding of the wind power characteristics of a proposed site. Calculation of available wind power relies on knowledge of the physics of kinetic energy. The kinetic energy (KE) of wind with total mass (M) and velocity (V) is given by the expression:

$$KE = \frac{1}{2} \times M \times V^2 \quad (1)$$

For purposes of wind turbine power calculation, consider the air moving onto a turbine's blades (Figure W9) as a parcel with the shape of a huge cylinder. In a given time, the turbine's blades sweep out cross-sectional area (A) and the cylinder has a depth (D) in the dimension horizontal to Earth's surface. So, the volume (Vol.) of this cylinder is given by the equation:

$$Vol = A \times D \quad (2)$$

The density of air (ρ) in the cylindrical parcel can be represented by:

$$\rho = M/Vol \quad (3)$$

Restated, this becomes:

$$M = \rho \times Vol \quad (4)$$

If a time (T) is required for the cylinder of air with depth (D) to pass through the plane of the wind turbine blades, then the air parcel's velocity (V) can be expressed as:

$$V = D/T \quad (5)$$

In Equation (4) can be reworked as:

$$D = V \times T \quad (6)$$

Equation (1) can be restated using the substitutions from the other equations. First, substitute for M using equation (4):

$$KE = \frac{1}{2} \times (\rho \times Vol) \times V^2 \quad (7)$$

Next, substitute for Vol . using equation (2):

$$KE = \frac{1}{2} \times (\rho \times A \times D) \times V^2 \quad (8)$$

Next, substitute for D using equation (6):

$$KE = \frac{1}{2} \times (\rho \times A \times V \times T) \times V^2 \quad (9)$$

Equation (9) can be restated as:

$$KE = \frac{1}{2} \times (\rho \times A \times V^3 \times T) \quad (10)$$

Power is defined as kinetic energy divided by time. Substituting the right side of equation (10) for KE, power is expressed as:

$$Power = (\frac{1}{2} \times \rho \times A \times V^3 \times T)/T \quad (11)$$

Equation (11) can be reduced to:

$$\text{Power} = \frac{1}{2} \times \rho \times A \times V^3 \quad (12)$$

In reality, the density of air (ρ) of the wind does not vary as widely as wind velocity (V) so that equation (12) means that power approximately varies as a cubic function of wind speed; the power that can be derived from the wind increases greatly with increases in wind speed.

The wind industry commonly uses wind power density (WPD) as a standard measure. WPD is independent of turbine blade size and efficiency. It is calculated by dividing power by the cross-sectional area (A) of the air parcel. Thus, WPD is dependent only on the velocity and density of the air parcel:

$$\text{WPD} = \text{Power}/A \quad (13)$$

Wind power density is expressed in W/m^2 . The US Department of Energy defines a site as economically suitable for large turbines if it has a wind power density greater 400 W/m^2 at 50 m above the surface; this equates to a wind of approximately 7 m/s and above with turbine sites close to sea level. The Department of Energy's wind power map of the continental United States is given in Figure W11.

The large capital investment in wind turbines dictates caution, so utility-scale projects are thoroughly researched with onsite meteorological instrumentation on tall towers mimicking turbine heights. Unfortunately, these specially instrumented usually have short lengths of record (several months) and are not of true climatological proportions.

A site's wind resource must also be evaluated on its time variability. Equation (13) is an average over time. Extreme care must be used with using equation (13). Almost always, the cube of long-term mean wind speed is less than the mean of the cubes of the individual wind speed observations. This is because wind speed/power plots approximate Rayleigh functions. An example is given in Figure W12. To accurately estimate wind power density, the calculations should be a summation of data taken frequently (e.g. every few minutes) over long time periods (years). The preferred form of the WPD equation becomes:

$$\text{WPD} = 0.5 \times 1/n \times \sum_{i=1}^n (\rho_i \times V_i^3) \quad (14)$$

In equation (14) n is the number of wind speed observations and ρ_i and V_i are, respectively, the i th (first, second, third, etc.) observations of air density and wind speed. Wind speed and air density vary between observation times so that the time variability of wind's kinetic energy is accounted for.

Few instrumented tall towers exist by which to service the data requirements of equation (14); therefore the more ubiquitous 10 m tower data area are usually used and faster wind speeds at higher levels occupied by large turbines inferred by a one-seventh power law.

Wind power mapping

In that long-term wind measurements are not present in all possible places, especially far from large cities, wind power mapping has been employed as a first approximation of the wind resource. Typically, the wind map is generated by using long-term wind observations from existing wind observation stations. Worldwide, wind reporting sites with observations an hour or less apart are much less common than temperature or precipitation measurement sites. Usually, relatively few sites

can be employed in wind power mapping of large areas. Moreover, the World Meteorological Organization 10 m standard height for wind observations applies directly to small turbines; calculation of long-term wind power density for utility applications must be interpolated by a power law unless using rare tall tower data.

There are various ways to spatially interpolate the wind between measurement sites. The most common involve computer models that incorporate atmospheric and land surface physics. By using generalized physical relationships between wind speed, terrain, and vegetation, these models adjust the wind power density between observation sites. An example output of this type of model is the US Department of Energy (USDOE) map in Figure W11. This model calculated wind power density for $1/4^\circ$ latitude by $1/3^\circ$ longitude grid blocks. The USDOE acknowledges that, because of local terrain features, their estimates might be off by 50–100% at individual sites. The USDOE and state entities have generated maps at scales ranging down to grid cells a few hundred meters across. Empirical models have also been employed as the basis for wind density mapping. By plotting the relationship between wind speed, wind density, altitude, and surface roughness, empirical functions are derived and then applied to individual grid cells over a large area. Both types of models (physical and empirically) require substantial spatially referenced data, and are limited by the quality of those data. In any case, model-based wind power density maps serve as only the background context by which to identify areas where wind power development might be feasible. Typically, developers erect tall instrument towers at proposed wind farm sites in order to examine wind speeds and directions over a series of months. The placement and juxtaposition of the turbines is a carefully planned balance of topography and wind characteristics.

Wind power climatologies

A wind power climatology is a data time-series in which the diurnal, seasonal, and interannual characteristics of wind are considered. Wind speed, direction, and variation (expressed as standard deviations) are commonly used. Wind power climatologies include wind power roses as diagnostic tools. Figure W13 is an example of a monthly wind power climatology derived from several years of data. In this example the average wind power is quite good, but the summer low in available wind power is of interest because it coincides with the peak electrical demands of the hot summer at this location.

Wind power climatology wind roses are variations on wind rose data usually seen. Figure W14 includes the usual wind rose data; that is, it shows the percentage of time that the wind comes from each of 16 directions. Additionally, Figure W14 shows the percentage of the wind power derived from various directions. The implication of this figure is that large turbines should be lined along a west–east axis on high ground so as to take advantage of the additional lift provided as the air ascends from northerly and southerly quadrants.

From wind power climatologies, the potential yield of a specific turbine type can be modeled. Using data such as Figure W12 the projected output capacity factor of specific turbines can be estimated and cost/benefits calculated.

Siting

Economies of scale suggest that large turbines be placed in proximity to each other. This lessens the amount of infrastructure

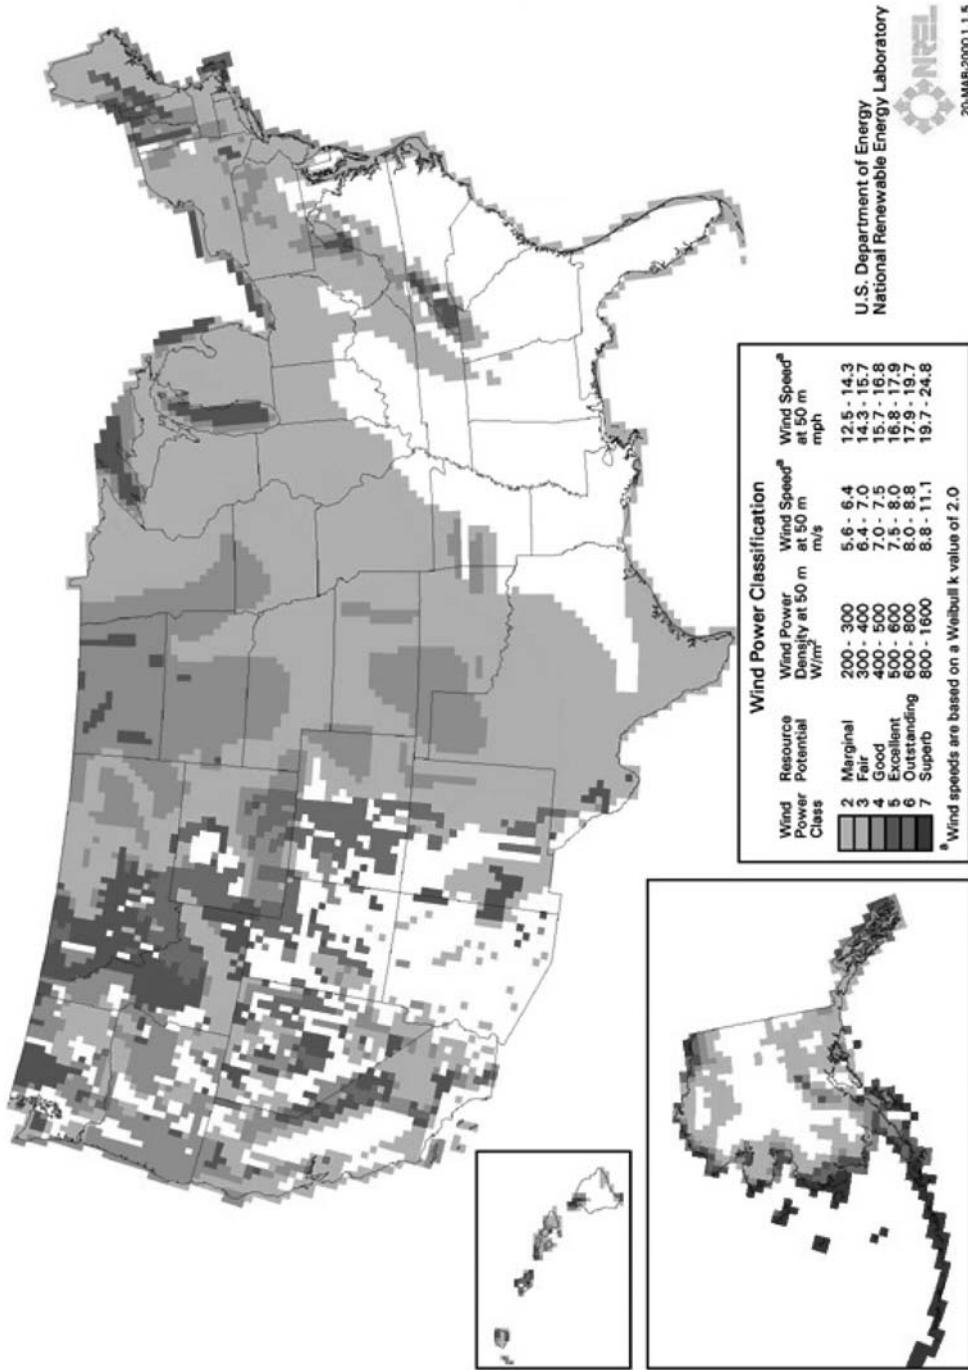

Figure W11 Wind power density in the continental United States. (US Department of Energy, National Renewable Energy Laboratory, Wind Energy Resource Atlas of the United States, 1987).

(roads, buried power lines, leases) that must be developed. However, individual turbines must not be too close to each other so as to minimize the rotor-caused turbulence that is inherited by the wind. Thus, wind turbines are usually found arranged in a line or generously separated multiple lines. For any given turbine the goal is to have it turn at capacity all the time. The temporal variability of wind precludes this, but

modern turbines can be profitable if the actual wind power is greater than 0.3 of the capacity over long time periods.

In that wind turbines do not turn at capacity at all times, the most rational economic decision is to site them where the winds blow the fastest and longest. In mountain areas this is typically on sharp ridge crests and in passes. In the former case higher altitudes are associated with faster wind speeds. In the

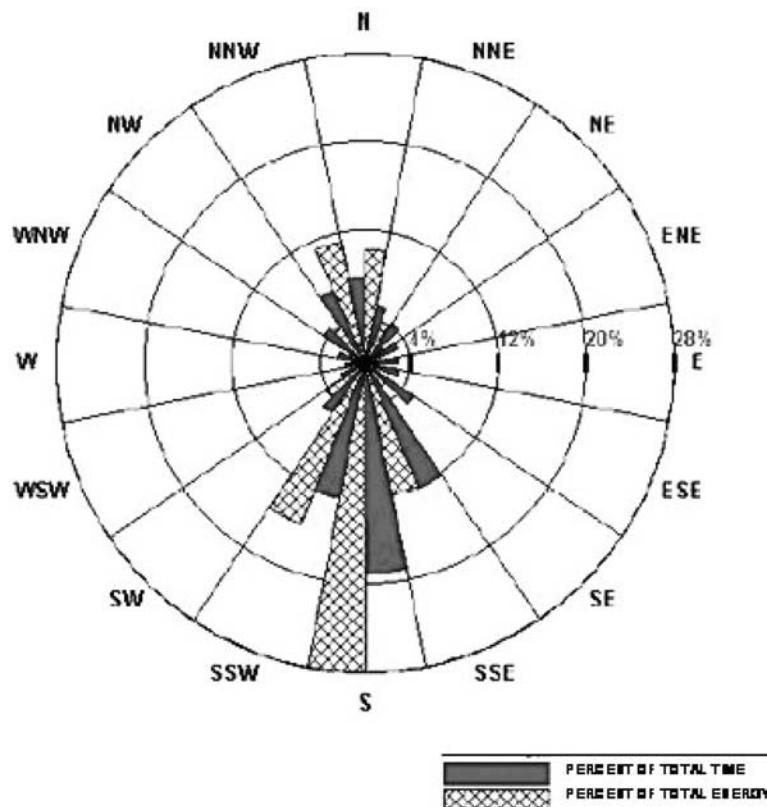

Figure W14 Wind speed and wind power rose at 10 m for Cheyenne, Oklahoma. The original data were in 5-min increments over 9 years (courtesy Oklahoma Wind Power Initiative).

latter case the Venturi effect causes local maxima of winds. Non-mountainous areas also require attention to siting detail. In general, lower areas on subdued terrain have lower wind power densities than higher areas, and forested areas are avoided because of the increased friction. For a line of turbines, preferred siting is on unforested ridges with map contour lines at right angles to the wind direction(s) providing the most wind power. The effect of a ridge – even a subdued ridge – is to increase the vertical speed (z) of the wind. This assists turbine rotor blades to turn because they move the blade edge.

Small wind turbines

The above discussion has focused on utility-scale wind, but small wind turbines (50 kW or less) are increasingly being used. Many times smaller than utility-scale turbines, the small turbines represent less up-front capital cost and great flexibility of siting. They are not as cost-efficient per kWh as large turbines, but they are able to provide electricity to places where there are no other sources or supplement power purchased from electrical utilities. There has been a large deployment of turbines in rural areas and, in particular, underdeveloped countries.

Downsides of wind power use

Two major downsides have slowed the development of the wind as an alternative to fossil fuels. They are the intermittency of the wind and the locational disconnect between windy sites and

population centers. The intermittency of the wind power source has been of great concern to power providers. Over very short periods of time the boundary layer wind is composed of gusts of multiple speeds and directions. This short-term intermittency has been largely solved through engineering of turbines that are geared to provide constant power output. Over scales of days and seasons, however, there are times that the wind will not blow enough to turn turbines to their capacity, if at all. In these cases a utility must have other energy to place on the power grid and such ability incurs costs.

A second sort of problem is the situation in which the best wind power sites are not proximal to population centers. The transmission of power entails loss of power over distance. For example, the Great Plains of the United States have large areas of excellent wind resources but much of that area is hundreds of kilometers from large cities. Some rural sites might be near transmission lines but the lines might not have enough capacity to accommodate the additional power. The building of new transmission lines is expensive and requires time to acquire rights of way and permitting.

The future

Non-fossil-fuel-derived electricity with little negative environmental impact is a great gift of the atmosphere. The beginning of the present century has seen a huge increase in wind-generated electricity, and it is clear that much development will ensue given current levels of technology. Also clear is the fact

that the temporal variability of wind power limits its use on power grids. As a small percentage of generation capacity placed on a power grid, the wind can be compensated for if it does not blow. When wind becomes a substantial part of the capacity (greater than 10% or so) calm conditions can create a shortage of power to the grid as a whole: this circumstance is unacceptable. Thus, utilities are wary of having too much wind in their generation portfolios and electrical wind generation regulated to a small minority of the power mix.

The future holds promise in the development of large turbines that can turn at lower wind speeds than present, and significantly decrease the amount of time the kinetic energy of wind can be tapped. Also the use of wind energy in hydrogen fuel cell production and the storage of converted wind energy in compressed fluids and next-generation batteries has the potential to open many avenues to increased use of the wind.

WINDS AND WIND SYSTEMS

Causes of wind

Wind is simply the movement of air. On a global scale the world's winds act as a primary thermal equilibrium mechanism helping to offset the persistent latitudinal energy imbalance of the Earth. This imbalance is caused by the equatorial region absorbing more radiation than it can effectively lose and the polar regions losing more radiation than they receive from the sun. The large-scale motion of the atmosphere – atmospheric circulation – transports a great amount of the excess heat from the equatorial regions into the colder high latitudes. Although the radiative imbalance of the Earth-atmospheric system drives the large-scale motions of the atmosphere, a variety of other mechanisms, such as topography, create the winds at smaller scales.

Five basic forces are primarily responsible for producing the world's wind systems; however, the relative importance of each force varies with scale. For example, a force that might be significant at the global circulation scale may be relatively unimportant at the scale of tornadoes. Therefore, to achieve an understanding of winds and wind systems, a consideration of both the forces and the specific scale of study is required.

Pressure gradient force

The initial force controlling most of the motions of the atmosphere is that induced by variations in the horizontal pressure field over the Earth. If pressure varies in a horizontal plane, the forces acting on the plane would not balance and air would flow from high to low pressure. This movement is created by a force referred to as the pressure gradient force (PGF). Variations in pressure on a horizontal plane could be created by surplus heating at certain locations and/or deficit heating (cooling) at other areas. Because density varies inversely with temperature and directly with pressure, a rise in temperature will cause a decrease in density and therefore a fall in pressure. In the east–west direction, Δx , PGF can be expressed as:

$$\text{PGF} = \frac{1}{\rho} \frac{p}{\Delta x}$$

where ρ is density and p is pressure.

Gravity

The only other force that can initiate atmospheric motion is gravity, which operates only in the vertical. All particles that make up the atmosphere, regardless of height or size, experience a downward acceleration due to the mass of the Earth. This acceleration per unit mass, called gravity, would collapse the atmosphere to the Earth's surface in the absence of some counterbalancing force. Fortunately, the decrease of pressure with height produces a strong vertical pressure gradient force that offsets the downward force of gravity. This counterbalancing relationship is commonly expressed in the hydrostatic equation as:

$$-\rho g = \frac{\Delta p}{\Delta z}$$

where g is the acceleration due to gravity and z is the vertical coordinate.

Coriolis force

An apparent force operating on atmospheric motion arises due to the rotation of the Earth. This force is a product of the acceleration observed by using the rotating Earth as a fixed frame of reference. It is not a true force since no mass is directly involved. As an example of the Coriolis effect, consider an air particle moving freely from the North Pole, P , with a velocity, v , in the direction of some point A , which the particle should reach in time dt (Figure W15). Given that the Earth's surface is rotating with counterclockwise angular velocity, ω , while the particle is traveling the distance vdt , point A rotates to point B while point A' rotates to position A . Consequently, the moving particle arrives at point A and appears to have followed the curved path PCA' relative to the Earth's surface or it was deflected from its original path. This force, postulated to account for this deflection, is termed the Coriolis effect after the physicist G.G. de Coriolis (1792–1843) who first treated it quantitatively.

The acceleration produced by the horizontal component of the Coriolis force is $2v\Omega \sin\Phi$ where Ω is the Earth's angular velocity, v is the velocity of the particle, and Φ is latitude (the quantity $2\Omega \sin\Phi$ is termed the Coriolis parameter, f). The Coriolis force is strongest at the poles and equal to 0 at the

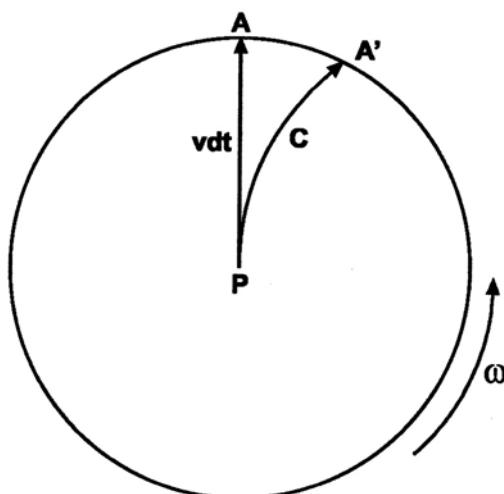

Figure W15 Coriolis effect due to Earth's rotation.

equator, and at all latitudes away from the equator it is directly related to the wind speed.

Centrifugal force

Another apparent force is related to the inertia built up by the air particle. As an example, consider a ball attached to a string and whirled at a constant angular velocity. If the ball is observed from a coordinate system rotating with the ball, it appears that the ball is stationary. However, there is still the force of the string acting on the ball, and an additional force is needed to balance the force of the string. The force of the string is balanced by the centrifugal force, which acts to move the ball in a direction tangent to the circle of motion. Simplistically for the atmosphere, the centrifugal force can be expressed as $\omega^2 r$, where r is the radius of curvature. Generally, this force is small compared to other major forces operating on large-scale atmospheric flows.

Friction

The last of the major forces influencing air movement is friction or viscosity. Normally, friction is important only throughout the planetary boundary layer, which may range in altitude from 30 m to 3 km, depending on atmospheric stability. Friction between moving air and the surface of the Earth produces a retarding stress with a direction opposite to the air motion. Its magnitude is a function of both the roughness of the terrain over which the air is passing and the actual wind speed. Frictional stresses also can occur between two adjacent layers of air moving in different directions and speeds; however, these stresses are generally less in magnitude than those between the surface and air.

Interaction between forces

These five forces – the pressure gradient force, the centrifugal force, the Coriolis effect, gravity, and friction – achieve a balance in our atmosphere and therefore all influence atmospheric motion. However, depending on the height in the atmosphere and/or the scale of motion, some of these forces might be far less important than others. For example, in the levels above the planetary boundary layer, an approximate balance can occur between the horizontal pressure gradient force and the Coriolis effect. If an exact balance of these two factors is achieved, the resulting air motion is called the geostrophic wind, v_g , defined in the east–west direction as:

$$v_g = \frac{1}{fp} \left(\frac{\Delta p}{\Delta x} \right)$$

Because the horizontal pressure gradient force operates from high to low pressure so that air is directed perpendicular to the isobars, the Coriolis effect also must be perpendicular to the isobars and directed from low to high pressure (Figure W16). In the northern hemisphere, the Coriolis force deflects to the right of the apparent direction of wind. The geostrophic wind velocity must exist such that low pressure is found to the left of the direction of motion. In the southern hemisphere low pressure is found to the right of the direction of motion because the Coriolis force acts to deflect motion to the left. This principle is known as Buys-Ballot's Law.

Below 1000 meters, in the planetary boundary layer, friction becomes important and a three-way balance between the pressure

gradient force, Coriolis force, and friction is achieved. Friction acts opposite to the wind direction, slowing the wind. This decreases the Coriolis effect and disrupts the geostrophic flow parallel to the isobars. As a result of the interplay of these three forces, the actual wind blows at an angle across the isobars, in a direction from higher to lower pressure (Figure W17). This creates

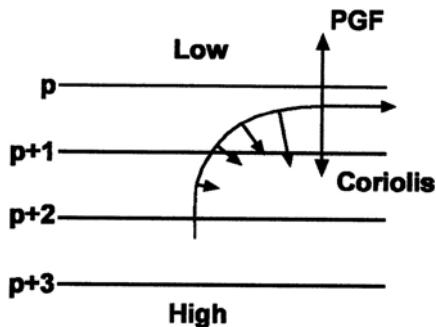

Figure W16 Approach to geostrophic equilibrium by a parcel initially at rest.

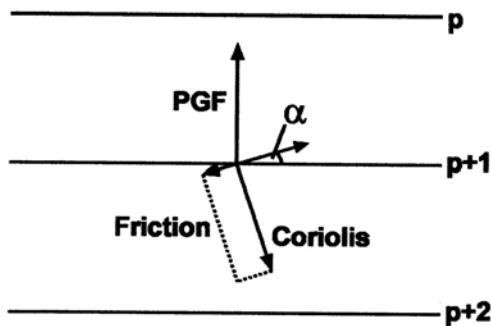

Figure W17 Balance among pressure gradient force, Coriolis force, and frictional force.

surface winds that flow clockwise and out of high-pressure areas (anticyclones) and counterclockwise and into low-pressure areas (cyclones).

Because pressure and temperature are directly related to one another, thermal patterns provide an alternative method of discussing winds. Through manipulation of the geostrophic wind equation and the quantitative relationship between temperature and pressure, the change in geostrophic wind speed with height to a first approximation can be expressed in the east–west direction as:

$$\frac{\Delta v}{\Delta x} = \frac{g}{fT} \left(\frac{\Delta T}{\Delta x} \right)$$

where $\Delta v/\Delta x$ is the change in north–south component of wind with height and T is temperature. This equation shows us that greater temperature changes in the horizontal will force larger wind speed changes with height.

The preceding discussion represents a simplistic explanation of the fundamental principles of dynamic meteorology and climatology. A solid mastery of these principles is a necessary prerequisite to a full understanding of the nature of the actual winds and wind systems that are found in the world's atmosphere.

The world's wind systems

Atmospheric circulations may range in size from a small gust or swirl of wind to the global circulation cells that give rise to the trade winds and the westerlies. The specific winds of a given location are often shaped by local conditions.

Planetary wind systems

The mean planetary wind pattern, also referred to as the general circulation of the atmosphere, represents the averaging of wind observations over a long period of time and thus depicts the largest of scales of atmospheric motion. The actual circulation at any moment can differ significantly from this time-averaged pattern. A very generalized model of the mean wind patterns (Figure W18)

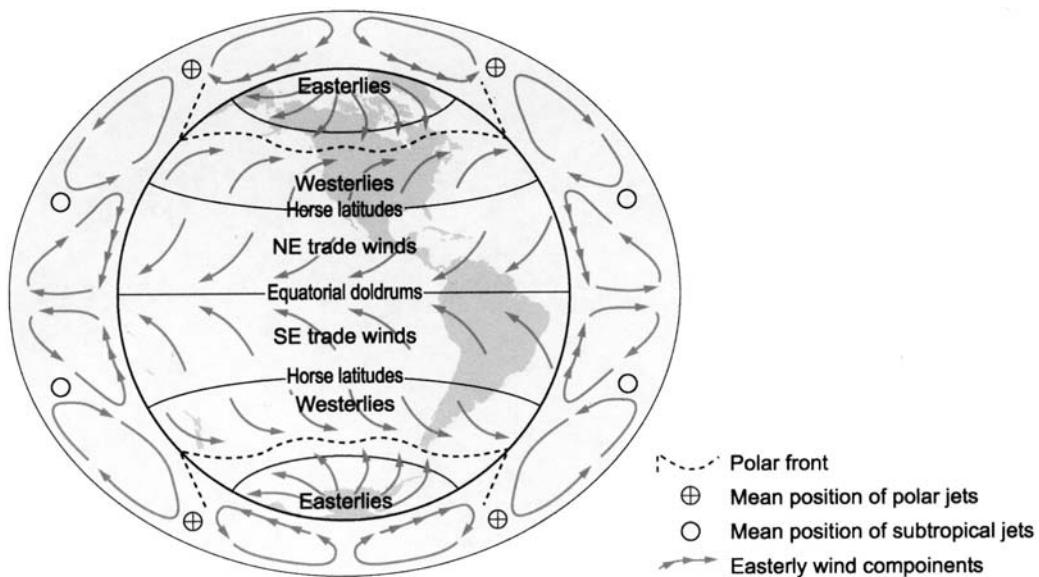

Figure W18 General circulation of the atmosphere. Double-headed arrows in cross-section indicate easterly wind components.

employs the assumption that the Earth is covered only by oceans and has normal rotational characteristics.

Under these conditions the equatorial zone would be the region of most consistent receipt of solar radiation (the noon sun is always within $23\frac{1}{2}^{\circ}$ of being directly overhead). The resulting intense surface heating produces an enormous vertical transport of air, leading to the development of a broad band of lower surface pressure straddling the equator. This heated, ascending air begins to cool and diverge at upper levels as it flows toward both of the polar zones. At one time (1735) the English philosopher and meteorologist George Hadley proposed that the poleward-moving air ultimately reached the poles and then the airstreams returned to the equator region along the Earth's surface. However, he noted, if the air at the Earth's surface flowed toward the equator from the polar zones, the Coriolis effect would eventually cause the air to be flowing from east to west in both hemispheres. This type of flow would be in direct opposition to the west to east rotation of the Earth. Hence, in later years a three-cell model was developed to explain the basic patterns of vertical airflow. The three-cell model has the poleward-flowing air beginning to descend, finally reaching the surface in the area around 30° latitude in both hemispheres.

Many of the surface circulation features have traditional names dating back to the period of sailing vessels during the eighteenth and nineteenth centuries. This zone of descending air near 30° latitude produces a region of relatively higher pressure dominated by fair weather and lack of strong surface horizontal airflow. Legend has it that sailing vessels were often becalmed as they attempted to pass through these areas and the horses were the first to go overboard in an attempt to lighten the vessels, hence the term Horse Latitudes was given to this region, which also is traditionally referred to as the subtropical high-pressure belt.

Because of this accumulation of air near the Earth's surface, airstreams begin to diverge from the subtropical high-pressure belt and flow toward both the polar region and the equator. Out of respect to Hadley, scientists today refer to this convectively driven cell immediately on either side of the equator as the Hadley Cell. Under the influence of the Coriolis force, the airstreams diverging from each of the hemispheric subtropical high-pressure zones are deflected to the right in the northern hemisphere and to the left in the southern hemisphere. The equatorward-moving air, termed the trade winds, is of a persistent nature and takes on the characteristics of southeasterly winds in the southern hemisphere and northeasterly winds in the northern hemisphere. These trade winds of each hemisphere converge along a zone called the Intertropical Convergence Zone (ITCZ). The exact location of the ITCZ varies with the time of year and is related to the migration of the direct rays of the sun. Generally, the ITCZ is located north of the equator during the northern hemisphere's summer months and to the south of the equator during the summer season of the southern hemisphere. Because this equatorial zone is both a region with little airmass contrast and dominated by persistent clouds and precipitation, it is often referred to as the doldrums.

Poleward of the subtropical zone in each hemisphere is an area of winds known as the westerlies. In reality, the mean airflow in this zone in the northern hemisphere is from the southwest and in the southern hemisphere from the northwest. The characteristic feature of the westerlies is the net transport of airmasses from west to east. Along the poleward margin of this region is an area referred to as the disturbed westerlies, which

has the traveling cyclones or low-pressure cells moving along frontal boundaries that separate the warm tropical airstreams from the colder polar airstreams. These cold polar airstreams (northeasterly winds in the northern hemisphere and southeasterly winds in the southern hemisphere) originate in another region dominated by high pressure, the polar zones. It should be noted, though, that this region of high pressure is not as extensive as the subtropical high-pressure region. These polar airstreams, also called polar easterlies, collide with the westerlies along what is known as the polar front. Considerable uplift occurs along this frontal zone and, as the air ascends, it diverges toward both the polar and subtropical regions completing the two circulation cells that are poleward of the equatorial Hadley Cell. This middle cell is termed the Ferrel Cell. The polar front zone is meteorologically the most active region of the world and is examined in more detail below in the section entitled "Traveling Systems".

One of the most dramatic features of the upper-air global circulation is the presence of jet streams. The two primary jet streams are the polar jet located above the polar front (at approximately 10–15 km above sea level) and the subtropical jet located at approximately the same elevation along the northern margin of the Hadley Cell. Each of these jet streams is hundreds of km wide and several km thick. Known as steering currents, they direct the low-pressure cells and provide quasi-barriers to the movement of the major air masses. Surface weather conditions such as droughts, heat waves, and storminess have been related to the positioning of the jet stream and the related attendant upper-air flow patterns.

One of the interesting aspects of the jet stream and all of the upper-air flow is the variation in wind velocities during the year. Using the concept of the thermal wind, the greater the contrast in thermal energy across a region, the greater the resulting wind velocity. Therefore, the jet stream (as well as most upper-air flow) reaches its maximum velocities during the winter season and early spring when the latitudinal thermal gradient is at a maximum. Conversely, during the summer season of either hemisphere, the latitudinal thermal gradient diminishes to a minimum along with the velocity of the upperair wind velocities. The jet stream is in a wavelike form and assists in the exchange of heat and momentum poleward in an attempt to maintain the hemispheric and global heat balance. This poleward and corresponding equatorward undulation in the upper-air flow is often called meridional flow, and the amplitude of this meridional energy exchange is also related to the latitudinal thermal gradient. The undulations observed in the upper-air flow reach the highest amplitudes, crossing the largest amount of latitude, during the winter season. During summer the high-amplitude wave pattern becomes one of greatly reduced amplitude as the result of a reduced latitudinal thermal gradient.

The concept of seasonality can be built into this model just as it was for the interpretation of annual variation in the velocity of the winds. During the northern hemisphere winter season, all of the circulation regimes migrate southward from their normal positions illustrated in the above model; conversely, these circulation features migrate northward with the advancement of summer into the northern hemisphere. This seasonal shift in zones of circulation results, for some cases, in dramatic reversals in prevailing wind patterns. For example, in India, the prevailing northeast winter winds gradually change over to southwesterly winds as the summer monsoon and zones of prevailing winds migrate northward with the advance of summer. In the United States, much of the country is dominated by northerly flow

during the winter season; however, as the circulation belts migrate northward with the direct rays of the sun, the polar circulation gives way to the dominant summertime pattern of westerlies. The northward movement of the subtropical high-pressure belt through California during summer is notable for the dramatic seasonality of precipitation, with almost all of the precipitation in this region occurring during winter while under the influence of the westerlies. As mentioned earlier, the migration of the ITCZ is also related to the seasonal migration of these generalized circulation features.

There are two major limitations in the use of this model of generalized circulation patterns. First, the three vertical cells are far too simplified to express the true complexity of upper-air flow. Many climatologists do not adhere to the three-cell model, preferring instead to illustrate only the Hadley Cell and a single more complex midlatitude-polar cell. Second, the horizontal patterns are so highly generalized that the actual circulation features at any given time would vary considerably from this model. However, it is generally agreed that this schematic diagram is a useful starting point for the much more detailed flow characteristics that evolve once the actual geographic distribution of landmasses, sea surfaces, and topographic features are included.

Traveling wind systems

Of all the regions of the world, the midlatitudes of each hemisphere are by far the most active in terms of moving atmospheric systems. Although the subtropics do have tropical cyclones (specific regional names include hurricanes, typhoons, cyclones, and Baguios), these are not daily occurrences and are in fact rare features of the day-to-day weather pattern. The primary features of the midlatitudes that produce variations in surface windflow characteristics are the cold, warm, and occluded portions of the polar front, the low-pressure cells traveling along the polar frontal system, and the high-pressure cells that originate in either the polar or the subtropical source region.

The low-pressure cells that originate along the polar front undergo a life cycle that was first described by J. Bjerknes in 1918. The first step in the stages of development is cyclogenesis. It is at this point that advection of northerly and southerly airstreams begins. The airstreams in the northern hemisphere move in a counterclockwise circulation (southern hemisphere, clockwise) as the airstreams ascend and converge toward the low center. As the pressure at the center of the low continues to fall, the warm and cold airstreams continue to advect over large regions and with increasing velocities. Eventually, the cold air sweeps around the low-pressure cell, eliminating the wedge of northward-moving air in a process called occlusion. As the occlusion process advances, the wind velocities drop off, and the latitudinal transport of polar and tropical air diminishes. Another interesting aspect of these traveling cyclones is their tendency to occur in a sequence known as the family of wave cyclones. Occasionally, near the region of cyclogenesis, the cold air breaks through the polar front in the form of a rapidly moving cold front known as a polar outbreak. On either side of the polar front are large high-pressure systems that make up distinctive airmasses. These airmasses take on the characteristics of their source region, extend over thousands of square kilometers, and have similar temperature and moisture structures. The basic airflow associated with these high-pressure cells is a descending and clockwise spiraling motion (southern hemisphere, counterclockwise).

Local winds

The surface winds associated with this scale are often shaped by local conditions such as topography, location, and differential heating. This scale of winds may be classified into five main groups: (a) diurnal winds, including those winds which are associated with the diurnal cycle; (b) jet-effect winds, including those winds which are strongly influenced by the local topography; (c) antitropic winds, including those winds arising from pressure and thermal gradients (such as land/sea breezes or Chinook/fohn winds) or by gravity (such as fall winds); (d) local winds created by local heating or instability created by the overrunning of cold air, such as dust storms or haboobs; and (e) winds created by strong pressure gradients over a relatively small area, the uninterrupted flow over a level surface, or both sets of conditions (such as the desert khamsin wind or winds associated with blizzard events).

Differential heating at the Earth's surface can result in several local wind circulations. The sea (and lake) breeze and corresponding land breeze are examples of local wind circulations that reverse direction on a diurnal basis. Mountain and valley breezes also typically occur with a diurnal reversal in circulation. It should be stressed that these circulation systems can be completely obscured by the larger-scale synoptic systems and are therefore most pronounced during clear and relatively weak synoptic weather conditions. During the winter months cold dense air can spill out of intermontane regions, descending into surrounding valleys in the form of strong cold airstreams. Throughout the world, literally hundreds of local winds have been identified and labeled with a labyrinth of vernacular names.

Small-scale or local winds have a direct impact on many human activities. Microbursts and the winds associated with thunderstorms pose serious concerns to the aviation industry. Sudden dust storms in desert environments such as the southwestern United States have caused death and injury on highways through the region. Chinook/foehn winds in many alpine regions of the world have caused rapid melting of snow that has contributed to flash flooding in some areas. Additionally, architects have begun to consider the impact on building design of air flow within the urban landscape. Such interrelationships between human activity and the climatology of local winds will undoubtedly continue to be expanded and researched in the future.

Observation and measurement of winds

Many practical and theoretical problems in meteorology and climatology require accurate measurements of wind speed, direction, and/or gustiness. From a theoretical perspective the study of the forces, laws, and effects of air motion lies near the heart of the atmospheric sciences. From a practical standpoint, examples of problems requiring wind observations include the siting of emission sources of noxious atmospheric pollutants, design of homes for optimum ventilation, studies of insect or disease migration, or analysis of the aeolian landforms. Increasingly, engineers, architects, scientists, and planners are requiring wind data for assessing both the useful and the destructive potential of atmospheric motions.

The science that deals with the study of wind measurements is called anemometry. The measurement techniques described below represent a limited sample of the many methods used to accurately measure or estimate wind parameters on various spatial and temporal scales.

Wind speed estimations

In 1804 British Navy Admiral Francis Beaufort created a system for estimating wind speeds for observations of wind effects. Originally, the system was designed for use at sea; later it was modified for use on land. In 1874 the Beaufort system was officially adopted for international use, and in 1955 the US Weather Service expanded the scale by adding additional force numbers to the original system.

The first known anemometer was a swinging-plate type instrument, which was described in literature found dating back to the 1450s. By hanging a plate with some string from a horizontal rod, the intensity of the wind speed was measured by the extent to which the angle of the plate deviated from the perfectly perpendicular position it took on during still wind conditions. These types of anemometers are known as pressure-type anemometers since they rely upon the pressure of the wind against the surface of the plate in positioning the plate in a static position away from its perpendicular position.

Theoretically, sound estimates of wind speed and direction can be derived from pressure and/or temperature measurements made throughout the atmosphere. Using the dynamical principles that govern the flow of a thermally active fluid over a spherical surface, remarkably precise estimates of wind parameters can be generated, particularly for heights above the planetary boundary layer where frictional influences can be ignored. However, the effects of friction and response time on instrumentation limit the effectiveness and precision of wind sensor as wind speeds approach zero and the structural support limits the sensor's survival at high speeds.

The World Meteorological Organization (WMO) has set standards for measurement of wind speed and direction. "Sustained" wind speeds are measured as 10-minute averages, in order to be compatible with most standard software (and literature on the subject) while gusts are the maximum speeds recorded above the sustained wind speed average within the 10-minute average period. Wind direction is measured in degrees in a clockwise direction from north. The WMO standard exposure height for surface winds is 10 km and the anemometer must have good exposure in all directions within about three km.

Langrangian measurements

Langrangian measurements of winds are taken from within the moving body of air. Observations of movements of clouds, smoke puffs, or visible plumes have long been used to calculate winds above the various levels of the atmosphere. Satellite estimates of wind speed, for example, have long been made particularly over oceanic areas. Alternative methods have employed scatterometers, altimeters, and synthetic aperture radars to measure the state of the ocean surface, e.g. wave height, for determining surface wind speeds.

More direct Langrangian measurements of the wind field may be made by tracking balloons that rise through the atmosphere. In clear conditions a pilot balloon (pibal) of known ascent rate may be released and tracked with an instrument called a theodolite. Altitude and azimuth angles measured by the theodolite at specific time intervals allow wind speed and direction at different heights to be determined trigonometrically using the pibal method. Similar techniques can be employed in cloudy conditions using balloons carrying radar targets or radio transmitters. The rawinsonde (rawin) method tracks the ascending target with radar, and wind speed and direction are trigonometrically determined. The rawinsonde and/or rabal methods

for wind determination also use radar for establishing altitude and azimuth angles, but the height of the balloon is determined from the radiosonde data. Above the 30-km ceiling for most balloons, various targets released from rockets can be tracked to calculate wind velocities in the high atmosphere.

Doppler radar and wind profiler now commonly obtained detailed wind information for lower tropospheric wind measurements on a regular basis. Doppler radars measure the radial velocity of targets (cloud droplets, dust or precipitation) in relation to the station to give a basic inflow/outflow speed determination in relation to the station. Wind profilers, in essence upward-oriented Doppler radars, conversely give vertical profile of wind speeds as a function of time. Doppler radars have even been mounted on vehicles for detailed observation of tornadic winds.

Eulerian measurements

Eulerian measurements of wind are taken by various instruments positioned at some fixed point near the ground. Four basic Eulerian methods are used in anemometry to measure wind speeds.

1. Pressure anemometers, such as pitot-static tubes, operate on the principle that the square of wind speed, v is functionally related to the pressure exerted by the airflow. The pressure types are very accurate in measuring the fine structure of the winds and, accordingly, are often called gust recorders.
2. Mechanical anemometers, such as the popular three-cup rotation anemometer, measure wind speeds by recording rotations per unit time interval, by generating electrical current, or by applying pressure on a set of springs. Air motion causes atmospheric pressure differences between the concave and convex sides of the cups, thereby forcing rotation about a vertical axis. The propeller, or windmill, mechanical anemometers operate on a similar principle, but the axis of rotation is generally parallel to the wind direction. Today the most common type of anemometer is a rotational device known as a cup anemometer. This consists of three cups made of lightweight material which are equidistantly attached with spokes to a rotating center rod. The speed of rotation varies with the magnitude of the wind speed. This is known as a "drag" device because its rotation is caused by the drag of the cups against the wind. Another increasingly popular type of anemometer is the propeller anemometer. This anemometer is simply a very small two- or three-blade propeller, calibrated so that the revolutions per minute (rpm) corresponds to specific wind speeds. This anemometer is known as a "lift" device because it relies upon the rational lift caused by the wind on the propellers to measure the wind speed.
3. Thermoelectric anemometers such as hot-wire anemometers are often required to measure very light wind speeds. Because the cooling rate of an object is a function of the flow rate of a fluid, the energy required to maintain a constant temperature of a probe can be directly related to the wind speed.
4. Sonic anemometers capitalize on the principle that true sound velocity is proportional to wind speed in the direction of air motion. Using a set of emitters and receivers, the true sound speed can be used to accurately determine existing wind speeds.

Wind direction is usually measured by various types of wind vanes. The most popular types are asymmetrically shaped

arrows with the center of gravity mounted on a vertical axis. The tail fins provide resistance, counterweight and move to the downwind position. Aerovanes, or bivanes, record both speed and direction by combining the propeller-type anemometer with a streamlined shape to keep the instrument facing the wind. Due to their exceptional visibility, wind socks are still widely used at smaller airports to display the existing wind direction.

Actual wind data

The great variability of surface winds through both time and space, caused in large part by significant frictional effects, poses problems in accurate and representative wind measurement. To standardize surface wind measurements, all instruments are to be exposed to freely flowing air at least 10 m away from any obstacle. However, practical considerations often lead to poor site selections for equipment, resulting in systematic errors in direction and speed measurement.

In the lowest portions of the atmosphere, wind speeds are retarded by the friction associated with the rough surfaces. Accordingly, in the first few hundred meters above the ground, wind speeds dramatically increase with height, but speeds increase more gradually with height above the lower friction layer. Because Coriolis force is directly related to wind speed, winds in the northern hemisphere tend to veer to the right with increasing altitude, resulting in the well-known Ekman spiral.

Most atmospheric measurements (i.e. temperature, precipitation, pressure, etc.) can be represented by using scalar quantities. However, because wind has both a speed and a direction, it is often represented as a vector quantity. Consequently, a variety of techniques are unique to the presentation of wind data.

Following WMO convention, wind direction is given according to compass headings expressed nominally as N, NNE, NE, NNW, or numerically such that 90° is east, 180° is south, and so on. In either case, wind direction always gives the directional origin of the wind; for example, a southerly wind blows from the south to the north. On maps, actual wind directions are often depicted by arrows that fly with the wind (Figure W18), whereas curved streamlines generally are used to show general air trajectories or theoretical flow patterns.

Wind speed is often given in knots, although miles per hour and meters per second are also popular units of measure. Speeds can be illustrated using barbs or feathers on the arrows of wind direction or they can be depicted using isotachs drawn through points with equal speed or wind force values.

The vectorial nature of wind allows many other diagrammatic techniques to be employed. Many types of wind roses can

be drawn, often with the relative length, or thickness, of lines radiating from the center indicating frequencies of principal wind directions.

The northerly and westerly components of the wind, calculated as $v \cos \theta$ and $-v \sin \theta$, respectively, with v equal to wind speed and θ equal to wind direction, allow scalar treatments of vectorial wind data. Resultant winds, calculated as vector summations of the winds, have proved to be particularly useful in studies on atmospheric diffusion processes.

Many Internet sites, both public and private, now offer real-time wind observations for an incredible number of sites around the world. Climatological compilations of surface and upper-air wind measurements are available for hourly, 3-hourly, daily, monthly, annual, and long-term averages for periods extending back more than 50 years for upper-air measurements and more than a century for surface winds. For the United States the primary archive of wind information is the National Climatic Data Center (NCDC) located in Asheville, North Carolina and accessible at www.ncdc.noaa.gov. Radiosonde and rawinsonde reports for daily winds at many levels of the atmosphere have been compiled for hundreds of land- and sea-based stations around the world.

Z

ZONAL INDEX

The zonal index is one of the two standard circulation index conditions, specifically, a measure of midlatitude westerlies (in both hemispheres) expressed as the horizontal pressure difference between latitudes 33° and 55° or as the corresponding geostrophic wind. A high-index weather situation (over 8 mb) represents a strong westerly component and a low index (less than 3 mb) relative weakening, i.e. implying a stronger meridional component; in extreme low-index conditions the usual poleward pressure gradient may be reversed and expressed with a negative figure. In Cartesian coordinates, the x axis is eastwest and the y axis northsouth, so that the zonal wind (x)

may be expressed as positive if it blows from west to east, and vice-versa. It may be compared with the meridional wind (y axis).

The index cycle

A roughly cyclic variation in the zonal index is called the index cycle. This cycle has a period that varies from 3 to 8 weeks, although extremely high- or low-index conditions generally do not persist for more than 2 weeks.

The typical index cycle can be divided into a number of stages beginning with a high zonal index with a long wavelength pattern (Figure Z1). The wavelength pattern aloft is shortened, leading to a complete breakup of the zonal winds at both the surface and aloft. Closed cells are formed, which are

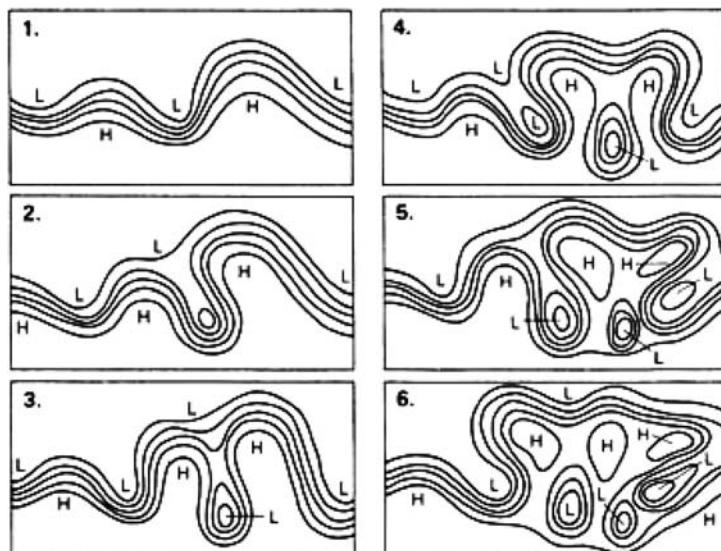

Figure Z1 Schematic representation of the stages in the breakdown of zonal flow at the 500 mb level. Time period involved in the breakdown may be 8–10 days and depicted waves may extend from the central United States to Eastern Europe (from Lockwood, 1979).

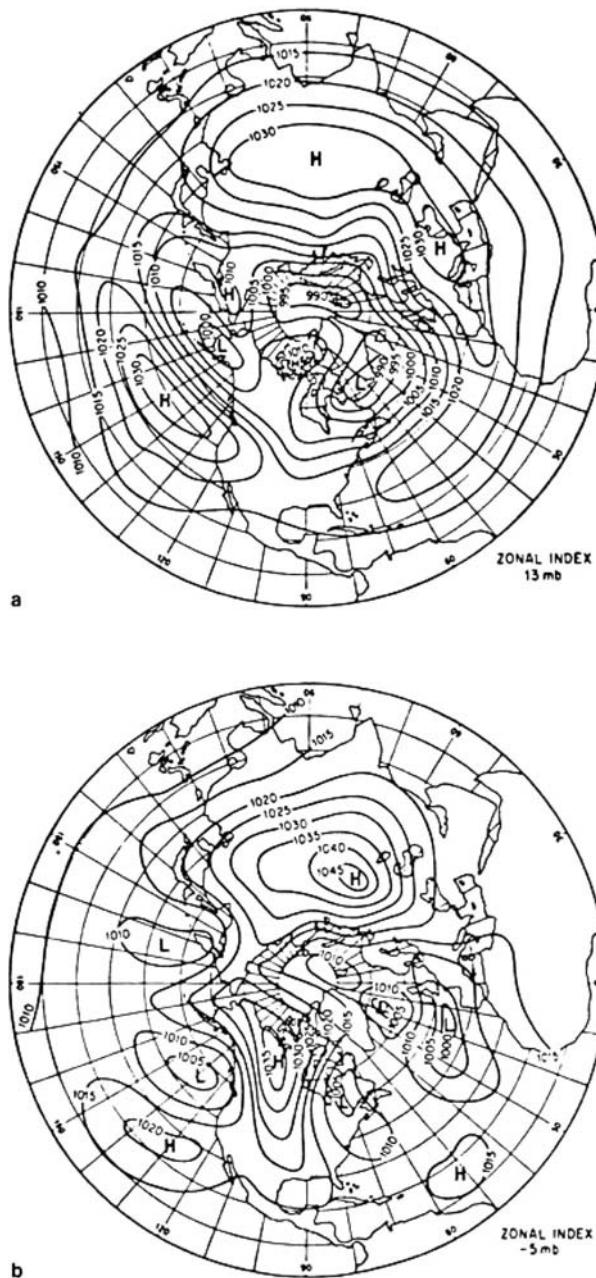

Figure Z2 Examples illustrating mean pressure distribution at sea level during one week of (a) high zonal index and (b) low zonal index.

eventually cut off to permit the re-establishment of the open wave pattern in the upper air.

During northern hemisphere high-index conditions:

1. Icelandic and Aleutian lows are strongly developed, often with double center in eastwest trough.
2. Atlantic and Pacific subtropical highs strongly developed, somewhat north of usual winter latitude, in eastwest orientation, extending over neighboring continental margins. Continental highs at 3540 °N.

3. Polar continental highs missing at high latitudes over Siberia and Canada, and replaced by lows, though polar anticyclone may be strong.
4. Frontal zones oriented more eastwest than usual, with lows migrating rapidly eastward at high latitude.
5. Midlatitude westerly weather is mainly fair, airmass contrasts being rather small.
6. Subpolar weather in the low-pressure belts is stormy with rapid succession of lows but with mild temperatures.

An example is given in Figure Z2a.

Northern hemisphere low-index conditions are characterized by

1. Icelandic and Aleutian lows subdivided into separate weak cells, one generally to the southwest and the other to the southeast of usual positions. Develop a northsouth orientation.
2. Atlantic and Pacific subtropical highs are weak, displaced to low latitudes and subdivided into secondary cells by the northsouth extensions of lows.
3. Polar continental highs are well developed over Siberia and Canada and are quite separate from the subtropical highs. They may form a continuous high-pressure belt around the Arctic.
4. Frontal zones are oriented more northsouth than usual, situated east of each low-pressure trough, generated between strong northern flows of tropical air on the west sides of highs and a spilling of polar air into the low-pressure troughs. Cyclogenesis reaches much farther toward the equator than usual.
5. Midlatitude weather marked by alternate very warm and very cold contrasts with high precipitation. Migrating lows move eastward into continents south of continental highs, thus from southern California to lower Mississippi and from Bay of Biscay to Mediterranean and South Russia. Maximum northsouth heat exchange results.
6. High-latitude weather is not stormy but sees rapid influxes of warm air.

An example of such low-index conditions is shown in Figure Z2b.
